An efficient algorithm for constructing restricted Boltzmann machine (RBM) architecture of arbitrary stabilizer group is presented. Some partial results of this problem have been given in arXiv:1802.03738 [1], in this work we give a complete solution of the problem by a different approach. We show that by transforming a stabilizer group into the standard form, every stabilizer code state can be efficiently represented by RBM architecture and we can explicitly get the RBM parameters in this algorithmic way.

Introduction.—To conquer one of the main challenges, the dimensionality problem (also known as Hamiltonian complexity [2, 3]), in condensed matter physics, many different representations of quantum many-body states are developed. For example, the well-known tensor network representations [4–6] including density-matrix renormalization group (DMRG) [7], matrix product states (MPS) [8], projected entangled pair states (PEPS) [8, 9], folding algorithm [10], entanglement renormalization [11], time-evolving block decimation (TEBD) [12] and string-bond state [13] etc. have gradually became a standard method in solving quantum many-body problems. The efficiency of the tensor network representations is partially based on the entanglement properties of the state.

Recently, a new representation based on a special kind of stochastic recurrent neural network, restricted Boltzmann machine (RBM) is introduced by Carleo and Troyer [14], they validate the power of the representation by calculating the ground states and unitary evolution of the transverse-field Ising model and the anti-ferromagnetic Heisenberg model. Later, many different aspects of the representation are investigated. Deng et al. analyze the entanglement properties of the RBM states [15]. Gao and Duan extend the representation to the deep Boltzmann machine [16]. The connection between tensor network and RBM representation is investigated in Refs. [16–19]. Many other neural networks call also be used to efficiently represent quantum many-body states, see Ref. [20] for a review of the quantum neural network states. Since RBMs allow efficient sampling, which makes it much more useful in practice, we will focus on the RBM representation in this work.

One central problem in studying RBM states is to understand their representational power. Although many numerical results have been given, There are very few analytical results about the exact representational power of RBM states. In Ref. [21] the exact analytic RBM parameters of toric code states and 1D symmetry-protected topological cluster state are given. RBM architecture for graph states is given in [16]. In Ref. [1], we try to prove the representational power of RBM states in stabilizer formalism which is much more general and subsumes the above results as special cases. We prove that there exits sparse RBM architecture for many special type of stabilizer groups for which the generators only contain the tensor products of X or Z (hereinafter, we denote Pauli matrices by X,Y and Z as conventionally done in error-correcting code theory). And we apply the result to give an exact RBM architecture for surface code with boundary and defect.

In this work, we comprehensively investigate the RBM representation for stabilizer code [22, 23]. An algorithmic way to construct RBM parameters of arbitrary given stabilizer group is given, which, together with the result of [1], give a complete solution of the problem to understand the representational power of RBM in stabilizer formalism. We begin by recalling some basic notions of RBM states and stabilizer code.

Preliminary notions.—A restricted Boltzmann machine is a neural network consists of two layers, the hidden one and the visible one. Hidden and visible neurons are neurons contained in hidden layer and visible layer respectively and are denoted by $h_j$ and $v_i$ respectively. Hidden neurons $h_j$ and visible neurons $v_i$ are connected with each other by weight $W_{ij}$, but there is no intra-layer connections. Each neuron has its own bias, denoted by $b_j$ for hidden neuron $h_j$ and $a_i$ for visible neuron $v_i$. To represent a quantum many-body state, we assume the local freedoms are represented by visible neurons. To characterize a quantum state $|\Psi\rangle = \sum_{\mathbf{v}} \Psi(\mathbf{v}) |\mathbf{v}\rangle$ (where $\mathbf{v}$ represents $v_1, \cdots v_n$ and $|\mathbf{v}\rangle = |v_1\rangle \otimes \cdots \otimes |v_n\rangle$), we only need to give the value of function $\Psi(\mathbf{v}_1, \cdots, \mathbf{v}_N)$ for all series of of input values. For RBM states it is given by

$$
\Psi_{\text{RBM}}(\mathbf{v}, \Omega) = \sum_{\mathbf{h}} \frac{e^{-E(\mathbf{h}, \mathbf{v})}}{Z},
$$

where

$E(\mathbf{h}, \mathbf{v}) = \sum_{ij} h_i v_j w_{ij}$.

*$Two authors are of equal contributions.
where \( E(h, v) = - \sum_{i,j} v_i h_j + \sum_i v_i a_i + \sum_j h_j b_j \), \( Z = \sum_{v, h} e^{-E(h, v)} \) is the partition function and \( \Omega \) represents the set of all involved parameters \( \{W_{i,j}, a_i, b_j\} \). The state is determined by Eq. (1) up to a normalization factor. See [1, 14, 20] for more details.

A stabilizer group \( S \) is defined as an Abelian subgroup of the Pauli group \( P_n = \{I, X, Y, Z\}^{\otimes n} \times \{\pm 1, \pm i\} \) that stabilizes an invariant subspace \( C \) of the total space \( H = (C^2)^{\otimes n} \) with \( n \) physical qubits. The space \( C \) is called the code space of the stabilizer group \( S \), more precisely, \( \forall T \in S, \forall |\Psi \rangle \in C \), the equation \( T|\Psi \rangle = |\Psi \rangle \) is always satisfied. Suppose \( S \) is generated by \( m \) independent operators, \( S = \langle T_1, T_2, \ldots, T_m \rangle \). It is easy to check the following properties for the stabilizer operators:

1. \( T_j^2 = I \) for all \( j \), \( [T_i, T_j] = 0 \) and \( -I, \pm i I \notin S \).

2. \( \langle T_{i_1}, \cdots, T_{i_k}, \cdots, T_{i_m} \rangle = \langle T_{i_1}, \cdots, T_{j} T_{k}, \cdots, T_{i_m} \rangle \), for any \( j \neq k \).

Our goal is to find the RBM representation of the code states \( |\Psi_L \rangle \in C \). We will present an algorithm to explicitly construct a set of basis code states \( \{ |\Psi_L \rangle \} \) that span the code space \( C \) for an arbitrary stabilizer group. To summarize, we will solve the problems as follows:

**Problem 1.** For a given stabilizer group \( S \) generated by \( m \) independent stabilizer operators \( T_{i_1}, \cdots, T_{i_m} \), do there exist an efficient RBM representations of code states \( |\Psi_L \rangle \)? And if exist, how can we find the corresponding RBM parameters?

To reach this, we first introduce the standard form for a stabilizer code [22–24].

**Binary representation of Stabilizer operators, check matrices and standard form of stabilizer code.** As defined in Ref. [25], every Pauli operator that squares to identity can be written as \( \pm P(x_1, z_1) \otimes P(x_2, z_2) \otimes \cdots \otimes P(x_n, z_n) \), where \( P(x_1, z_1) \) is one of the Pauli matrices,

\[
P(x_i, z_i) = \begin{cases} 
I & \text{if } x_i = 0, z_i = 0 \\
X & \text{if } x_i = 1, z_i = 0 \\
Y & \text{if } x_i = 1, z_i = 1 \\
Z & \text{if } x_i = 0, z_i = 1 
\end{cases}
\]

In this way, every stabilizer operator \( T_k \) can be written as the combination of a phase factor and a binary vector \( a_k = (x_1, \cdots, x_n, z_1, \cdots, z_n) \). It is easy to prove that if \( T_l = T_j T_k \), then \( a_l = a_j \oplus a_k \), where \( \oplus \) denotes for bitwise addition modulo 2.

For the set of stabilizer generators \( \{T_{i_1}, \cdots, T_{i_m}\} \), we can stack all the binary vectors \( a_k \) together to form an \( m \times n \) matrix \( A \), called the check matrix [24]. Each row of \( A \) is a vector \( a_k \) that corresponds to a stabilizer operator \( T_k \). Since \( \{T_{i_1}, \cdots, T_{i_k}, \cdots, T_{i_m}\} \) and \( \{T_{i_1}, \cdots, T_{j} T_{k}, \cdots, T_{i_m}\} \) generates the same stabilizer group, one can add one row of \( A \) to another row of \( A \) (modulo 2) without changing the code space \( C \). Meanwhile, swapping rows and columns of \( A \) corresponds to relabelling stabilizer generators and qubits. This indicates that we can perform Gaussian elimination to the check matrix \( A \) [24, 25].

We start from the original check matrix \( A = (A_1 | A_2) \). Performing Gaussian elimination to \( A_1 \), we obtain

\[
\begin{pmatrix}
I_p & B_1 & B_2 & C_1 & 0 & D_3 \\
0 & 0 & 0 & E_1 & I_q & F_1
\end{pmatrix}
\]

where \( I_p \) is a \( p \times p \) identity. Note that we must keep track of the phase factors during this procedure. Further performing Gaussian elimination to \( F \), we get another identity \( I_q \):

\[
\begin{pmatrix}
I_p & B_1 & B_2 & C_1 & 0 & D_3 \\
0 & 0 & 0 & E_1 & I_q & F_1
\end{pmatrix}
\]

Eq. (4) is called the standard form of a stabilizer code. There are \( p + q \) independent stabilizer generators, and the number of qubits encoded is \( k = n - p - q \). If the stabilizer generators we start with are not independent with each other, zero rows will be encountered during the elimination, which we can simply discard and finally reaching a set of independent generators.

One advantage of Eq. (4) is that it is easy to construct logical \( X \) and \( Z \) operators from it. The check matrix for logical \( X \) and \( Z \) operators can be chosen as \( A_X = (0 \; F_1^T \; I \; D_3^T \; 0 \; 0) \) and \( A_Z = (0 \; 0 \; 0 \; B_2^T \; 0 \; I) \) [24]. One can verify that these operators all commute with the stabilizer generators and commute with each other except that \( X_j \) anti-commutes with \( Z_j \).

**Construction of RBM representation for an arbitrary stabilizer group.** In this section, we illustrate how to construct the RBM representation for any given stabilizer group.

Suppose the set of stabilizer generators have already been brought into the standard form like Eq. (4). To begin with, we need to specify one code state in the code space \( C \). As an example, we choose the logical \( Z \) eigenstate with eigenvalue 1, i.e., \( Z_i |\Psi \rangle = |\Psi \rangle, 1 \leq i \leq k \). We can see that we are actually treating the logical \( Z \) operators \( Z_i \) as new independent stabilizer operators, and the stabilized subspace is narrowed down to containing one state only. The set of independent stabilizer generators now becomes \( \{T_1, \cdots, T_m, Z_1, \cdots, Z_k\} \), with the new check matrix being

\[
\begin{pmatrix}
I_p & B_1 & B_2 & C_1 & 0 & D_3 \\
0 & 0 & 0 & E_1 & I_q & F_1
\end{pmatrix}
\]
Algorithm 1 Constructing RBM representation for code states for stabilizer group $S = \langle T_1, \ldots, T_m \rangle$

**Input:** The set of stabilizer group generators $G = \{T_1, T_2, \ldots, T_m\}$ for a stabilizer code.

**Output:** The RBM parameters $\Omega = \{a_i, b_j, W_{ij}\}$ for code states.

1. Start with no hidden neurons and all parameters set to 0.
2. Bring the stabilizer generators into standard form.
3. Construct the logical $X$ and $Z$ operators.
4. Choose one eigenstate of the logical operators, and add the corresponding logical operators to the set of stabilizer generators.
5. Perform Gaussian Elimination to the set of new stabilizer generators, obtaining a check matrix like Eq. (6).

   for $\tilde{T}_j \in \{\tilde{T}_1, \ldots, \tilde{T}_p\}$ do
   
   for $k = 1$ to $i - 1$ do
   
   if $\tilde{T}^{(k)} = \equiv Y$ then
   
   $a_j = a_j + \pi/2$
   
   end if
   
   end for
   
   if $\tilde{T}^{(k)} = \equiv Z$ then
   
   $a_j = a_j + \pi$
   
   end if
   
   end for
   
   end for
   
   end for

6. For $\tilde{T}_j \in \{\tilde{T}_1, \ldots, \tilde{T}_p\}$ do

7. Add a visible connection between $v_j$ and $v_k$ with weight $\pi r$.

8. end for

9. for $k = 1$ to $p$ do

10. if $\tilde{T}^{(k)} = \equiv Y$ then

11. $a_j = a_j + \pi/2$

12. end if

13. $a_j = a_j + \pi$

14. end if

15. if There is a minus sign in $\tilde{T}_j$ then

16. $a_j = a_j + \pi$

17. end if

18. end for

19. for $\tilde{T}_j \in \{\tilde{T}_p+1, \ldots, \tilde{T}_m\}$ do

20. Add a hidden neuron $h_j$ with bias 0.

21. Add a connection between $v_j$ and $h_j$ with weight $\pi r$.

22. for $k = 1$ to $p$ do

23. if $\tilde{T}^{(k)} = \equiv Z$ then

24. $a_j = a_j + \pi$

25. end if

26. end for

27. if There is a minus sign in $\tilde{T}_j$ then

28. $a_j = a_j + \pi$

29. end if

30. end for

31. Convert all visible connections to hidden connections using Eqs. (9) and (10)

Upon introducing new independent stabilizer operators, Eq. (5) can be further simplified. Eliminating $D_3$ and $F_1$ with $I_k$, we obtain the final form of the check matrix:

$$
\begin{pmatrix}
I_p & B \\
0 & C & 0 \\
0 & 0 & E & I_r
\end{pmatrix}
$$

(6)

where $r = q + k$, and $p + r = n$. Denote the $n$ stabilizer generators corresponding to Eq. (6) as $\{\tilde{T}_1, \ldots, \tilde{T}_n\}$. We call $\tilde{T}_1, \ldots, \tilde{T}_p$ $x$-type stabilizers, denoted by $\tilde{T}^x$, and $\tilde{T}_{p+1}, \ldots, \tilde{T}_n$ $z$-type stabilizers, denoted by $\tilde{T}^z$. It is worth mentioning that exact RBM representations of this kind of stabilizer groups have been given in Ref. [1] in a slightly different way.

Since $\tilde{T}^z$ only consists of $Z$ and $I$, in the computational basis, $\tilde{T}^z$ can only bring an additional phase and cannot change basis kets. Suppose $|\Psi\rangle = \sum_c \Psi(c)|\psi\rangle$, in order for $\tilde{T}_j^z|\Psi\rangle = |\Psi\rangle$ to hold, if $\tilde{T}_j^z|\psi_1\rangle = -|\psi_1\rangle$, we must have $\Psi(\psi_1) = 0$.

Meanwhile, since we already have put the stabilizer generators into standard form, the $I_p$ in Eq. (6) indicates that there is a one-to-one correspondence between the $r$ $z$-type stabilizers and the last $r$ qubits. Given the first $p$ qubits of a basis ket, in order for the coefficient of that basis ket not to be 0, the last $r$ qubits are uniquely determined by the $r$ equations $\tilde{T}_j|\psi\rangle = |\psi\rangle$, $j = p + 1, \ldots, n$. Because of this property, we denote basis kets with non-zero coefficients as $|v_1v_2 \cdots v_p \times \cdots \times \rangle$, where $\times$ means that we currently don’t care about that qubit, and that it can be uniquely determined by the equation $\tilde{T}_j|\psi\rangle = |\psi\rangle$, $j = \{p + 1, \ldots, n\}$.

Note that the check matrix for the $x$-type stabilizers $\tilde{T}_1, \ldots, \tilde{T}_p$ is $(I_p, B(C 0))$. $I_p$ means that each $\tilde{T}_j$ only flips the $j$th qubit, and every qubit among the first $p$ qubits has a corresponding operator that flips it. Starting from the basis ket $|00 \cdots 0 \times \cdots \times \rangle$, $|v_1v_2 \cdots v_p \times \cdots \times \rangle$ can be reached by successively applying $\tilde{T}_1, \ldots, \tilde{T}_p$, in which each operator $\tilde{T}_j$ is applied only when $v_j = 1$. Expanding $\tilde{T}_j|\psi\rangle$:

$$
\tilde{T}_j|\psi\rangle = \sum_v \Psi(v_1 \cdots v_j \cdots v_p \times \cdots \times) \tilde{T}_j|v_1 \cdots v_j \cdots v_p \times \cdots \times\rangle = \sum_v \Psi(v_1 \cdots v_j \cdots v_p \times \cdots \times) \tilde{T}_j|v_1 \cdots v_j \cdots v_p \times \cdots \times\rangle
$$

(7)

where $c_j$ is the phase factor created when $\tilde{T}_j$ acts on $|\psi\rangle$, and $\tilde{c}_j = 1 - v_j$. Recalling the check matrix $(I_p, B(C 0))$, the 0 indicates that when applying the operator $\tilde{T}_j$, the last $r$ qubits do not contribute to the phase factor, confirming that we can currently ignore them. Using $\tilde{T}_j|\psi\rangle = |\psi\rangle$, we obtain:

$$
\Psi(v_1 \cdots v_j \cdots v_p \times \cdots \times) = c_j \Psi(v_1 \cdots v_j \cdots v_p \times \cdots \times)
$$

(7)

Start from $\Psi(00 \cdots 0 \times \cdots \times)$ and use Eq. (7) repeatedly, we obtain:

$$
\Psi(v_1v_2 \cdots v_p \times \cdots \times) = \tilde{c}_p \tilde{c}_{p-1} \cdots \tilde{c}_2 \tilde{c}_1 \Psi(00 \cdots 0 \times \cdots \times)
$$

$$
\tilde{c}_j = \begin{cases} 
1, & v_j = 0 \\
0, & v_j = 1 
\end{cases}
$$

(8)

For an unnormalized arbitrary quantum state, we can multiply an arbitrary overall constant to it. Without loss of generality, we set $\Psi(00 \cdots 0 \times \cdots \times) = 1$, so that

$$
\Psi(v_1v_2 \cdots v_p \times \cdots \times) = \tilde{c}_p \tilde{c}_{p-1} \cdots \tilde{c}_2 \tilde{c}_1
$$

(8)
The first part of the RBM representation of $|\Psi\rangle$ relies on Eq. (8). Constructing a procedure $|00\cdots0\times\cdots\times\rangle \rightarrow |v_10\cdots0\times\cdots\times\rangle \rightarrow |v_1v_20\cdots0\times\cdots\times\rangle \rightarrow \cdots \rightarrow |v_1v_2\cdots v_p\times\cdots\times\rangle$, the phase factor $\tilde{c}_j$ on each step can be easily calculated and efficiently represented by RBM.

To be specific, on the $j$th step, we multiply the factor $\exp(v_j f_j(v_1, v_2, \ldots, v_{j-1}))$ in the RBM representation of $\Psi(v)$:

1. When $v_j = 0$, we don’t need to apply the operator $\tilde{T}_j$, and accordingly $\exp(v_j f_j(v_1, v_2, \ldots, v_{j-1})) = \exp(0) = 1$.

2. When $v_j = 1$, we need to compute $c_j$ from the equation

$$\tilde{T}_j |v_1 \cdots v_{j-1}00 \cdots 0 \times \cdots \times\rangle = c_j |v_1 \cdots v_{j-1}10 \cdots 0 \times \cdots \times\rangle$$

and express it as $\exp(f_j(v_1, v_2, \ldots, v_{j-1}))$. This is a simple task, since the operator $\tilde{T}_j$ only contains $Z$ or identity on sites $1$ to $j - 1$. Denoting the Pauli matrix on site $k$ in $\tilde{T}_j$ as $\tilde{T}_j^{(k)}$, it is easy to show that $f_j(v_1, v_2, \ldots, v_{j-1}) = i\pi \sum_k v_k + \theta_j$, in which $\sum^*$ means we add $v_k$ to the sum only when $\tilde{T}_j^{(k)} = Z$, and $\theta_j = 0$, $\frac{i\pi}{2}$, $i\pi$ or $\frac{3i\pi}{2}$ is an additional constant phase factor, indicating there might be a minus sign in $\tilde{T}_j$ or a $Y$ on the $j$th site.

In this procedure, we introduced terms like $\exp(i\pi v_j)$ and $\exp(i\pi v_j v_k)$. In the RBM representation, the former simply corresponds to setting the bias for the visible neuron $v_j$, and the latter means that we introduced a connection between visible neurons $v_j$ and $v_k$. Using the conclusion in [16], this is corresponding to adding a hidden neuron that connects to $v_j$ and $v_k$, with the connection weights computed from Eq. (9):

$$\exp(J v_j v_k) = \sum_h \exp(a - \ln 2 + b(v_j + v_k)(2h - 1) + c(2h - 1) + d(v_j + v_k))$$

(9)

One solution is:

$$a = -d = -J/2, b = -c = -i \arccos(e^{J/2})$$

(10)

Then we treat the last $r$ qubits. In order for the equations $\tilde{T}_j^r |\Psi\rangle = |\Psi\rangle$, $j = p + 1, \ldots, n$ to hold, we need to set the coefficients $\Psi(v)$ to be 0 for all the basis kets $|v\rangle$ with $\tilde{T}_j^r |v\rangle = -1 |v\rangle$. Using the conclusion in [1], this can be done by adding one hidden neuron in the RBM that connects with all the $v_k$ with a $Z$ on the $4th$ site in $\tilde{T}_j^r$ with connection weight $i\pi$. The bias for the hidden neuron is either 0 or $i\pi$, corresponding to a plus or minus sign in $\tilde{T}_j^r$, respectively. This is corresponding to multiplying the factor $1 + \exp(i\pi \sum_k v_k)$ or $1 + \exp(i\pi + i\pi \sum_k v_k)$ in $\Psi(v)$, which equals to 0 when the number of 1 in $v_k$ is odd/even.

In this way, we have finished the construction of the logical $X$ eigenstate of an arbitrary stabilizer group, and the eigenstate of other logical operators can be constructed in the same way. The number of hidden neurons is at most $p(p - 1)/2 + r$, meaning that the representation is efficient. In summary, our method can be organized into Algorithm 1.

**Examples.**—We take the $[[5, 1, 3]]$ code as an example to illustrate the construction procedure. The stabilizer generators are:

$$T_1 = X Z Z X I$$
$$T_2 = I X Z Z X$$
$$T_3 = X I X Z Z$$
$$T_4 = Z X I X Z$$

(11)

After Gaussian elimination, the stabilizer generators become:

$$T_1 = Y Z I Z Y$$
$$T_2 = I X Z Z X$$
$$T_3 = Z Z X I X$$
$$T_4 = I Z I Z Y$$

(12)

As an example, we construct the eigenstate for the logical $X$ operator with eigenvalue 1. The logical $X$ operator $\tilde{X} = ZZIZX$. Since $\tilde{X} |\Psi\rangle = |\Psi\rangle$, treating $\tilde{X}$ as the fifth stabilizer operator $T_5$ and further carry out Gaussian elimination using $T_5$, we obtain the final form of the stabilizers:

$$\tilde{T}_1 = X Z I I Z$$
$$\tilde{T}_2 = Z X Z I I$$
$$\tilde{T}_3 = I Z X Z I$$
$$\tilde{T}_4 = I I Z X Z$$
$$\tilde{T}_5 = Z I I Z X$$

(13)

There are no $z$-type stabilizers, and $\Psi(v_1v_2v_3v_4v_5)$ is obtained by the procedure stated in the former section. Explicitly writing down every term during the transition

![FIG. 1: The RBM representation of the logical X eigenstate of the [[5,1,3]] code](image-url)
from \( |00000 \rangle \) to \( |v_1 v_2 v_3 v_4 v_5 \rangle \), we obtain:

\[
\Psi(v_1 v_2 v_3 v_4 v_5) = \exp(v_1 \cdot 0) \exp(v_2 \cdot i\pi v_1) \exp(v_3 \cdot i\pi v_2) \times \exp(v_4 \cdot i\pi v_3) \exp(v_5 \cdot i\pi (v_1 + v_4)) = \exp(i\pi (v_1 v_2 + v_2 v_3 + v_3 v_4 + v_4 v_5 + v_5 v_1))
\]

The structure of the RBM is shown in Fig. 1.

**Conclusion and discussions.**—We investigate the RBM representations of stabilizer code states and give an algorithmic way to construct the RBM parameters for a given stabilizer group \( S \). With the explicit construction of RBM architecture, we show that the representation is efficient. Our results pave the way to carry out quantum error-correcting code using RBM, where we need to know the exact RBM parameters for the code states. And the result can also be applied to build RBM architectures for local a large number of local commutative Hamiltonians.
