Abstract

At present, the spark plugs are used to trigger the discharge in the pulsed plasma thruster (PPT), which has been known to be life-limiting component, due to plasma corrosion and carbon deposition. The strong electric field could be formed in cathode triple junction (CTJ) to achieve trigger function under vacuum condition. We propose an induction triggered electrode structure on the basis of CTJ trigger principle. The induction triggered electrode structure could increase the electric field strength of CTJ with the electrode voltage unchanged, contributing to the reduction of electrode breakdown voltage. Additionally, it can maintain the plasma generation effect when the breakdown voltage is reduced in the discharge experiments. The induction triggered electrode structure could ensure the trigger effectively when the ablation distance of Teflon increases, and the magnetic field produced by discharge current could further improve the plasma density and propagation velocity. The induction triggered coaxial PPT we propose has simplified trigger structure, and it is an effective attempt to optimize the micro-satellite thruster.

Keywords: pulsed plasma thruster (PPT); cathode triple junction (CTJ); discharge characteristics, trigger structure.

1 Induction

The pulsed plasma thruster (PPT) is one of the most popular thrusters applied in the field of micro-satellites. PPT mainly uses the ablation of Teflon propellant to generate plasma, to achieve the thrust effect [1-4]. The PPT employed in micro-satellites is usually equipped with
spark plug. The high voltage is applied to the electrodes and the spark plug is used to initiate discharge by providing a large supply of free electrons to start an avalanche in the discharge gap between the electrodes [5-8]. The operation of spark plug needs an independent power supply, thus increasing the volume, mass and the structural complexity of thruster. Meanwhile, spark plugs have been known to be life-limiting component of the thruster due to carbon deposition and erosion [9]. The cathode cannot fully contact with the Teflon in coaxial PPT, and the important role of cathode triple junction (CTJ) is presented in the small gap. According to the theory of vacuum surface discharge, when the voltage is applied between the cathode and anode, the potential line will distribute abnormally, forming the strong electric field region, and leading to surface discharge [10-12]. The CTJ trigger method was used in our previous experimental research of ablative PPT [13]. While, the CTJ trigger method requires high breakdown voltage, which will increase the design difficulty of PPT power. The surface discharge in coaxial PPT shows a diffuse arc, and there is no filamentary discharge current with high current density. Based on the discharge characteristic of coaxial PPT, we propose an induction triggered electrode structure. In the induction triggered electrode structure, a potential floating induction electrode is set in Teflon sleeve. The induction electrode is arranged in the inner space of Teflon sleeve near the cathode position, in close contact with the Teflon sleeve surface. We aim at increasing the electric field strength in CTJ through induction electrode, reducing the breakdown voltage of electrode, and improving the discharge effect of coaxial PPT.

2 Experimental Setup

2.1 Discharge circuit and measurement system

Figure 1 shows the discharge circuit and measurement system. The power of negative impulse voltage is employed. We applied the negative impulse voltage to the cathode and the anode is grounded. The vacuum chamber can be pumped down to the pressure of $10^{-4}$ Pa by a combination of mechanical pump and oil pump [14]. The high voltage probe is used to investigate the breakdown voltage of electrode, and the discharge current is acquired through the resistance in series with the discharge circuit. To characterize the plasma, the improved Langmuir probe method is adopted. The Langmuir probe is cylindrical with radius of 0.5
**mm and height of 5 mm.** The specific procedures are as follows: one Langmuir probe is placed behind the anode and kept 150 mm away from the electrode. During the discharge, the plasma propagates along the axial direction and the electron current waveform is recorded when the plasma pass through the probe. To eliminate the measure error, the mean value of 10 times discharge electron current is adopted as the electron current under certain probe voltage. The V-I characteristics curve of electron current could be drawn by altering the probe voltage. The plasma parameters, such as plasma density, could be calculated from the curve [13]. The second probe was set in the direction of away from the electrode, and the distance with the first probe is 20 mm. The plasma propagation velocity could be determined through the electron current waveform of the two probes.

### 2.2 The induction triggered electrode model

The induction triggered coaxial PPT laboratory model designed in the experiment and its parameters are shown in Figure 2. The Teflon sleeve is used in laboratory model as propellant, which internal diameter is 5 mm and external diameter is 10 mm. A cylindrical metal cathode is placed in the Teflon sleeve and in closely contact with the inner surface. The ring-shaped metal anode is fixed on the outer end of the Teflon sleeve. The induction electrode is **in the shape of a cross**, which **consists of** two metal bars intersecting with each other. The metal bar is 0.4 mm in diameter, and both ends point against Teflon sleeve inner surface. The distance between the induction electrode and the cathode is 1 mm. The cathode, anode and the induction electrode are made of stainless steel material.
Analysis of the discharge characteristic of induction triggered electrode

3.1 The electric field distribution characteristic of induction triggered electrode structure

The simulation of electric field distribution in the coaxial PPT laboratory model with and without induction electrode was performed by Ansys Maxwell 3D software (the 2015 edition). The electric field strength distribution of axial section of coaxial electrode structure are shown in Figure 3, when -15 kV is applied to the cathode, the anode kept grounded and induction electrode suspended. The simulation results indicate that the electric field strength of CTJ exhibits a maximum, and the maximum of electric field strength with induction electrode is about 2 times of that without induction electrode.
(b) With induction electrode

Figure 3. The electric field distribution of coaxial electrode structure

![Electric field distribution with induction electrode](image)

The electric field distribution on the inner surface of Teflon sleeve is analyzed. The electric field strength with line along the upper inner surface of Teflon sleeve is shown in Figure 4. It is concluded from the simulation results that the electric field strength on Teflon sleeve inner surface presents an irregular distribution. The electric field strength in the area between induction electrode and cathode is much higher than that without induction electrode. Furthermore, the electric field strength in the area between the induction electrode and the anode is about the same in both situations. As a result, the induction electrode could enhance the maximum electric field strength of CTJ as well as the entire electric field distribution over the inner surface of Teflon sleeve when the applied voltage is unchanged.

![Electric field strength distribution](image)
3.2 The discharge effect of induction triggered electrode

The discharge experiment is carried out to verify the actual effect of coaxial PPT with induction electrode. The distance between cathode and the outlet of Teflon sleeve is 10 mm, which means the axial ablation distance is 10 mm. Figure 5 shows that the breakdown voltage of coaxial PPT with induction electrode is about 10 kV, which is 66% of the breakdown voltage without induction electrode. However, the maximal value and duration time of discharge current in both cases keep unchanged. The simulation on induction triggered electrode is performed when -10 kV voltage is applied to the cathode. The maximum electric field of $7.01 \times 10^6 \text{ V/m}$ correlated with the experiment results.

3.3 The plasma generation characteristics of induction triggered coaxial PPT model

The improved Langmuir probe method is employed in the measurement of plasma parameters on coaxial PPT with and without induction electrode. The discharge of coaxial PPT is single pulse process, and the electron current will alter when plasma move through the probe. The electron current waveforms of both electrode model with probe voltage of 0 V are shown in Figure 6. Which characters by the peak value and the duration time. The peak value of electron current waveform is taken as electron current to calculate. The discharge is repeated for ten times and the mean peak value is obtained as the electron current in certain probe voltage. As described in section 2.1, the plasma propagation velocity can be calculated through the time elapsed between the electron current waveform peak values of both probes. The plasma parameters for both coaxial electrode structures are listed in Table 1.

From Table 1, we found that the discharge current of coaxial PPT model with induction electrode remained unchanged when breakdown voltage was reduced. The plasma density of coaxial PPT model with induction electrode decreased slightly, while the plasma propagation velocity increased in a small amount. It can be inferred that the discharge current and plasma generation parameter are related to the Teflon sleeve ablation distance. Furthermore, the induction electrode could reduce the breakdown voltage effectively with the plasma generation parameter unchanged.
Optimization of induction triggered coaxial PPT model

4.1 The ablation distance with induction electrode

The correlation of plasma generation characteristics and Teflon ablation distance is investigated in this section. In the coaxial PPT laboratory model designed in the experiment, the increment in the distance between the cathode and the sleeve outlet can increase the axial ablation distance of Teflon. It can be seen in Figure 7. Whereas, it also reduces the electric field strength of CTJ, which made it more difficult to trigger the electric discharge. When the distance between cathode and outlet is 15 mm, the discharge hardly happens below 20 kV voltage without induction electrode. The experiment of induction triggered electrode is performed with the distance of cathode and outlet is 7.5, 10, 12.5 and 15 mm. The distance of cathode and induction electrode is 1 mm. The plasma generation parameters with different ablation distance are list in Table 2.

From Table 2, we found that the discharge triggers at about 16 kV with the induction electrode when axial ablation distance was 15 mm. The discharge current evidently increases when compared to that at the ablation distance of 10 mm. The plasma was generated by the process of ablation and ionization of Teflon. The increase of discharge current enhances the ablation effect of Teflon propellant, along with the prolonged ablation distance, which made the plasma density to increase. Under the combined action of electric and magnetic field, the Lorentz force accelerates the particles [15]. Meanwhile, the pressure inside the Teflon sleeve increases because a large amount of particles are ablated from Teflon, and the pressure outside the Teflon remains relatively low. The generated particles will be accelerated by the force due to the pressure difference [15]. The enhancement of ablation effect will raise the pressure inside the Teflon sleeve further, making the acceleration effect to increase. On the basis of the acceleration mechanisms mentioned before, the plasma propagation velocity increases.

It can be concluded that the induction electrode could reduce the breakdown voltage of coaxial PPT model to effectively make the ablation distance be prolonged. And it will improve the ablation area of Teflon sleeve and increase the plasma density and propagation velocity.

4.2 The spiral coil

The particles generated by ablation of Teflon will compact with the inner surface of Teflon sleeve in the process of propagation, which will cause the loss of charged particles and influence the propagation velocity of plasma. The loss of particles on the inner surface can be reduced by applying axial magnetic field in coaxial PPT model. We propose a method of generating magnetic field to confine the ablated Teflon plasma. The confining magnetic field is produced by discharge current and doesn’t need extra power supply. As is shown in Figure 8, the anode is connected to the spiral coil. The negative pulse voltage is applied to cathode and anode is grounded. The discharge current flows through the coil and generates a magnetic field in the Teflon sleeve during the electric discharge process.
The plasma confinement effect of spiral coil with ablation distance of 10 mm is verified. The plasma parameters with and without spiral coil are shown in Table 3. It could be concluded from Table 3 that the discharge current increases when coaxial PPT model was equipped with the spiral coil. In addition, the coaxial PPT model with spiral coil exhibits much higher plasma densities and propagation velocity. The results show that the magnetic confinement using the discharge current can constrain the radial diffusion of the plasma and increase its density. The plasma confinement can also reduce the energy losses of the plasma on the Teflon sleeve inner surface and increase the plasma propagation velocity.

5 Conclusion

We propose an induction trigger electrode coaxial PPT laboratory model in the research based on the vacuum discharge theory of CTJ. The induction triggered coaxial PPT model is
simple in structure and does not require additional power supply circuit. It can solve the problem of high trigger voltage of CTJ and ensure the good discharge effect. The main conclusions are as follows:

1. The electric field analysis proves that the induction electrode can significantly increase the electric field strength of CTJ in coaxial electrode, holding the overall field strength on the inner surface of Teflon sleeve unchanged. The electric discharge experiments of coaxial electrode show that the induction electrode has a significant effect of reducing the discharge voltage.

2. The induction electrode can keep the lower discharge voltage when the relative distance of electrodes increases, which can ensure the prolonged ablation distance of the Teflon sleeve, improve the density and propagation velocity of the plasma.

3. The spiral coil proposed in the study generates a magnetic field using the discharge current. Its application in coaxial PPT can significantly increase the plasma density and propagation speed, and further provide the possibility to improve the thrust efficiency for coaxial PPT.
