Studying a particle trapped by a time-dependent periodic anharmonic potential, we identify large amplitude trajectories stable for millions of oscillation periods in the presence of stochastic laser cooling. The competition between energy gain from the potential’s time-dependence and the damping leads to the stabilization of such stochastic limit cycles, in the regions of phase-space where the frequency of the particle oscillation is close to a multiple of the periodic drive. As a result, instead of converging to the region where the trap forces vanish. Our results suggest that such distinct nonequilibrium behaviour can be observed in realistic radio-frequency traps with laser-cooled ions, suggesting that Paul traps offer a well-controlled test-bed for studying transport and dynamics of microscopically driven systems.

An atomic ion trapped in near-vacuum is a highly isolated system whose quantum motion can be controlled exquisitely \cite{1}. Notwithstanding this, it is a system where chaos and randomness at the microscopic level give rise to intriguing classical states of motion.

Paul traps are based on radio-frequency (10–200 MHz) time-periodic potentials \cite{2}. The time-dependent drive affects the dynamics qualitatively and the trapping is based on dynamical stabilization, akin to a stabilization of an inverted pendulum \cite{3-5}. Even for motion of one particle in one spatial dimension, the time-dependent drive renders the Hamiltonian phase-space effectively three-dimensional (3D), counting the time (which can be treated as periodic), the space coordinate and the momentum. For a general anharmonic potential, this results in a complex phase-space structure (see below). With dynamics that can be tuned through different regimes of integrability and chaos, Paul traps provide a good setup for studying microscopic Hamiltonian transport \cite{6}.

Laser cooling is widely used in ion trapping \cite{7-17}. With the cooling beam turned on, the ion may be expected to be damped to the minimum of the effective potential or, in some cases \cite{18}, heat up or diffuse to a larger amplitude where it may escape from the trap. However, in nonequilibrium scenarios, the peaks of the spatial probability distribution may not necessarily coincide with the minimum of the potential. Rather, the distribution may develop new maxima and, even more strikingly, a particle may be captured in complex stochastic limit cycles or show hysteretic behaviour \cite{19,21}.

In this Letter, we show that the anharmonicity and periodic drive in Paul traps can capture an ion at a large amplitude motion, corresponding to a stable limit cycle even in the presence of damping by laser cooling and the associated randomness. The time-dependence of the potential is a critical ingredient for such stochastic limit cycles since, in contrast to a time-independent setup, it prevents the damping from erasing the signatures of the Hamiltonian phase-space in the long-time limit. Instead, the stochastic dynamics reflects the complex structure of the underlying Hamiltonian phase-space, with multiple peaks of the probability distribution of the ion emerging away from the effective potential minimum. Hence, although the realization that we focus on is that of a trapped ion, the basic required ingredients (time-dependence, anharmonicity, and weak damping), are relevant to many dynamical systems, as we briefly discuss in the conclusions.

Model. We consider dynamics in a time-periodic potential in the presence of weak damping and first examine the stability of limit cycles in a model that can be expanded analytically in one spatial dimension. In the second step we use this expansion to demonstrate that this mechanism remains robust under the complex stochastic process of laser cooling in a realistic trap potential.

We first consider a time-dependent anharmonic potential,\footnote{For simplicity, we consider Paul traps that are based on radio-frequency (rf) potentials instead of the usual time-varying DC potentials.} \begin{equation}
V(z,t) = \frac{1}{2}a_z(z - z_0)^2 + qV_2(z)\cos 2t, \label{eq:potential}
\end{equation}
where the time $t$ is in units of $2/\Omega$ with $\Omega$ being the angular frequency of the trap rf-drive and the coordinate is in units of a length-scale $d$, defined below. The charge and mass of the ion and the trap geometry parameters and voltages are absorbed into the nondimensional parameters $a_z$ and $q$. Setting $z_0$ to be a point where $V_2(z)$ vanishes and choosing the parameters appropriately, makes $z_0$ a stationary point with stable motion in the phase-space around it. Since the periodic drive’s frequency has been rescaled to 2, the trap potential is $\pi$-periodic.

In numerical simulations we take $V_2(z)$ to be the potential of a model five-wire surface trap \cite{6} along an axis perpendicular to the electrodes (with $d$ the width of each of the electrodes carrying the rf-modulated voltage), and $V_2 = \frac{1}{2}\left[\arctan \left( \frac{z}{d} \right) - \arctan \left( \frac{z}{2d} \right) \right]$ which van-
Mixed phase-space structure, wherein the chaotic “sea”, every closed curve and every “island chain” result from one initial condition. See the text for details of the parameters. (b) A close-up of the region around one island of the chain of $s = 11$ islands. (c, d) With deterministic damping added [Eq. (2)], an ion starting at the right edge of panel (b) will be slowly damped towards the effective potential minimum (the color code indicates the time along one trajectory, up to $10^5$ drive periods). (d) An ion starting deeper within an island of a chain, is captured in a stable, large amplitude motion being damped towards the island centres. The stability of this motion is confirmed when considering laser-cooling dynamics in three spatial dimensions, with the phase-space distribution of the ion developing multiple peaks, around the island centres.

The phase-space is mixed (with chaotic and integrable regions). Each closed curve corresponds to regular motion. It is characterized by the existence of a quantity that is conserved during the Hamiltonian motion (in contrast to the energy in a time-dependent potential), the action. The action is given (up to a proportionality constant) by the area bounded by each closed curve. There is a large chaotic “sea” and some sizeable “island chains” of regular motion forming within bounded narrow strips of chaotic motion, in regions where the anharmonic oscillation frequency of the ion is at a rational ratio with the drive frequency. Figure 1(b) shows a close-up on the trajectories around one island in a chain which has $s = 11$ islands.

Limit cycles. A trajectory starting at the center of one island of an island chain constitutes a periodic orbit repeating itself after $t = s\pi$, with the ion moving between the $s$ island centres in a fixed order. When adding dissipation, the ion is attracted from (almost) the entire island area towards the periodic orbit, a phenomenon previously studied mostly in terms of chaotic maps [22, 23]. To model the mechanism of trapping in the island chain we start by adding a friction coefficient $\gamma > 0$ to the ion’s equation of motion:

$$\ddot{z} = F(z, t) - \gamma \dot{z}, \quad F(z, t) = -\partial V(z, t)/\partial z. \quad (2)$$

A numerical simulation of the time evolution using two (different) initial conditions is shown in Figs. 1(c)-(d). In (c), the ion is damped toward $z_s$, while in (d) it gets trapped in the chain of $s = 11$ islands.

The limit cycle is a generic feature that results from the interplay of the nonlinearity of the Hamiltonian forces acting on the ion in the vicinity of island chains, where the time-dependent drive counteracts the damping. Assume that $\bar{z}(t)$ is an $s\pi$-periodic and time-reversal invariant orbit that connects the island centres for $\gamma = 0$, i.e. $\ddot{\bar{z}}(t) = F(\bar{z}(t), t)$. We write

$$z(t) = \bar{z}(t) + u(t), \quad \bar{z} = \sum_n B_{2n} e^{i2nt/s}, \quad (3)$$

where $n \in \mathbb{Z}$ and $B_{2n} = B_{-2n}$, and substitute Eq. (3) into Eq. (2). After linearizing the motion around $\bar{z}(t)$, we get

$$\ddot{u} + f(t)u = -\gamma (\dot{\bar{z}}(t) + \dot{u}), \quad f(t) = \frac{-\partial F}{\partial z}(\bar{z}(t), t). \quad (4)$$

Substituting $u(t)$ by the ansatz $u(t) = w(t)e^{-\gamma t/2}$ gives

$$\ddot{w} + \left[f(t) - \frac{\gamma^2}{4}\right] w = g(t), \quad g(t) \equiv -\gamma \dot{\bar{z}}(t) e^{\gamma t/2}. \quad (5)$$

The general solution for $w$ is composed of the sum of a particular solution growing exponentially as $e^{\gamma t/2}$, and the two linearly independent solutions of the homogeneous equation [with $g(t) = 0$, see below]. Since $\bar{z}$ is $s\pi$-periodic and $F$ is $\pi$-periodic, the function $f(t)$ in Eq. (4) can be Fourier expanded in the form $f = \sum F_{2n} e^{i2nt/\pi s}$. A particular solution of Eq. (3) can be obtained by substituting $u_0(t) = e^{\gamma t/2} \sum W_{2n} e^{i2nt/\pi s}$, which gives an inhomogeneous system of recursion relations for $W_{2n}$, with a unique solution under general conditions [24]. The homogeneous equation in $w$ [Eq. (5)] with $g(t) = 0$, whose
coefficients are periodic in time, is a Hill equation [25]. The homogeneous solutions $u(t)$ determine the stability of $u(t)$ [since the exponential growth of the inhomogeneous $u_0$ is cancelled when going back to $u$]. In fact, Eq. (5) with $\gamma = g(t) = 0$ determines the linear stability of the periodic orbit in the Hamiltonian case. If the area of the islands about the periodic orbit is not too small, perturbations about the periodic orbit are stable for a range of amplitudes of the motion, which implies that the motion would be linearly stable also for a small non-vanishing value of $\gamma$ in Eq. (5). The friction coefficient taken here is $\gamma = 1 \times 10^{-5}$ which guarantees that the damping is a slow process compared to the ion dynamics [26]. We note in particular that to leading order the effect of the damping is eliminated from the dynamics, which explains the numerical observation that although the ion is gradually damped towards the island chain centres [Fig. 1(d)], it is being damped much more slowly than outside the island chain [Fig. 1(c)].

Laser-cooling. To treat laser cooling more realistically, we assume a beam that is uniform over all positions in $\bar{z}$ and apply a recently developed semiclassical theory of laser-cooling that is valid for motion within the time-dependent potential of Paul traps [18]. We approximate the ion as a two-level system, whose excited level has a decaying rate $\Gamma$. The validity of our approach requires a low saturation of the internal transition, guaranteed by setting the saturation parameter $s_I$ which is proportional to the laser intensity to $s_I \ll 1$ [18]. This condition is often chosen in experiments, since it leads to the lowest final temperatures. The instantaneous Doppler shift due to the ion’s velocity determines its probability to absorb a photon at any phase-space point along the trajectory. For optical photons, many scattering events are required in order to change the Hamiltonian action significantly. This allows us to describe the scattering as adiabatic perturbations leading to a drift and diffusion of the ion between the tori of the Hamiltonian motion.

With large detuning $\Delta$ of the laser frequency from the internal electronic transition an ion is efficiently cooled from high amplitude motion in the approximately integrable part of phase-space in a surface-electrode trap [18], whereas at low-detuning ($\Delta \sim -\Gamma/2$) the ion is likely to be heated out of the trap. We show here that a laser beam with a large detuning can actually capture the ion within the island chain about the periodic orbit.

The coordinate $u(t)$ of Eq. (3) represents linearized perturbations (a periodically driven Harmonic oscillator) expanded about periodic orbit $\bar{z}(t)$, that can fluctuate, heat up and be damped by the laser. We numerically calculate $\varepsilon(t)$, $\varepsilon(t)$ and $f(t)$ from Eq. (1) [with $\gamma = 0$], to obtain the Fourier expansion [24] of the Hill oscillator of Eq. (1). This is a key step allowing us to introduce a canonical time-dependent transformation to the Hamiltonian action-angle coordinates $(I, \theta)$ describing the linearized motion about the periodic orbit. The value of $I$ is 0 for the periodic orbit $\bar{z}(t)$ since the area bounded by the corresponding phase-space torus is 0. By the linearity of the expanded motion, the transformation can be obtained in analytic closed form, with the coefficients of the Fourier expansion calculated numerically [24, 27, 28].

Averaging over the angle $\theta$, we obtain an effective Fokker-Planck equation for the probability distribution $P(I, t)$, which is a probability density function that depends on time and action only [18],

$$\partial_t P(I, t) = -\partial_I S(I, t) \equiv -\partial_I [\Pi I P] + \frac{1}{2} \partial_{II} [\Pi_{II} P] \, ,$$

(6)

with $S(I, t)$ a probability flux, $\Pi I (I)$ an action drift coefficient and $\Pi_{II} (I)$ a diffusion coefficient. If we find a region of action where the ion remains bounded for a very long time (as determined by the Fokker-Planck dynamics), we can assume an approximately stationary probability distribution in the action of the form

$$P(I) \propto [\Pi_{II} (I)]^{-1} \exp \left\{ 2 \int dI \Pi I (I')/\Pi_{II} (I') \right\} \, .$$

(7)

The method of calculation of the action drift and diffusion coefficients for a linearized periodically driven system is presented separately [29].

Taking concrete physical parameters we consider a $^9\text{Be}^+$ ion and set the natural units of the model trap to $d = 50 \mu m$ and $\Omega = 2 \pi \times 100 \text{ MHz}$. The determination of the nondimensional parameters $a_z$ and $q$ is given in [6], with the resulting oscillation frequency at the effective minimum being $\omega_z \approx 2 \pi \times 11.44 \text{ MHz}$. The laser parameters used in our numerical simulation are $k \approx \cos(\phi) \times 2 \pi / 313 \text{ nm}^{-1}$ with $\phi = 0.42 \pi$ giving a projection of laser wavevector on the coordinate axis, and $\Gamma \approx 120 \times 10^6 \text{s}^{-1}$.

We find that relatively large values of the laser detuning $\Delta$ are required to stabilize the periodic orbit. For detunings within the range $-24 \Gamma \lesssim \Delta \lesssim -27 \Gamma$, we find a stationary distribution in the action within the island chain with a strong (exponential) suppression of the probability of $I$ values away from the island centres. The lifetime within the island can be estimated (by calculating the mean first passage time at the island boundary [30]) to exceed tens of seconds around $\Delta = -26.8 \Gamma$. In addition we find other ranges of the detuning with lifetimes smaller by an order of magnitude (for example around $\Delta = -20 \Gamma$). Figure 2(a) shows the action drift coefficient for a few representative values of the detuning, and Fig. 2(b) shows the corresponding steady-state distributions. For $\Delta = -27.5 \Gamma$ we see that the ion is
The stabilization of a particle in a large amplitude periodic motion in a certain phase-space region, due to a combination of time-dependence, damping and noise is reminiscent of a nonequilibrium phase transition [38], and relates to the dynamics of active inertial systems [39, 40] and Hamiltonian and Brownian ratchets [41], which are a basic model of transport [42, 43]. Transport in a mixed phase-space is especially rich [44, 54] and the ability to control and accurately measure motion in complex time-dependent potentials make ion-trap experiments suitable for quantitative tests of such ideas [51, 52]. The possibility of exploring quantum effects in phase-space [49, 50, 51] with a single trapped ion could constitute a promising future direction.
