We present a new class of non-adiabatic approximations in time-dependent density functional theory derived from an exact expression for the time-dependent exchange-correlation potential. The approximations reproduce dynamical step and peak features in the exact potential that are missing in adiabatic approximations. Central to this approach is an approximation for the one-body reduced density-matrix as a functional of the Kohn-Sham density-matrix, and we demonstrate two such examples.

Time-Dependent Density Functional Theory (TDDFT) is in principle an exact reformulation of many-electron quantum mechanics [1], where non-interacting electrons evolve in a one-body potential, the Kohn-Sham (KS) potential, such that the exact one-body density \( n(r,t) \) of the true system is reproduced. In practice, the exchange-correlation (xc) contribution to the potential must be approximated, as a functional of the density, the initial interacting state \( \Psi(0) \) and the initial KS state \( \Phi(0) \): \( v_{\text{xc}}[n; \Psi(0), \Phi(0)](r, t) \). Almost all TDDFT calculations today use an adiabatic approximation, in which the instantaneous density is simply inserted into a chosen ground-state functional approximation, \( v_{\text{xc}}[n; \Psi(0), \Phi(0)](r, t) \). This yields \( v_{\text{xc}} \) that is in principle an exact reformulation of many-electron mechanisms involved in the various processes. They have a form that produces the elusive dynamical step and peak features of the correlation potential, missing in the adiabatic approximations, even for simple 1RDM-approximations.

The exact expression for the xc potential is derived from equating the equation of motion for the density of the interacting system,

\[
\frac{\partial^2 n(r,t)}{\partial t^2} = \nabla \cdot \left( \frac{1}{4} (\nabla^2 - \nabla^2)(\nabla^2 - \nabla^2) \rho_1(r, r', t)|_{r=r'} \right. \\
+ \nabla v_{\text{xc}}(r)n(r,t) + \left. \int d^3r \nabla w(r, \bar{r}) \rho_2(r, \bar{r}, r, \bar{r}, t) \right)
\]  

(1)

to that of the KS system [28–30]. Here the 1RDM \( \rho_1(r, r') = N \int dr_2..dr_N \Psi^*(r', r_2, ..., r_N) \Psi(r, r_2, ..., r_N) \), and the two-body reduced density-matrix (2RDM) \( \rho_2(r_1, r_2, r_1', r_2') = N(N-1) \int dr_3..dr_N \Psi^*(r_1', r_2', r_3, ..., r_N) \Psi(r_1, r_2, r_3, ..., r_N) \).

This yields \( v_{\text{xc}} = v_{\text{xc}}^W + v_{\text{xc}}^T \) where the interaction component \( v_{\text{xc}}^W \) satisfies

\[
\nabla \cdot (n \nabla v_{\text{xc}}^W) = \nabla \cdot \left[ n \rho_1(r, t) \int n_{\text{xc}}(r', r, t) \nabla w(|r' - r|) d^3r' \right],
\]

(2)

and the kinetic component \( v_{\text{xc}}^T \) satisfies:

\[
\nabla \cdot (n \nabla v_{\text{xc}}^T) = \nabla \cdot \left[ D(\rho_1(r', r, t) - \rho_{1,\text{s}}(r', r, t))|_{r'=r} \right],
\]

(3)

with \( D = \frac{1}{2} (\nabla^2 - \nabla^2)(\nabla^2 - \nabla^2) \). Here \( n_{\text{xc}} \) is the time-dependent xc hole defined as

\[
n_{\text{xc}}(r, r') = \rho_2(r, r'; r, r') / n(r') - n(r),
\]

(4)

and \( \rho_{1,\text{s}} \) is the 1RDM of the KS system.

In this work, we introduce a class of approximations derived from an exact expression for the xc potential. The approximations do not rely on any variational principle, immediately break free of the adiabatic approximation, and can be viewed as functionals of the xc hole and one-body reduced density-matrix (1RDM) of the KS system. They have a form that produces the elusive dynamical step and peak features of the correlation potential missing in the adiabatic approximations, even for simple 1RDM-approximations.
A first approximation, which has been previously explored [16, 18, 30–33], is to replace both $\rho_1$ and $n_{xc}$ by their KS counterparts. In this approximation, which we dub $v_{xc}^0$, the interaction component generally approximates the exact $v_{xc}^W$ very well, but the kinetic component vanishes. Although in general it is non-adiabatic, the dynamical step and peak features are absent, since these appear in $v_T^r$. These features have been shown to be crucial to accurately capture dynamics in a number of situations, e.g. electron scattering [16, 18], charge-transfer out of a ground state [15], quasiparticle propagation through a wire [14]. An approximation for $v_T^r$ is essential.

To this end, we first introduce a fictitious system represented by a 1RDM $\tilde{\rho}_1(t)$, with $\tilde{\rho}_1(0) = \rho_1(0)$ provided by the initial interacting wavefunction, which follows the equation of motion

$$i \frac{\partial \tilde{\rho}_1}{\partial t} = [-\nabla^2/2 + v_{ext}, \tilde{\rho}_1](r, r', t) + \int d^3\bar{r}(w(r, \bar{r}) - w(r', \bar{r}))\tilde{\rho}_2(\tilde{\rho}_1, \rho_{1,s})(r, \bar{r}; r', \bar{r})$$

where we consider $\tilde{\rho}_2$ as a functional of $\tilde{\rho}_1$ and $\rho_{1,s}$. This equation has the form of the first equation in the BBGKY hierarchy for density-matrices [34]. The problem then becomes one of finding an approximation to $\tilde{\rho}_2[\tilde{\rho}_1, \rho_{1,s}]$. Armed with such an approximation, one can proceed in two equivalent ways. In one, the approximate $\tilde{\rho}_2[\tilde{\rho}_1, \rho_{1,s}]$ is used at each time-step in Eq. (5) to determine $\tilde{\rho}_1(t)$ for input into Eq. (3) for $v_T^r$ and also into the right-hand-side of Eq. (4) for input into Eq. (2) for $v_{xc}^W$. In terms of the explicit dependences, one can write:

$$v_{xc}^W[n(t), n_{xc}(t)] \rightarrow v_{xc}^W[\tilde{n}(t), \tilde{n}_{xc}(t)]$$

(6)

and, with the potentials defined in this way, $\tilde{\rho}_1(r, r, t) = \rho_{1,s}(r, r, t) = \tilde{n}(r, t)$ (see shortly). Here $\tilde{n}_{xc}(t)$ is defined as in Eq. (4) but with $\tilde{\rho}_2[\tilde{\rho}_1, \rho_{1,s}]$. One propagates Eq. (5) alongside the TDKS equation,

$$i \partial_t \phi_1(r, t) = (-\nabla^2/2 + v_{ext}(r, t) + v_H(r, t) + v_{xc}(r, t)) \phi_1(r, t)$$

(8)

with the resulting $\rho_{1,s}$ input into $\tilde{\rho}_2[\tilde{\rho}_1, \rho_{1,s}]$, which in turn determines $\tilde{n}_{xc}$ and $\tilde{\rho}_1$ through Eq. (5) to obtain the KS potentials for Eq. (8).

From an alternative but equivalent view, the diagonal of the $\rho_1$ obtained from propagation of Eq. (5) with the approximate $\tilde{\rho}_2[\tilde{\rho}_1, \rho_{1,s}]$ yields a density, $\tilde{n}(r, t)$, which is required to be the KS density of the KS system. That is, $v_{xc}^W$ and $v_T^r$ are defined such that, once added to $v_{ext}$ and the Hartree potential $v_H$, result in a non-interacting KS system that has density $\tilde{n}(r, t)$. This requires, alongside Eq. (5), an inverse problem of a similar nature to that considered in Ref. [35], to be solved at each time-step to obtain the potentials to propagate the TDKS system, from which $\rho_{1,s}$ is extracted.

That these two ways give the same result, can be seen by applying Eq. (1) to the fictitious system, where $n \rightarrow \tilde{n}, \rho_1 \rightarrow \tilde{\rho}_1$ and $\rho_2 \rightarrow \tilde{\rho}_2[\tilde{\rho}_1, \rho_{1,s}]$ are used. Forcing $\partial_t^2 n$ and $\partial_t^2 \tilde{n}$ to be equal results in equations (2) and (3) for $v_{xc}^W$ and $v_T^r$ but in terms of $\tilde{n}, \tilde{n}_{xc}[\tilde{n}, \rho_2]$ and $\tilde{\rho}_1$.

A crucial aspect in the definition of $\tilde{\rho}_2[\tilde{\rho}_1, \rho_{1,s}]$ is the dependence on $\rho_{1,s}$. If $\tilde{\rho}_2$ is taken as a functional of only $\tilde{\rho}_1$ then the propagation of $\tilde{\rho}_1$ is simply that of reduced-density matrix functional theory (RDMFT), and the KS system would be simply the non-interacting system that reproduces this RDMFT density, if it exists. In this situation, the KS propagation is redundant, as all the information comes from the RDMFT. Approximations in time-dependent RDMFT still struggle with much of the same problems that adiabatic approximations in TDDFT struggle with [36]. The point of this paper is instead to focus on TDDFT with KS propagation, where $\tilde{\rho}_1$ is used only to provide an approximation for $v_T^r$. Contrary to RDMFT, $\tilde{\rho}_1$ does not need to be $\mathbf{N}$-representable as it is not intended to be a physical quantity, but instead its purpose is as a calculation tool for our KS system. The RDMs $\tilde{\rho}_2$ and $\tilde{\rho}_1$ are not contraction-consistent, and only the near-diagonal elements of $\tilde{\rho}_1$ have some physical meaning.

For a first approach within this class of approximations we take

$$\tilde{\rho}_2[\tilde{\rho}_1, \rho_{1,s}] \rightarrow \rho_{2,s},$$

(9)

the 2RDM of the KS system. In fact, the interaction component then reduces to the $v_{xc}^W$ approximation:

$$v_{xc}^W[n(t), n_{xc}(t)] \rightarrow v_{xc}^W[\tilde{n}(t), \tilde{n}_{xc}(t)]$$

(6)

but, importantly, the $v_{xc}^W$-component is no longer zero. We denote the xc potential arising from this approximation as $v_{xc}^0$.

We also briefly discuss a second approximation, denoted HF-driven, which is in a sense complementary to that of Eq. (9): instead of having no explicit dependence of $\rho_2$ on the fictitious 1RDM $\tilde{\rho}_1$, HF-driven ignores the $\rho_{1,s}$ dependence and takes $\tilde{\rho}_2$ as the Hartree-Fock (HF) functional of $\tilde{\rho}_1$. That is

$$\tilde{\rho}_2[\tilde{\rho}_1, \rho_{1,s}] \rightarrow \rho_{2,H}^F[\tilde{\rho}_1],$$

(10)

which, for a spin-singlet, gives $\tilde{\rho}_2(r_1, r_2; r'_1, r'_2) = \hat{\rho}(r_1, r_2; r'_1, r'_2) = \hat{\rho}(r_1, r'_2)\hat{\rho}(r'_1, r_2)$. The KS potential found is that which reproduces the density of the TDHF evolution of an initially-correlated wavefunction. As discussed above, such an approximation would not yield a useful method for TDDFT; its only purpose here is to illustrate that dynamical step and peak features in $v_{xc}^W$ can be retrieved with relatively simple approximations for $\tilde{\rho}_2[\tilde{\rho}_1, \rho_{1,s}]$.

We point out that $v_{xc}^0$ satisfies two fundamental exact conditions in TDDFT. Perhaps most important is the Zero Force Theorem (ZFT) [22–24, 37, 38], since violation of this can lead to self-excitation and numerical instabilities [39]. The ZFT states that the xc potential cannot exert a net force, $\int n(r, t)\nabla v_{xc}(r, t)dr = 0$, and in Ref. [30]
it was shown that \( v_{\text{XC}}^S \) satisfies this. It remains to investigate whether \( v_{\text{XC}}^T, \rho_1 \) (i.e. \( v_{\text{XC}} \) of Eq. (3), with \( \rho_1 \) computed as in Eq. (5) with Eq. (9)), also satisfies the ZFT. First, we write \( v_{\text{XC}}^{T,\rho} \) as the difference of two terms \( v_{\text{XC},\text{int}}^{T,\rho} \) and \( v_{\text{XC},\text{S}}^{T,\rho} \) as defined as:

\[
\nabla \cdot (n \nabla v_{\text{XC},\text{int}}^{T,\rho}) = -\nabla \cdot \left[ D \bar{\rho}_1 (t', r, t) \right]_{r'=r}
\]

with \( v_{\text{XC},\text{S}}^{T,\rho} \) defined in the same way but with \( \bar{\rho}_1, \rho(t', r, t) \) on the right-hand-side. In fact, \( v_{\text{XC},\text{int}}^{T,\rho} \) and \( v_{\text{XC},\text{S}}^{T,\rho} \) independently satisfy the ZFT; we show the proof for \( v_{\text{XC},\text{int}}^{T,\rho} \) only as that for \( v_{\text{XC},\text{S}}^{T,\rho} \) follows analogously. Writing \( \bar{\rho}_1(r, r') \) as

\[
\bar{\rho}_1 (r, r') = \sum_i \tilde{\omega}_i \tilde{\phi}_i^*(r') \tilde{\phi}_i (r), \quad (11)
\]

we compute

\[
\int n(r, t) \nabla v_{\text{XC},\text{int}}^{T,\rho}(r, t) d^3 r = \int d^3 r D \bar{\rho}_1 (r', r, t) |_{r'=r}
\]

\[
= \frac{1}{4} \sum_i \tilde{\omega}_i \int d^3 r \nabla \left( 4 |\nabla \tilde{\phi}_i|^2 - \nabla^2 |\tilde{\phi}_i|^2 \right) \quad (12)
\]

which involves the values of the orbitals and derivatives at the boundary. The integral thus vanishes for finite systems, or if the system is periodic. Hence, \( v_{\text{XC},\text{S}}^{T,\rho} \) satisfies the zero-force theorem.

The approximation \( v_{\text{XC}}^h \) also satisfies the Generalized Translation Invariance (GTI), which states that in a frame uniformly boosted by \( b(t) \), the xc potential transforms as

\[
v_{\text{XC}}^h[n; \Psi(0), \Phi(0)](r) = v_{\text{XC}}^h[n; \Psi(0), \Phi(0)](r + b(t), t) . \quad (13)
\]

The proof follows similarly to those given for the exact potential in Ref. [30]. The proofs for the HF-driven TDDFT of Eq. (10) follow in a similar way.

We also note that \( v_{\text{XC}}^h \) is one-electron self-interaction free: \( v_{\text{XC}}^h \) cancels \( v_{\text{HF}} \) and \( v_{\text{XC},\text{S}}^{T,\rho} \) is zero since \( \rho_1 = \rho_{1,\text{S}} = \bar{\rho}_1 \) for one electron.

Turning now to the numerical implementation of the approach, one requires two propagations: one is Eq. (5) to obtain \( \rho_1 \), and the other is the KS equation Eq. (8). These need to be run self-consistently, with \( \bar{\rho}_1 \) from Eq. (5) feeding into the potentials in Eq. (8) and \( \rho_{1,\text{S}} \) from Eq. (8) feeding into Eq. (5). We have found that because of the multiple derivatives involved and the sensitivity to error in the potential, using the formula in Eq. (3) directly is numerically challenging. Even using the exact time-dependent quantities, a straightforward implementation of this expression does not generate the exact density. Instead, we follow the equivalent approach, of requiring that the KS potential \( v_{\text{KS}}^n \) is such that Eq. (8) reproduces the density \( \tilde{n} \) at each time-step. To do so, we minimize

\[
||\partial_t^2 n(v) - \partial_t^2 \tilde{n}||^2 + \varepsilon^2 ||\nabla v_{\text{KS}}||^2
\]

where \( n(v) \) is the density resulting from the TDKS propagation, and \( \varepsilon \) is a smoothing parameter: ideally this is zero to make a perfect match between the density of \( \bar{\rho}_1 \) and the KS evolution, but numerically we find that taking it as zero rapidly yields large oscillations in the low-density regions that lead to instability and noise in the physical density-regions later on. Taking \( \varepsilon \) as small (10\(^{-5}\)–10\(^{-3}\)) discourages large changes in the KS potential, so taming these oscillations while leaving unaffected the potential in the regions of non-negligible density. We checked convergence in the physical regions of the potential and density with respect to \( \varepsilon \). We use a fourth-order Runge-Kutta propagator for the density-matrix propagation of Eq. (5) where \( \partial_t^2 n_{\text{exact}}(v) \) is linear with respect to \( v \), so minimization in Eq. (14) reduces to a linear matrix problem. The supplementary information presents more detail of the main concepts we used to propagate the two quantum systems, Eq. (5) and (8) while forcing the respective densities to stay equal.

To test the density-matrix coupled approximation Eq. (9), we studied a model system of two soft-Coulomb interacting electrons in 1D. Such a simple model allows us to have access to the exact solution and the exact KS potential, while retaining essential features of the exact 3D Coulomb-interacting problem [40–43]. The external potential is \( v_{\text{ext}}(x) = -2/\sqrt{1 + x^2} \) while the interaction is \( v(x, x') = 1/\sqrt{1 + (x - x')^2} \). In the following, \( \Psi_0 \) and \( \Psi_1 \) refer to the ground and first excited singlet states of the interacting Hamiltonian respectively.

First we consider field-free evolution of the state

\[
\Psi(t = 0) = (\Psi_0 + \Psi_1)/\sqrt{2} \quad , \quad (15)
\]

resulting in a density that is periodic in time, with a period of \( 2\pi/(E_1 - E_0) = 11.788 \) a.u. This initial wave-function defines \( \rho_1(0) \) for the initial condition of Eq. (5). The TDDFT KS system may begin in any initial state that reproduces the density \( n(0) \) of Eq. (15) and its time-derivative \( \partial_t n(0) \). We consider choices of the form

\[
\Phi(t = 0) = \frac{1}{\sqrt{1 + a^2}}(\Phi_0^{(a)} + a\Phi_1^{(a)}) \quad (16)
\]

with

\[
\Phi_0^{(a)}(x_1, x_2) = \phi_0^{(a)}(x_1)\phi_0^{(a)}(x_2), \quad \Phi_1^{(a)}(x_1, x_2) = \frac{1}{\sqrt{2}}(\phi_0^{(a)}(x_1)\phi_1^{(a)}(x_2) + \phi_1^{(a)}(x_1)\phi_0^{(a)}(x_2))
\]

The single-particle orbitals \( \phi_i^{(a)} \) are computed so that \( \Phi(t = 0) \) has the right initial conditions for the density. Here, we will discuss the cases \( a = 1 \) and \( a = 0 \).

We first consider the case \( a = 1 \). Figure 1 shows the potential and density obtained by the approximations \( v_{\text{XC}}^S \) and \( v_{\text{XC}}^h \) alongside the exact, and, for illustration, the HF-driven; a movie is provided in the supplementary information. The figure also shows the \( v_{\text{XC}}^w \) component of the exact potential.
Initially, since $\rho_1(0) = \rho(0)$, the $v_{xc}^T(0)$ component of the potential $v_{xc}^\delta(0)$ is equal to the exact $v_{xc}^T(0)$. The density oscillates from side to side, with its small bump at $x \approx \pm 4$ a.u. As it evolves, the potential $v_{xc}^\delta$ reproduces qualitatively the peaks and steps of the exact potential, although not exactly in phase. On the other hand, $v_{xc}^S$ stays relatively smooth; as in previous work [16, 29, 32] the complex structures of the exact potential come from $v_{xc}^T$, while $v_{xc}^S$ cradles the density and closely mimics $v_{xc}^W$ at all times. The steps and peaks are also reproduced by the simple HF-driven propagation, showing that they arise with even the simplest non-zero approximation for $\rho_1 - \rho_{1,s}$. Crucial is the structure of $v_{xc}^T$ itself. However, after some time in the propagation, $v_{xc}^\delta$ develops a fatal problem: self-amplifying needle-like peak structures appear that go to infinity causing the propagation to collapse. An example of this structure is visible at $t = 11$ a.u. just before the calculation collapses. As we will shortly argue, the development of such non-$\nu$-representable structures in the $v_{xc}^\delta$ approximation is not a numerical feature, but rather is intrinsic to the approximation itself; it does not show up in the HF-driven potential. The effect of the peaks and steps on the density is difficult to discern in Fig. 1, but the dipole shown in the lowest right panel shows the improvement of $v_{xc}^\delta$ over $v_{xc}^S$ before the collapse.

We also studied the case $a = 0$ which is more challenging for TDDFT, as the initial KS state is a ground-state with a structure totally different from the interacting state. The initial step in the exact potential is larger than for $a = 1$ as evident in Fig. 2 and in the movie in supplementary material. The kinetic component $v_{xc}^T$ is crucial to obtain correct dynamics in this situation, and propagation with $v_{xc}^S$ does not provide a good dipole moment (lower right panel), although it is still close to the exact $v_{xc}^W$. Our approximation $v_{xc}^\delta$ gives a better dipole and density, approximately capturing step structures, but again, after some time, develops the sharp needle-like structure that goes to infinity, killing the propagation. Again the HF-driven potential is shown to illustrate that this simplest approximation for $\rho_1 - \rho_{1,s}$ also reproduces step structures (and its propagation remains stable).

To see if we can numerically get rid of these needles we varied the smoothing parameter $\epsilon$. In Fig. 3 we plot the density in logscale (lower panel) and the potential $v_{xc}^\delta$ (upper subpanels) just before our calculation collapses. For the smaller $\epsilon$, the potential creates a needle in the region of very low density, where the logarithmic density-derivative is almost discontinuous. One can assert that low density region is not so important and increase $\epsilon$ but this just enables the propagation to go a little further until it creates another needle at the next derivative “discontinuity”. Even with bigger $\epsilon$ we cannot get rid of this infinite peak that now appears well inside the region of interest. Increasing $\epsilon$ further would have an impact on the large density regions and drastically alter the intention of the approximation. This behavior and the fact that reducing $dt$ does not improve our calculation suggest that the needles are a feature of the approximation and not a numerical problem.

Finally, we briefly discuss the case of electron-scattering off a hydrogen atom initially in its ground state (third movie in the supplementary material). The $v_{xc}^\delta$ propagation reproduces the density and exact po-
FIG. 3. The potential $\rho_{\text{xc}}^0$ (upper panel) and logarithm of the density (lower panel) of the calculation of Fig. 2, at its final time $t_f$, with different smoothing parameters: $\varepsilon = 10^{-6}$ (black solid, $t_f = 5.45$ a.u.), $\varepsilon = 10^{-5}$ (green dashed, $t_f = 5.6$ a.u., with $\rho_{\text{xc}}^0$ scaled by a factor of 10), $\varepsilon = 10^{-4}$ (brown dotted, $t_f = 5.9$ a.u., with $\rho_{\text{xc}}^0$ scaled by a factor of 20).

tential accurately, even capturing the large peak behind the target atom on electron approach, until again the calculation is killed by a needle structure.

In conclusion, we have presented a new, first-principles approach to developing non-adiabatic functionals, that begins with an exact expression for the tional for a 1RDM, with information feeding back and forth between the equations, as the system is solved. The dynamical step and peak features which have remained elusive, appear even when a simple HF-driven approximation is made in the 1RDM equation; these features arise from the the form of the equation that defines $\rho_{\text{xc}}^0$. The initial approximation explored here satisfies the ZFT, the GTI, is self-interaction-free, and contains memory, however after a short time unphysical instabilities appear. A better understanding of these divergences could lead to a better $\rho_2/\rho_1, \rho_{\text{xc}}, s$ and work is underway in this direction. The general approach also opens the door to possibly by-passing the 1RDM calculation altogether, for example by searching for a paradigmatic system for which one can obtain the interacting 1RDM as a functional of KS accessible quantities.
