Abstract

We study polynomial time algorithms for estimating the mean of a random vector $X$ in $\mathbb{R}^d$ from $n$ independent samples $X_1, \ldots, X_n$ when $X$ may be heavy-tailed. We assume only that $X$ has finite mean $\mu$ and covariance $\Sigma$. In this setting, the radius of confidence intervals achieved by the empirical mean are large compared to the case that $X$ is Gaussian or sub-Gaussian. In particular, for confidence $\delta > 0$, the empirical mean has confidence intervals with radius of order $\sqrt{\text{Tr} \Sigma / \delta n}$ rather than $\sqrt{\text{Tr} \Sigma / n} + \sqrt{\lambda_{\text{max}}(\Sigma) \log(1/\delta)/n}$ from the Gaussian case.

We offer the first polynomial time algorithm to estimate the mean with sub-Gaussian confidence intervals under such mild assumptions. Our algorithm is based on a new semidefinite programming relaxation of a high-dimensional median. Previous estimators which assumed only existence of $O(1)$ moments of $X$ either sacrifice sub-Gaussian performance or are only known to be computable via brute-force search procedures requiring $\exp(d)$ time.

1 Introduction

This paper studies estimation of the mean of a high-dimensional random vector from independent samples. Our goal is to design an estimator which is both statistically and computationally efficient. For us, that means it should achieve essentially optimal rates of statistical error and also be computable in polynomial time.

We address a simple problem: given i.i.d. copies $X_1, \ldots, X_n$ of an unknown random vector $X \in \mathbb{R}^d$ with finite mean $\mu$ and covariance $\Sigma$, and an error tolerance $\delta > 0$, find an estimate $\hat{\mu}_\delta(X_1, \ldots, X_n)$ such that $\mathbb{P}\{\|\hat{\mu} - \mu\| > r_\delta\} \leq \delta$ for as small a number $r_\delta$ as possible. Our main result is the first polynomial-time algorithm for this problem which achieves essentially optimal confidence radius $r_\delta$ (up to constant factors). Our algorithm is based on semidefinite programming.

Under only the assumption that $X$ has finite covariance, the samples $X_1, \ldots, X_n$ may contain many outliers. Consider their effect on the empirical mean $\overline{\mu}_n = \frac{1}{n} \sum_{i \leq n} X_i$. While among all estimators $\overline{\mu}_n$ minimizes the mean squared error, $\mathbb{E}\|\mu - \overline{\mu}_n\|^2 = \text{Tr} \Sigma/n$, the concentration of $\|\mu - \overline{\mu}_n\|$ may be rather poor. Chebyshev’s inequality shows that $\mathbb{P}\{\|\mu - \overline{\mu}_n\| > \sqrt{\text{Tr} \Sigma / \delta n}\} \leq \delta$.

By constructing $X$ where outliers at radius $\text{Tr} \Sigma / \delta$ occur with probability of order $\delta$ one may see that this analysis of the empirical mean is tight.

If $X$ were Gaussian, however, the story would be different. By applying Gaussian concentration to $\|\mu - \overline{\mu}_n\|$, one may show that

$$
\mathbb{P}\left\{\|\mu - \overline{\mu}_n\| > \sqrt{\frac{\text{Tr} \Sigma}{\delta n}} + \sqrt{\frac{2\|\Sigma\| \log(1/\delta)}{n}}\right\} \leq \delta,
$$

(1.1)

where $\|\Sigma\| = \lambda_{\text{max}}(\Sigma)$ is the maximum eigenvalue of $\Sigma$. This bound is improved in two ways: the $1/\delta$ term has become $\log(1/\delta)$, and that term multiplies $\|\Sigma\|$ rather than $\text{Tr} \Sigma$, which may may differ by a factor of the dimension $d$. Following [LM18], we say that an estimator which achieves Eq. (1.1) (up to a constant factor) has sub-Gaussian performance.

In the classical case $d = 1$, many estimators are known which achieve sub-Gaussian performance even when $X$ has only finite mean and covariance [C+12, DLL+16]. One is the median of means [NY83, JVV86, AMS99]. Suppose $X_1, \ldots, X_n$ are i.i.d. copies of a real-valued random variable $X$ with variance $\sigma^2$, and for $k = \Theta(\log 1/\delta)$, let $Z_i$ for $i \leq k$ be the average of samples $X_{i:n/k}$ through $X_{(i+1):n/k}$. Then it is an exercise to show that the median (or indeed any fixed percentile) of the $Z_i$’s satisfies

$$
\mathbb{P}\left\{|\text{median}(Z_1, \ldots, Z_k) - \mu| > \frac{C \sigma \sqrt{\log(1/\delta)}}{\sqrt{n}}\right\} \leq \delta
$$
for some universal constant $C$.

Our main result is the first algorithmically efficient estimator with sub-Gaussian performance for large dimensions $d$. Our algorithm combines the median of means idea with a convex relaxation approach to compute a high-dimensional median.

**Theorem 1.1.** For every $n \in \mathbb{N}$ and $\delta > 0$ there is an algorithm which runs in time $O(nd) + (d \log(1/\delta))^{O(1)}$ such that for every $X$ with $\mathbb{E}X = \mu$ and $\mathbb{E}(X - \mu)(X - \mu)^T = \Sigma$, given i.i.d. copies $X_1, \ldots, X_n$ of $X$ the algorithm outputs a vector $\hat{\mu}_{\delta}(X_1, \ldots, X_n)$ such that

$$\mathbb{P}\left\{ \|\mu - \hat{\mu}_{\delta}\| > 640 \left( \sqrt{\frac{\text{Tr} \Sigma}{n}} + \sqrt{\frac{2\|\Sigma\| \log(1/\delta)}{n}} \right) \right\} \leq \delta.$$  

No effort has been made to optimize the constant 640 in the theorem statement. The constant hidden by $O(1)$ in the $(dk)^{O(1)}$ term in the running time is at most $7 + o(1)$, using general-purpose solvers for semidefinite programs. We expect substantial improvement in the running time is possible.

**Previous polynomial time estimators** As we have already discussed, while it is trivially computable in polynomial time, the empirical mean is far from achieving sub-Gaussian performance under the assumptions of Theorem 1.1. Naive outlier removal – discarding samples $X_i$ with large norms $\|X_i\|$ before computing the empirical mean – is more successful. However, it is not a translation-invariant operation, so while the first-order growth rate of the confidence radius it achieves is sub-Gaussian, the radius depends at second order on $\mathbb{E}\|X\|^2$ rather than $\mathbb{E}\|X - \mu\|^2 = \text{Tr} \Sigma$ [CG18].

The previous polynomial-time estimator which comes closest to sub-Gaussian performance under the same assumptions as Theorem 1.1 is Minkser’s geometric median algorithm [M+15]. The geometric median of $Z_1, \ldots, Z_k \in \mathbb{R}^d$ is

$$\text{geometric-median}(Z_1, \ldots, Z_k) = \arg\min_{x \in \mathbb{R}^d} \sum_{i \leq k} \|Z_i - x\|.$$  

Minsker proves that if $Z_1, \ldots, Z_k$ are each the average of $n/k$ samples $X_i$ for $k = \Theta(\log 1/\delta)$ then

$$\mathbb{P}\left\{ \|\text{geometric-median}(Z_1, \ldots, Z_k) - \mu\| > C \sqrt{\frac{\text{Tr} \Sigma \cdot \log(1/\delta)}{n}} \right\} \leq \delta$$  

for some universal constant $C$.

A result of Cohen et al. shows that geometric-median$(Z_1, \ldots, Z_k)$ is computable in nearly-linear time (that is, time $dk\cdot(\log d k)^{O(1)}$ – slower but still polynomial time algorithms were known previously) [CLM+16]. Theorem 1.1 of this work improves on the geometric median by moving the log$(1/\delta)$ term to multiply $\|\Sigma\|$ rather than $\text{Tr} \Sigma$, matching the
performance of the empirical mean in the Gaussian setting. Recall that $\text{Tr} \Sigma$ may be as large as $d\|\Sigma\|$ if $X$ is isotropic. In modern settings, with thousands or millions of dimensions, this difference in the confidence radius is appreciable.

**Sub-Gaussian performance, but in exponential time** Our work has been preceded by substantial exploration of generalizations of the median of means to larger dimensions $d$ [LO11, HS16, M+15, LM18]. The culmination of these works is the median-of-means estimator of Lugosi and Mendelson [LM18], which was the first to achieve sub-Gaussian performance for arbitrary $d$. Key to their estimator is a new notion of the $d$-dimensional median of vectors $Z_1, \ldots, Z_k \in \mathbb{R}^d$. For Lugosi and Mendelson, the median is

$$\arg\min_{x \in \mathbb{R}^d} \max_{y \in \mathbb{R}^d} \|x - y\| \text{ such that } \|Z_i - x\| \geq \|Z_i - y\| \text{ for at least } \frac{k}{2} Z_i \text{'s.} \quad (1.2)$$

While this estimator achieves sub-Gaussian performance, it is difficult to imagine any computationally-efficient method of evaluating it. In particular, it appears to require either optimization of a non-convex function in $\mathbb{R}^d$ or combinatorial search through all subsets of the vectors $Z_i$ of size $k/2$.

In numerous well-studied cases, inference problems with similarly combinatorial solutions seem to entirely lack computationally-efficient algorithms. One major example is the *planted clique* problem, where the goal is to test for the presence of a hidden clique of size about $n^{0.01}$ in an Erdős-Rényi graph $G(n, 1/2)$. There is strong evidence from theoretical computer science that no polynomial-time hypothesis testing algorithm substantially beats random guessing for this problem, in spite of the fact that hidden cliques of size $2^{0.01 \log n}$ remain detectable if algorithmic considerations are ignored [Kar76, BE76, Jer92, Kuc95, BHK+16]. A similar story applies to many more traditional statistics problems: estimation of a sparse principal component of high-dimensional data, for instance [AW08, KNV+15, HKP+17]. Thus prior to this work it was uncertain whether or not there should exist a polynomial time algorithm whose statistical performance matches Lugosi and Mendelson’s median of means estimator.

While the algorithm we present does run in polynomial time, it is far from practical on data sets of even moderate dimension, or for moderately small $\delta$. This is due to the use of a semidefinite programming relaxation which our algorithm solves. Impractical running times are typical for semidefinite programming based algorithms, until they are further refined. However, many semidefinite programs in both combinatorial and statistical applications (for example, the classic max-cut semidefinite program [GW95]) are by now known to be solvable in nearly-linear time – that is, in time $N(\log N)^{O(1)}$ for a size-$N$ input [AK16, Ste10, HSSS16]. Thus, it seems likely that an algorithm similar to the one we present here can be made truly practical.
Our approach Rather than compute Eq. (1.2) directly, our approach begins with a convex relaxation. In particular, we employ a semidefinite program (SDP) from the Sum of Squares hierarchy, a powerful family of SDP relaxations for polynomial optimization problems. Sum of Squares (SoS) SDPs have recently seen numerous applications to computationally-challenging problems in statistics and machine learning. For instance, they offer the best available polynomial-time guarantees for parameter estimation of high-dimensional mixture models and for estimation in Huber’s contamination model [H+64, HL18, KSS18, KKM18]. SoS has also been key to progress in computationally-challenging tensor problems with statistical applications, such as tensor decomposition and tensor completion [MSS16, BM16, PS17].

At a high level, our strategy is to show that by choosing a sufficiently strong convex relaxation of Eq. (1.2), the main properties of Eq. (1.2) established by Lugosi and Mendelson in the course of proving its sub-Gaussian performance apply also to optimal solutions of the convex relaxation. Of course, one must be sure that the relaxation does not become so complex that polynomial-time solvability is lost. The main work in this paper shows that a \((d \cdot \log(1/\delta))^{O(1)}\)-size SDP suffices; this is the reason our algorithm runs in polynomial time.

Organization The rest of the paper has two parts. In Section 2 we describe our median of means estimator and the convex relaxation which underlies it. We reduce the proof our main theorem to a simpler algorithmic problem, which we resolve in Section 3.

2 Main Algorithm and Analysis

Our algorithm employs a median-of-means scheme: first, the samples \(X_1, \ldots, X_n\) are placed into \(k = \Theta(\log 1/\delta)\) buckets at random, and the algorithm computes the empirical means \(Z_1, \ldots, Z_k\) inside the buckets. Then, the algorithm computes a certain median of the vectors \(Z_1, \ldots, Z_k\). The polynomial time algorithm for this median computation is the main technical contribution of this paper. It is captured in the following lemma.

**Lemma 2.1 (median-sdp).** For every \(k, d \in \mathbb{N}\) there is an algorithm median-sdp with running time \((kd)^{O(1)}\) such that for every \(\mathbb{R}^d\)-valued random variable \(Z\) with \(\mathbb{E} Z = \mu\) and \(\mathbb{E}(Z - \mu)(Z - \mu)^\top = \Sigma\), given \(k\) i.i.d. copies \(Z_1, \ldots, Z_k\) of \(Z\) median-sdp returns a vector \(\hat{\mu}\) such that with probability at least \(1 - \exp(-k/100)\) over \(Z_1, \ldots, Z_k\),

\[
\|\mu - \hat{\mu}\| \leq 64 \left( \sqrt{\frac{\text{Tr} \Sigma}{k}} + \sqrt{\|\Sigma\|} \right)
\]

From Lemma 2.1 we can prove the main theorem.
Proof of Theorem 1.1. Let $k = 100 \log(1/\delta)$. Without loss of generality, assume that $k$ divides $n$. Then let $Z_i$ be the average inside the $i$-th bucket:

$$Z_i = \frac{k}{n} \sum_{j=i}^{(i+1)n/k} X_i .$$

The vectors $Z_1, \ldots, Z_k$ are i.i.d. with mean $\mathbb{E} Z = \mathbb{E} X = \mu$ and covariance $\Sigma_Z = \frac{k}{n} \Sigma$. The output of our algorithm is the algorithm median-sdp of Lemma 2.1 on the vectors $Z_1, \ldots, Z_k$. With probability at least $1 - \delta$ (by the definition of $k$), then the resulting estimator $\hat{\mu}$ satisfies

$$\|\mu - \hat{\mu}\| \leq 64 \left( \sqrt{\frac{\text{Tr} \Sigma_Z}{k}} + \sqrt{\|\Sigma_Z\|} \right) \leq 64 \left( \sqrt{\frac{\text{Tr} \Sigma}{n}} + \sqrt{\|\Sigma\| \log(1/\delta)} \right) . \quad \Box$$

The remainder of the paper is devoted to the algorithm median-sdp and the proof of Lemma 2.1.

2.1 The median polynomial program

We recall the setting: there is a $d$-dimensional random vector $Z$ with finite mean $\mu$ and covariance $\Sigma$ (we drop the subscript $Z$ on $\Sigma$ from the previous subsection, since now the random variable $X$ has left the picture). Given $k$ i.i.d. samples $Z_1, \ldots, Z_k$ from $Z$, the goal is to find a vector $\hat{\mu}$ such that $\|\mu - \hat{\mu}\| \leq 64(\sqrt{\text{Tr} \Sigma/k} + \sqrt{\|\Sigma\|})$, with probability at least $1 - \exp(-k/100)$. The starting point of median-sdp is a semidefinite relaxation of the following optimization problem.

Definition 2.2 (Median Polynomial Program). Let $Z_1, \ldots, Z_k \in \mathbb{R}^d$. The median polynomial program is:

$$\min_{x \in \mathbb{R}^d} \max_{v \in \mathbb{R}^d} \|v\|^2$$

such that $b_i^2 = b_i$ for $i \leq k$

$$\sum_{i \leq k} b_i = \frac{k}{2}$$

$$b_i \langle Z_i - x, v \rangle \geq b_i \cdot \|v\|^2 .$$

Notice that the constraints $b_i^2 = b_i$ are solved only by $b_i \in \{0,1\}$. By rearranging the constraints one may see that feasible solutions are pairs $b, v$ where $b$ is the indicator of $B \subseteq [k]$ with $|B| \geq k/2$ such that for every $i \in B$ it holds that $\|Z_i - (x + 2v)\| \leq \|Z_i - x\|$.

Implicit in the work of Lugosi and Mendelson [LM18] is the following lemma:
Lemma 2.3 ([LM18], implicit). With probability at least $1 - \exp(-k/C)$, any minimizer $x^*$ of the median polynomial program satisfies $\|x^* - \mu\| \leq C(\sqrt{\text{Tr} \Sigma/k} + \sqrt{\|\Sigma\|})$ for some universal constant $C$.

Thus, an efficient algorithm to find a minimizer of the median polynomial program would solve our mean estimation problem. Unfortunately, there is no clear algorithm to solve the median polynomial program. Instead, our algorithm will solve a semidefinite relaxation of it. Our main technical lemma will be an analogue of Lemma 2.3 for our relaxation.

In the remainder of this section we describe \textsc{median-sdp}, which is our semidefinite relaxation, and provide its main analysis. First we need some background.

### 2.2 Linear operators, semidefinite programs, and the SoS method

The median polynomial program involves three sets of variables, $x, v$ and $b$, and polynomial inequalities of degree 3 among them. A first attempt at a semidefinite relaxation would relax the variables $x, v$ to matrices $X \succeq 0, V \succeq 0$, acting respectively as relaxed proxies for the rank-one matrices $xx^T$ and $vv^T$, and the variables $b$ to a matrix $B \succeq 0$ with $b_{ii} \leq 1$ as a proxy for $bb^T$. However, cross-terms like $b_i v_j$ also need proxies in the relaxation, and even with this accomplished, some inequalities between degree 3 polynomials, like $b_i \langle Z_i - x, v \rangle \geq b_i \cdot \|v\|^2$, still need to be expressed.

The \textit{sum of squares method} is a principled approach to designing semidefinite programming relaxations for such complicated polynomial optimization problems. Solutions to the sum of squares semidefinite program are certain nonnegative linear operators from polynomials in the variables $x, v, b$ to $\mathbb{R}$.

**Definition 2.4 (Pseudoexpectation).** A degree-$t$ \textit{pseudoexpectation} in variables $y = y_1, \ldots, y_n$ is a linear operator $\hat{E} : \mathbb{R}[y_1, \ldots, y_n]_{\leq t} \to \mathbb{R}$, where $\mathbb{R}[y_1, \ldots, y_n]_{\leq t}$ are the polynomials in $y_1, \ldots, y_n$ with real coefficients and degree at most $t$. A pseudoexpectation is:

1. Normalized: $\hat{E} 1 = 1$, where $1 \in \mathbb{R}[y_1, \ldots, y_n]_{\leq d}$ on the left side is the constant polynomial.

2. Nonnegative: $\hat{E} p(y)^2 \geq 0$ for every $p$ of degree at most $t/2$.

In keeping with the computer science literature, we use the names \textit{pseudoexpectation} and \textit{pseudodistribution} interchangeably.

**Definition 2.5 (Satisfying constraints).** A pseudoexpectation of degree $t$ satisfies a polynomial equation $p(y) = 0$ if for every $q(y)$ such that $p(y)q(y)$ has degree at most $t$ it holds that $\hat{E} p(y)q(y) = 0$. The pseudodistribution satisfies an inequality $p(y) \geq 0$ if for every $q(y)^2$ such that $\deg q(y)^2 p(y) \leq t$ it holds that $\hat{E} p(y)q(y)^2 \geq 0$. 

6
**Example 2.6.** To demystify pseudoexpectations slightly, consider the classic semidefinite relaxation of the set \( \{\pm 1\}^n \) to the set \( \{ X \in \mathbb{R}^{(n+1)\times (n+1)} : X \succeq 0, X_{ii} = 1 \} \). (This is exactly the set of PSD matrices employed in the classic SDP-based max-cut algorithm of Goemans and Williamson [GW95].)

Each such \( X \) defines a degree 2 pseudoexpectation, by setting \( \tilde{E} x_i x_j = X_{ij} \) for \( 1 \leq i \leq n \) and \( \tilde{E} x_i = X_{0,i} \), and finally \( \tilde{E} 1 = X_{0,0} = 1 \). Since \( X \succeq 0 \), it also follows that for every polynomial \( p \in \mathbb{R}[x_1, \ldots, x_n]_{\leq 2} \), one has \( \tilde{E} p(x)^2 = p^T X p \geq 0 \), where by abuse of notation we have identified \( p \) with its vector of coefficients. Last, since \( \tilde{E} x_i^2 = X_{ii} = 1 \), the pseudoexpectation satisfies \( x_i^2 - 1 = 0 \) for each \( i \); these equations exactly characterize \( \{\pm 1\}^n \) as a variety in \( \mathbb{R}^n \).

As in this simple example, it is always possible to write an explicit semidefinite program whose solutions are pseudoexpectations satisfying some chosen set of polynomial equations, which we do for completeness in Section A. However, as the degrees of polynomials and number of different types of variables involved grow, these SDPs become notationally unwieldy. In this regard, the pseudoexpectation approach carries significant advantages.

**2.3 MEDIAN-SDP**

We need just one more definition before setting up median-SDP.

**Definition 2.7.** Let \( \tilde{E}_1 \) be a degree \( t \) pseudoexpectation on variables \( x = x_1, \ldots, x_n \) and \( \tilde{E}_2 \) be of degree \( t' \geq t \) on variables \( x_1, \ldots, x_n, y_1, \ldots, y_m \). We say \( \tilde{E}_2 \) extends \( \tilde{E}_1 \) if \( \tilde{E}_1 p(x) = \tilde{E}_2 p(x) \) for all \( p \in \mathbb{R}[x_1, \ldots, x_n]_{\leq t} \).

**Definition 2.8 (median-SDP).** Let \( Z_1, \ldots, Z_k \in \mathbb{R}^d \). In the following, \( \tilde{E} \) is a pseudodistribution on variables \( x_1, \ldots, x_d \) and \( \tilde{E}' \) is on \( x_1, \ldots, x_d, v_1, \ldots, v_d, b_1, \ldots, b_k \). (Notice that this is the same set of variables as in the median polynomial program.) \( \tilde{E}, \tilde{E}' \) are both of degree 4. The median-SDP is:

\[
\text{median-SDP}(Z_1, \ldots, Z_k) = \min_{\tilde{E}} \max_{\tilde{E}'} \tilde{E}' \|v\|^2 \quad \text{such that} \quad \begin{align*}
\tilde{E}' & \text{ satisfies } b_i^2 - b_i = 0 \text{ for all } i \leq k \\
\tilde{E}' & \text{ satisfies } \sum_{i \leq k} b_i - \frac{k}{2} = 0 \\
\tilde{E} b_i & \langle Z_i - x, v \rangle \geq \tilde{E} b_i \|v\|^2 \text{ for all } i \leq k. \tag{2.3}
\end{align*}
\]

Our main lemma on median-SDP, and the main technical lemma of this paper, is the following.
Lemma 2.9. Suppose $Z_1,\ldots,Z_k$ are i.i.d. with mean $\mu$ and covariance $\Sigma$. Let $\mathbf{E}^*$ be the optimizer of median-sdp on $Z_1,\ldots,Z_k$. With probability at least $1 - \exp(-k/100)$, the vector $\mathbf{E}^* x$ (whose $i$-th entry is $\mathbf{E}^* x_i$) has $\|\mathbf{E}^* x - \mu\| \leq 64(\sqrt{\text{Tr} \Sigma / k} + \sqrt{\|\Sigma\|})$.

In Section A, we design more explicit semidefinite programs whose solutions are the pseudodistributions $\mathbf{E}$ and $\mathbf{E}'$ of median-sdp. It then becomes clear that the function $f(\mathbf{E}) = \max_{\mathbf{E}'} \mathbf{E}' \|v\|^2$ is convex in $\mathbf{E}$, and can be evaluated by solving a semidefinite program; median-sdp is therefore solvable by the Ellipsoid algorithm. Thus, along with the running time analysis in Section A, Lemma 2.9 implies Lemma 2.1. We expect that by solving the optimization problem with a more tailor-made algorithm (using a first or second order descent method, for instance) will lead to much faster running times, but this requires a more sophisticated analysis.

In the remainder of this section, we prove Lemma 2.9 from sublemmas, which we then prove in subsequent sections. The first lemma bounds the inner variational problem in median-sdp (the maximization over $\mathbf{E}'$) in the case that $\mathbf{E} p(x) = p(\mu)$ for all $p$. We prove it in Section 3.

Lemma 2.10. Let $Z_1,\ldots,Z_k$ in $\mathbb{R}^d$ be i.i.d. with mean $\mu$ and covariance $\Sigma$. Let $\mathbf{E}$ be the degree 4 pseudoexpectation in variables $x_1,\ldots,x_d$ such that $\mathbf{E} p(x) = p(\mu)$. With probability at least $1 - \exp(-k/100)$,

$$\max_{\mathbf{E}'\text{ extends }\mathbf{E}} \mathbf{E}' \|v\|^2 \leq 60 \left( \frac{\text{Tr} \Sigma}{k} + \|\Sigma\| \right),$$

where the maximization is over $\mathbf{E}'$ satisfying the constraints of median-sdp.

The second lemma is a pseudoexpectation version of the observation that for every pair of vectors $x_0,x_1 \in \mathbb{R}^d$, either $\|x_0 - Z_i\| \geq \|x_1 - Z_i\|$ for at least half of the vectors $Z_i$, or $\|x_1 - Z_i\| \geq \|x_0 - Z_i\|$ for at least half of the $Z_i$'s.

Lemma 2.11. Suppose $\mathbf{E}_0$ is a degree 4 pseudodistribution on variables $x_1,\ldots,x_d,v_1,\ldots,v_d$. Then at least one of the following holds.

1. $\mathbf{E}_0$ can be extended to $\mathbf{E}'$ which is feasible for median-sdp.
2. Let $\mathbf{E}_1 p(x,v) = \mathbf{E} p(x + 2v, -v)$. Then $\mathbf{E}_1$ can be extended to $\mathbf{E}'$ which is feasible for median-sdp.

We prove Lemma 2.11 in Section 2.4. We also need an elementary fact.

Fact 2.12. Suppose that $\mathbf{E}$ is a degree 2 pseudoexpectation on $x$, and that $\mu \in \mathbb{R}^d$. Then $\|\mathbf{E} x - \mu\|^2 \leq \mathbf{E} \|x - \mu\|^2$. 

8
**Proof.** Since \( \|x - \mu\|^2 = \sum_{i \leq d} (x_i - \mu_i)^2 \), this follows from the more general statement that \( \hat{E} p(x)^2 \geq (\hat{E} p(x))^2 \). This in turn follows from \( \hat{E}(p(x) - \hat{E} p(x))^2 \geq 0 \), since

\[
0 \leq \hat{E}(p(x) - \hat{E} p(x))^2 = \hat{E} p(x)^2 - (\hat{E} p(x))^2.
\]

Now we can prove Lemma 2.9.

**Proof of Lemma 2.9.** Suppose that the event of Lemma 2.10 occurs. Let \((\hat{E}, \hat{E}')\) be the optimizers of median-sdp. Since \( \hat{E}_\mu \), given by \( \hat{E} p(x) = p(\mu) \), is also a feasible solution to median-sdp, by Lemma 2.10 we know that \( \hat{E}' \|v\|^2 \leq 64 \left( \frac{\|v\|}{k} + \|\Sigma\| \right) \).

Consider the pseudodistribution \( \hat{E}_0 \) on \( x_1, \ldots, x_d, v_1, \ldots, v_d \) given by \( \hat{E}_0 p(x, v) = \hat{E} p(x, \frac{1}{2}(\mu - x)) \). Suppose that the first case of Lemma 2.11 applies to it, so there exists a pseudodistribution \( \hat{E}_0' \) extending \( \hat{E}_0 \) and feasible for median-sdp. Then \( \hat{E}_0' \|v\|^2 \leq \hat{E}' \|v\|^2 \leq 64 \left( \frac{\|v\|}{k} + \|\Sigma\| \right) \). But since \( \hat{E}_0 \|v\|^2 = \hat{E}_0 \|v\|^2 = \frac{1}{4} \hat{E} \|\mu - x\|^2 \), we are done by Fact 2.12. If the second case of Lemma 2.11 applies, then notice that \( \hat{E}_1 p(x, v) = \hat{E}_0(\mu, \frac{1}{2}(x - \mu)) \), and the same argument applies using Lemma 2.10.

**2.4 Proof of Lemma 2.11**

In this section we prove Lemma 2.11.

**Proof of Lemma 2.11.** In both cases we will construct the solution by taking \( \hat{E}' p(x, v, b) = \hat{E} p(x, v, b) \) for some \( b \in \{0, 1\}^k \) where either \( \hat{E} = \hat{E}_0 \) or \( \hat{E} = \hat{E}_1 \). That is, \( \hat{E}' \) will look like an integral solution with respect to the \( b \) variables. Consider the numbers \( a_i = \hat{E}_0(Z_i - x, v) - \hat{E}_0 \|v\|^2 \). If at least half of them satisfy \( a_i \geq 0 \), then let \( b \) be the indicator of a set of exactly \( k/2 \) indices with \( a_i \geq 0 \).

Otherwise, consider \( a_i' = \hat{E}_1(Z_i - x, v) - \hat{E}_1 \|v\|^2 \). We have

\[
\hat{E}_1(Z_i - x, v) - \hat{E}_1 \|v\|^2 = \hat{E}_0(Z_i - x - 2v, -v) - \hat{E}_0 \|v\|^2 = 2 \hat{E}_0 \|v\|^2 - \hat{E}_0(Z_i - x, v) - \hat{E}_0 \|v\|^2.
\]

Thus if \( a_i < 0 \) then \( a_i' \geq 0 \). So, choose \( b \) to be the indicator of a set of exactly \( k/2 \) indices where \( a_i' \geq 0 \).

**3 SDP certificates for the median**

In this section we prove Lemma 2.10. The proof has two main steps, an expectation step and a concentration step. Both steps involve another semidefinite program, used only for purposes of analysis, which we call threshold-sdp. This SDP is a relaxation of the following problem: given vectors \( Z_1, \ldots, Z_k \), find \( v \) on the unit sphere maximizing the number of \( i \in [k] \) such that \( \langle Z_i, v \rangle \geq r \) for some threshold \( r > 0 \).
Lemma 3.2

This lemma states that if \( Z \) is a random variable with \( \mathbb{E} Z = 0 \) and \( \mathbb{E} ZZ^\top = \Sigma \), then for any parameter \( r > 0 \), the threshold-SDP \( \text{threshold-SDP}_r(Z_1, \ldots, Z_k) \) is bounded by \( r/4 \). The proof involves bounding the expectation of the difference between the threshold-SDP and the expectation of the threshold-SDP over all possible sets of vectors.

**Proof of Lemma 3.2.** For any parameter \( r > 0 \), the threshold-SDP \( \text{threshold-SDP}_r(Z_1, \ldots, Z_k) \) is bounded by \( r/4 \). The proof involves bounding the expectation of the difference between the threshold-SDP and the expectation of the threshold-SDP over all possible sets of vectors.
3.1 Expectation step

In this section we prove Lemma 3.2. The main tools will be a variant of Grothendieck’s inequality and a bound on the expected 2-to-1 norm of a random matrix. We start with a definition.

**Definition 3.4.** Let $A \in \mathbb{R}^{n \times m}$ be a matrix with rows $A_1, \ldots, A_n$. The 2-to-1 norm of $A$ is defined as

$$\|A\|_{2 \to 1} = \max_{\|x\|_1 = 1} \|Ax\|_1 = \max_{\|x\|_1 = 1, \sigma \in \{\pm 1\}^n} \sum_{i \leq n} \sigma_i \langle A_i, x \rangle.$$ 

The following lemma is due to Nesterov. It follows fairly easily from the observation that $\|A\|_{2 \to 1}^2 = \max_{\sigma \in \{\pm 1\}^n} \sigma^T A^T A \sigma$ and the fact (also due to Nesterov) that semidefinite programming yields a $\frac{2}{\pi}$-approximation algorithm for the maximization of a positive semidefinite quadratic form over $\{\pm 1\}^n$ (see e.g. [WS11], section 6.3 for a simple proof).

**Lemma 3.5 ([Nes98]).** There is a constant $K_{2 \to 1} \leq 2$ such that for every $n \times m$ matrix $A$ and every degree 2 pseudodistribution on $\sigma_1, \ldots, \sigma_n, v_1, \ldots, v_m$ which satisfies $\sigma_i^2 - 1 = 0$ and has $\mathbb{E}\|v\|^2 = 1$, it holds that $\mathbb{E}\langle \sigma, Av \rangle \leq K_{2 \to 1} \|A\|_{2 \to 1}$.

The next lemma, which we prove in Section 3.3, bounds the expected 2-to-1 norm of a random matrix with i.i.d. rows.

**Lemma 3.6.** Let $Z$ be an $\mathbb{R}^d$-valued random variable with mean $\mathbb{E}Z = 0$ and covariance $\mathbb{E}ZZ^T = \Sigma$. Let $Z_1, \ldots, Z_k$ be iid copies of $Z$, and let $A \in \mathbb{R}^{k \times d}$ be the matrix whose rows are $\frac{1}{k}Z_1, \ldots, \frac{1}{k}Z_k$. Then

$$\mathbb{E}\|A\|_{2 \to 1} \leq 2 \sqrt{\frac{\text{Tr} \Sigma}{k}} + \sqrt{\|\Sigma\|}$$

where $\|\Sigma\|$ denotes the operator norm, or maximum eigenvalue, of $\Sigma$.

Now we can prove Lemma 3.2.

**Proof of Lemma 3.2.** Let $\mathbb{E}$ be a feasible solution to threshold-sdp. Then

$$C \cdot \mathbb{E}\|v\|^2 \leq \mathbb{E} \sum_{i \leq k} b_i \|v\|^2 \leq \frac{1}{r} \mathbb{E} \sum_{i \leq k} b_i \langle Z_i, v \rangle$$

using that $\mathbb{E}$ satisfies $\sum_{i \leq k} b_i \geq C$ and $\mathbb{E} b_i \langle Z_i, v \rangle \geq \mathbb{E} b_i \|v\|^2 r$. Let $\sigma_i = 2b_i - 1$ and notice that if $b_i^2 - b_i = 0$ then $\sigma_i^2 - 1 = 0$. We rearrange the right-hand side of the above to

$$\frac{1}{r} \mathbb{E} \sum_{i \leq k} b_i \langle Z_i, v \rangle = \frac{1}{r} \left( \frac{1}{2} \mathbb{E} \sum_{i \leq k} \sigma_i \langle Z_i, v \rangle + \frac{1}{2} \mathbb{E} \sum_{i \leq k} \langle Z_i, v \rangle \right).$$
By Lemma 3.5, we have $\hat{E} \sum_{i \leq k} \sigma_i \langle Z_i, v \rangle \leq 2 \|A\|_{2 \rightarrow 1}$, where the rows of $A$ are the vectors $Z_1, \ldots, Z_k$. Also,

$$\hat{E} \sum_{i \leq k} \langle Z_i, v \rangle \leq \|\hat{E} v\| \cdot \left\| \sum_{i \leq k} Z_i \right\| \leq \left\| \sum_{i \leq k} Z_i \right\|.$$ 

So in the end we obtained

$$\mathbb{E} c^*(Z_1, \ldots, Z_k) \leq \frac{1}{r} \left( \mathbb{E} \|A\|_{2 \rightarrow 1} + \mathbb{E} \left\| \sum_{i \leq k} Z_i \right\| \right) \leq \frac{4}{r} \left( \sqrt{k \text{Tr} \Sigma} + k \sqrt{\|\Sigma\|} \right).$$

(Here we used Lemma 3.6 to bound $\mathbb{E} \|A\|_{2 \rightarrow 1}$.) This proves the lemma. □

### 3.2 Concentration step

We prove Lemma 3.3.

**Proof of Lemma 3.3.** By symmetry, without loss of generality we assume $i = k$. Let $\hat{E}$ be a feasible solution to $\text{threshold-sdp}(Z_1, \ldots, Z_k)$ with objective value $C$. We claim that $\hat{E}$ satisfies $\sum_{i \leq k-1} b_i \geq C - 1$. To see this first note that for any $p$ with $\deg p^2 \leq 2$,

$$\hat{E} p^2(1 - b_i) = \hat{E} p^2(1 - b_i)^2 \geq 0$$

because $\hat{E}$ satisfies $b_i^2 - b_i = 0$. So,

$$\hat{E} \left[ p^2 \cdot \left( \sum_{i \leq k-1} b_i - (C - 1) \right) \right] = \hat{E} \left[ p^2 \sum_{i \leq k} b_i - C \right] + \hat{E} \left[ p^2(b_i - 1) \right] \geq 0.$$ 

Thus, $\hat{E}$ restricted to $v, b_1, \ldots, b_{k-1}$ is feasible for $\text{threshold-sdp}(Z_1, \ldots, Z_{k-1})$ with objective value $C - 1$, which means

$$\text{threshold-sdp}(Z_1, \ldots, Z_k) \leq \text{threshold-sdp}(Z_1, \ldots, Z_{k-1}) + 1.$$ 

However, any feasible solution $\hat{E}$ for $\text{threshold-sdp}(Z_1, \ldots, Z_{k-1})$ can be extended to a feasible solution to $\text{threshold-sdp}(Z_1, \ldots, Z_k')$ by adding the variable $b_k$ but setting it to 0. So

$$\text{threshold-sdp}(Z_1, \ldots, Z_{k-1}) \leq \text{threshold-sdp}(Z_1, \ldots, Z_k')$$

which finishes the proof. □
3.3 The 2-to-1 norm of a random matrix

In this section we prove Lemma 3.6. The proof uses ideas from the empirical process literature. Lugosi and Mendelson prove a similar statement in the course of proving [LM18] Lemma 1. We will also need the Ledoux-Talagrand contraction:

Lemma 3.7 (Ledoux-Talagrand Contraction, as stated in [LM18]). Let $X_1, \ldots, X_n$ be i.i.d. random vectors taking values in $\mathbb{R}^d$. Let $\mathcal{F}$ be a class of real-valued functions defined on $\mathbb{R}^d$. Let $\sigma_1, \ldots, \sigma_n$ be independent Rademacher random variables, independent of the $X_i$. If $f : \mathbb{R} \to \mathbb{R}$ is a function with $\phi(0) = 0$ and Lipschitz constant $L$, then

$$E \sup_{f \in \mathcal{F}} \sum_{i \leq n} \sigma_i \phi(f(X_i)) \leq L \cdot E \sup_{f \in \mathcal{F}} \sum_{i \leq n} \sigma_i f(X_i).$$

Proof of Lemma 3.6. First, for any unit $v \in \mathbb{R}^d$,

$$E \frac{|Z_i, v|}{Z} \leq \sqrt{E \langle Z, v \rangle^2} = \langle v, \Sigma v \rangle^{1/2} \leq \sqrt{\|\Sigma\|}.$$

Let $Z = Z_1, \ldots, Z_k$. We have that

$$E \|A\|_{2 \rightarrow 1} = \frac{1}{k} E \sup_{Z \|v\|=1} \sum_{i \leq k} |\langle Z_i, v \rangle|$$

$$\leq \frac{1}{k} \left[ E \sup_{Z \|v\|=1} \left( \sum_{i \leq k} |\langle Z_i, v \rangle| - E \langle Z_i, v \rangle \right) \right] + \sup_{Z \|v\|=1} E |\langle Z, v \rangle|$$

$$\leq \frac{1}{k} E \sup_{Z \|v\|=1} \left( \sum_{i \leq k} |\langle Z_i, v \rangle| - E |\langle Z_i, v \rangle| \right) + \|\Sigma\|^{1/2}.$$

Thus it will suffice to show that $\frac{1}{k} E \sup_{Z \|v\|=1} (\sum_{i \leq k} |\langle Z_i, v \rangle| - E |\langle Z_i, v \rangle|) \leq 2 \sqrt{k/\log k}.$

Let $Z_i'$ be an independent copy of $Z_i$ and let $Z' = Z_1', \ldots, Z_k'$. Replacing $E |\langle Z_i, v \rangle|$ with $E |\langle Z_i', v \rangle|$ and using convexity of the sup,

$$\frac{1}{k} E \sup_{Z \|v\|=1} \left( \sum_{i \leq k} |\langle Z_i, v \rangle| - E |\langle Z_i, v \rangle| \right) \leq \frac{1}{k} E \sup_{Z \|v\|=1} \left( \sum_{i \leq k} |\langle Z_i, v \rangle| - |\langle Z_i', v \rangle| \right).$$

Let $\sigma_1, \ldots, \sigma_k \sim \{\pm 1\}$ be uniformly random signs. By exchangeability of $Z_i, Z_i'$,

$$\frac{1}{k} E \sup_{Z, Z' \|v\|=1} \left( \sum_{i \leq k} |\langle Z_i, v \rangle| - |\langle Z_i', v \rangle| \right) = \frac{1}{k} E \sup_{Z, Z', \sigma \|v\|=1} \left( \sum_{i \leq k} \sigma_i (|\langle Z_i, v \rangle| - |\langle Z_i', v \rangle|) \right).$$
This in turn is at most
\[
\frac{1}{k} \mathbb{E}_{\|v\|=1} \left( \sum_{i \leq k} \sigma_i |\langle Z_i, v \rangle| \right) + \frac{1}{k} \mathbb{E}_{\|v\|=1} \left( \sum_{i \leq k} \sigma_i |\langle Z'_i, v \rangle| \right) = \frac{2}{k} \mathbb{E}_{\|v\|=1} \left( \sum_{i \leq k} \sigma_i |\langle Z_i, v \rangle| \right).
\]

Now since the absolute value function is 1-Lipschitz, by Lemma 3.7 this is at most
\[
\frac{2}{k} \mathbb{E}_{\|v\|=1} \sum_{i \leq k} \sigma_i \|\langle Z_i, v \rangle\| = \frac{2}{k} \mathbb{E}_{\|v\|=1} \sum_{i \leq k} \sigma_i Z_i.\]
Squaring and expanding this norm,
\[
\frac{2}{k} \mathbb{E}_{\|v\|=1} \left( \sum_{i \leq k} \sigma_i Z_i \right) \leq \frac{2}{k} \left( \mathbb{E}_{\|v\|=1} \sum_{i, j \leq k} \sigma_i \sigma_j \langle Z_i, Z_j \rangle \right)^{1/2} = \frac{2}{k} \cdot (k \cdot \text{Tr} \Sigma)^{1/2} = 2 \sqrt{\text{Tr} \Sigma / k}.
\]

This concludes the proof. \(\square\)

**Acknowledgements**

Thanks to Siva Balakrishnan and Stas Minsker for bringing the mean estimation problem to my attention. I am most grateful to Gabor Lugosi, Prasad Raghavendra, Tarun Kathuria, Pravesh Kothari, Jacob Steinhardt, and Jerry Li for helpful conversations as this manuscript was being prepared.

I was supported while doing this work by the Miller Institute at UC Berkeley and by NSF Award No. 1408673.

A An Explicit SDP

In this section we record an explicit semidefinite program whose solutions are the feasible pseudodistributions for median-sdp. This construction is not novel: the ideas originate with Lasserre, Parrilo, Nesterov, and Shor [Las01, Sho87, Par00, Nes00], and the correspondence between SDPs and pseudodistributions has become standard in the Sum of Squares optimization and algorithms literature.

We define two sets of PSD matrices, corresponding to the pseudodistributions \( \hat{\mathbf{E}} \) and \( \hat{\mathbf{E}}' \) in median-sdp. We start with \( \hat{\mathbf{E}}' \), which will correspond to an SDP we call inner-sdp.
The variables in our semidefinite program are indexed by triples of multi-indices \((\alpha, \beta, \gamma)\) where \(\alpha, \beta\) are over \([d]\) and \(\gamma\) is over \([k]\), and \(|\alpha| + |\beta| + |\gamma| \leq 4\). For each, we introduce a variable \(Y_{\alpha,\beta,\gamma}\). To obtain the operator \(\tilde{\mathbb{E}}'\) of median-sdp from the variables \(Y\), set \(\tilde{\mathbb{E}}' x^\alpha v^\beta b^\gamma = Y_{\alpha,\beta,\gamma}\). Throughout suppose \(Z_1, \ldots, Z_k \in \mathbb{R}^d\).

The SDP involves several families of constraints on these variables. The first will enforce that \(\tilde{\mathbb{E}}'\) satisfies \(b_i^2 - b_i = 0\).

\[
Y_{\alpha,\beta,\gamma} = Y_{\alpha,\beta,\gamma'} \text{ if } \gamma = \gamma' \text{ as subsets of } [k].
\] (Boolean constraints)

(Note the important distinction between sets and multisets.) The next will enforce that \(\tilde{\mathbb{E}}'\) satisfies \(\sum b_i = k/2\).

\[
\sum_{i \leq k} Y_{\alpha,\beta,\gamma \cup \{i\}} = \frac{k}{2} \sum_{i \leq k} Y_{\alpha,\beta,\gamma} \text{ if } |\alpha| + |\beta| + |\gamma| \leq 3.
\] (Size constraints)

The third set enforces that \(\tilde{\mathbb{E}}' b_i \langle Z_i, v \rangle \geq \tilde{\mathbb{E}}' b_i \|v\|^2\).

\[
\sum_{j \in [d]} Z_{ij} Y_{\emptyset,(j),(i)} - \sum_{j \in [d]} Y_{(j),(j),(i)} \geq \sum_{j \in [d]} Y_{\emptyset,(j),(i)} \text{ for all } i \leq k.
\] (Threshold constraints)

The final linear constraint enforces normalization:

\[
Y_{\emptyset,\emptyset,\emptyset} = 1.
\] (Normalization constraint)

Finally, let \(M\) be the matrix with rows and columns indexed by \((\alpha, \beta, \gamma)\) such that \(|\alpha| + |\beta| + |\gamma| \leq 2\), with

\[
M(\alpha, \beta, \gamma, (\alpha', \beta', \gamma')) = Y_{\alpha \cup \alpha', \beta \cup \beta', \gamma \cup \gamma'}.
\]

Then

\[
M \succeq 0.
\] (Positivity constraint)

**OUTER-SDP** We move on to the SDP corresponding to \(\tilde{\mathbb{E}}\) in median-sdp. Let outer-sdp be the set \((X_\alpha)_{|\alpha| \leq 4}\) where \(\alpha\) is a multi-index over \([d]\) such that

\[
X_{\emptyset,\emptyset} = 1 \text{ and } (X_{\alpha \cup \alpha'})_{\alpha,\alpha'} \geq 0.
\]

**Solution via ellipsoid algorithm** Recalling the definitions of inner-sdp and outer-sdp from the last section, median-sdp can be written as

\[
\begin{align*}
\min_{X \in \text{OUTER-SDP}} \max_{Y \in \text{INNER-SDP}} \sum_{i \leq d} Y_{\emptyset,(i),(i)}, 0.
\end{align*}
\]
It is not hard to check that the function

\[ f(X) = \max_{Y \in \text{INNER-SDP}, Y_{\alpha,0,0} = X_{\alpha}} \sum_{i \in d} Y_{0,\{i,i\},0} \]

is convex. Furthermore, it can be computed to accuracy \( \varepsilon \) in time \((dk \log(1/\varepsilon))^{O(1)}\) by standard semidefinite programming solving algorithms. Thus by the ellipsoid method (see e.g Theorem 4.3.13 of [GLS12]) applied to \( \min_{X \in \text{OUTER-SDP}} f(X) \) it is possible to solve \text{MEDIAN-SDP} in polynomial time.
