(Dated: October 9, 2018)

We theoretically investigate the effect of multi-mode dynamics on the creation of macroscopic superposition states (spin-cat states) in Bose-Einstein condensates via one-axis twisting. A two-component Bose-Einstein condensate naturally realises an effective one-axis twisting interaction, under which an initially separable state will evolve toward a spin-cat state. However, the large evolution times necessary to realise these states is beyond the scope of current experiments. This evolution time is proportional to the degree of asymmetry in the relative scattering lengths of the system, which results in the following trade-off: faster evolution times are associated with an increase in multi-mode dynamics, and we find that generally multi-mode dynamics reduce the degree of entanglement present in the final state. However, we find that highly entangled cat-like states are still possible in the presence of significant multi-mode dynamics, and that these dynamics impose a speed-limit on the evolution such states.

I. INTRODUCTION

Atom interferometers are precision measurement devices with many applications in both fundamental science and industry [1]. Aside from a handful of proof-of-principle experiments, the phase sensitivity $\Delta \phi$ of most atom interferometers with $N$ atoms is shot-noise limited, $\Delta \phi \geq 1/\sqrt{N}$ [2]. This precision limit may be surpassed by employing states that exhibit $N$-body entanglement [3] [4], up to the ultimate Heisenberg limit $\Delta \phi \geq 1/N$. The states that achieve this maximum sensitivity are the ‘spin-cat states’, which are coherent macroscopic superpositions of the maximum and minimum projections of the collective spin [5]. As well as providing Heisenberg limited sensitivity [2] [5-7], it has recently been shown that the ability to create these states can provide robustness against detection noise [8-11]. These states can be generated from unentangled states via one-axis twisting (OAT) dynamics [12] [13]. One-axis twisting (OAT) [14] is naturally realised due to atom-atom interactions in two-component Bose-Einstein condensates (BECs) [15], and has emerged as an extremely successful method of generating entanglement in BECs [16] [21]. OAT dynamics have also been demonstrated with cold atoms in a cavity-QED setting [22] [26] and with trapped ions [27-31]. Current OAT experiments are performed with small, tightly confined condensates [2]. In this regime spatial dynamics are unimportant and may be neglected, resulting in a single-mode analysis. Usually, the twisting rate is slow relative to timescales associated with sources of decoherence such as dephasing and particle losses, and thus making spin-cat states with OAT is outside the realm of current experiments [2] [22]. This challenge is compounded by the notorious fragility of these states [32-39]. Nevertheless, small spin-cat states have been created in other systems, such as superconducting flux qubits [40], nuclear spins [41], angular momentum states of a single Rydberg atom [42] and in trapped ions [25] [30]. Macroscopic superpositions of optical coherent states have also been realised [13].

More rapid twisting dynamics occur in systems with highly asymmetric scattering lengths [17] [18] [43], which usually results in significant multimode dynamics, especially when combined with large particle number [44] [45]. In Ref. [46] the authors perform a multi-mode analysis of spin-cat states, with a focus on studying losses and finite temperature effects as sources of decoherence. In this paper we take a slightly different approach, and study the effect of multi-mode dynamics on OAT with the goal of producing spin-cat states (perhaps approximately) more rapidly than in a single-mode regime. This approach has already been suggested as a possibility for enhancing spin-squeezing under OAT [47] [48]. We do not study decoherence per se as the state remains pure, however multi-mode dynamics can take the system away from ideal OAT behaviour and thus, compared to single-mode dynamics, may reduce the entanglement of the final state.

The structure of this paper is as follows: In Section [IV] we revise ideal single-mode OAT and spin-cat states. Starting from the general multi-mode Hamiltonian for a two-component BEC, we show that under a single-mode approximation the dynamics reduce to an effective OAT interaction which can be used to generate nonclassical states. We define spin-cat states, as well as the quantum Fisher information (QFI), which we use throughout this paper to quantify the metrological usefulness of states produced under multi-mode OAT. In Section [III] we argue that working in a more multi-mode regime should give rise to faster twisting dynamics, and introduce a numerical formalism that we use throughout the remainder of the paper. In Section [IV] we investigate the ef-
fect of multi-mode dynamics on the QFI. As these states are no longer Heisenberg limited, strictly speaking they are not spin-cat states. Nevertheless, we wish to investigate conditions under which large QFI states may be created which would still be extremely valuable resources for quantum-enhanced metrology. Thus, in Section V we explore a range of parameters and find that so long as the chemical potential is carefully chosen, states with large QFI are still achievable in a highly multi-mode regime.

II. SINGLE-MODE MODEL OF SPIN-CAT STATE CREATION VIA ONE-AXIS TWISTING

A. Deriving the One-Axis Twisting Hamiltonian

The physical system we consider is a two-component Bose-Einstein condensate (BEC), with components labelled \(a\) and \(b\). In terms of the bosonic field operators \(\hat{\psi}_j(r)\), which obey commutation relations \([\hat{\psi}_j(r), \hat{\psi}_k^\dagger(r')] = \delta(r - r')\delta_{jk}\), the full multi-mode Hamiltonian for the system is

\[
\hat{H} = \sum_{j=a,b} \int dr \hat{\psi}^\dagger_j(r) \hat{H}_0 \hat{\psi}_j(r) + \sum_{j,k=a,b} \frac{g_{jk}}{2} \int dr \hat{\psi}^\dagger_j(r) \hat{\psi}_k^\dagger(r) \hat{\psi}_j(r) \hat{\psi}_k(r),
\]

(1)

where \(\hat{H}_0 = \vec{p}^2/2M + V(r)\) is the single-particle Hamiltonian (momentum operator \(\vec{p}\), mass \(M\), and external trapping potential \(V(r)\)) and \(g_{jk} = 4\pi\hbar^2a_{jk}/M\) is the interaction strength for \(s\)-wave scattering length \(a_{jk}\).

It is common to study this system within the single-mode approximation, which assumes each mode is well described by the same wavefunction \(\phi_j(r)\), with \(j = a, b\). This is a good approximation for sufficiently small, tightly trapped condensates that the motional dynamics are effectively “frozen” over timescales of interest, and may be integrated out \([10]\). Quantitatively, the single-mode Hamiltonian is obtained by making the approximation

\[
\hat{\psi}_a(r) \approx \hat{a} \phi_a(r)
\]

(2)

\[
\hat{\psi}_b(r) \approx \hat{b} \phi_b(r)
\]

(3)

with \([\hat{a}, \hat{a}^\dagger] = \hat{b}, \hat{b}^\dagger = 1\), \([\hat{a}, \hat{b}] = [\hat{a}, \hat{b}^\dagger] = [\hat{a}^\dagger, \hat{b}] = 0\). The wavefunctions \(\phi_j(r)\) are normalised to unity.

A convenient description for a system of \(N\) conserved, two-level bosons is the SU(2) angular momentum algebra. In terms of ladder operators \(\hat{J}_+ = \hat{a} \hat{b}^\dagger\), \(\hat{J}_- = (\hat{J}_+)^\dagger\) and number operators \(\hat{N}_a = \hat{a}^\dagger \hat{a}\), \(\hat{N}_b = \hat{b} \hat{b}^\dagger\), the population difference \(\hat{J}_z = (\hat{N}_a - \hat{N}_b)\) obeys the standard angular momentum commutation relations with \(\hat{J}_x = (\hat{J}_+ + \hat{J}_-)/2\) and \(\hat{J}_y = -i(\hat{J}_+ - \hat{J}_-)/2\).

Neglecting the single-particle energies, which amount only to a trivial rotation, in the single-mode regime the multi-mode Hamiltonian \([\text{Eq. (1)}]\) becomes

\[
\hat{H} = \hbar \chi_{aa} \hat{N}_a^2 + \hbar \chi_{bb} \hat{N}_b^2 + 2\hbar \chi_{ab} \hat{N}_a \hat{N}_b + \hbar \chi_{aa} \hat{N}_a + \hbar \chi_{bb} \hat{N}_b,
\]

(4)

where

\[
\chi_{jk} = \frac{g_{jk}}{2} \int dr |\phi_j(r)|^2 |\phi_k(r)|^2,
\]

(5)

with \(j, k = a, b\). To account for asymmetric interactions \(\chi_{aa} \neq \chi_{bb}\), we insert a \(\pi\)-pulse half-way through the evolution, which is described by the unitary operator \(\hat{U}_\pi = \exp(-i\hat{J}_z \pi)\). The single-mode time evolution is generated by

\[
\hat{U}(t) = \exp \left[-\frac{it}{2} \left(\chi_{aa} (\hat{N}_a^2 + \hat{N}_b^2) + \chi_{bb} (\hat{N}_a^2 + \hat{N}_b^2)
\]

\[
+ 4\chi_{ab} \hat{N}_a \hat{N}_b + (\chi_{aa} + \chi_{bb}) \hat{N}_a \hat{N}_b\right]
\]

(8)

with total number operator \(\hat{N} = \hat{N}_a + \hat{N}_b\). Making use of the relations \(\hat{N}_a^2 + \hat{N}_b^2 = 2 \left(\hat{N}^2/4 + \hat{J}_z^2\right)\) and \(\hat{N}_a \hat{N}_b = \hat{N}^2/2 - \hat{J}_z^2\), \(\hat{U}(t)\) can be re-written

\[
\hat{U}(t) = \hat{U}_\pi \hat{U}_N e^{-i\hat{J}_z^2 \chi t},
\]

(9)

with the effective twisting rate

\[
\chi = \chi_{aa} + \chi_{bb} - 2\chi_{ab}.
\]

(10)

We have also defined the unitary

\[
\hat{U}_N = e^{-it\left(\frac{1}{2}(\chi_{aa} + \chi_{bb}) \hat{N}^2 + \frac{1}{2}(\chi_{aa} + \chi_{bb}) \hat{N}\right)}
\]

(11)

which in an SU(2) system amounts only to a global phase, and is henceforth neglected. The \(\pi\)-pulse is similarly unimportant as its only contribution is to reverse the sign of \(\hat{J}_z\) and \(\hat{J}_\phi\). Thus, the single-mode Hamiltonian is equivalent to the well known one-axis twisting (OAT) interaction,

\[
\hat{H} = \hbar \chi \hat{J}_z^2 \equiv \hat{H}_{\text{OAT}}.
\]

(12)

B. Creating Spin-Cat States with One-Axis Twisting

The OAT Hamiltonian is capable of producing macroscopic superpositions of collective-spin eigenstates. It is
convenient to work in the $J_z$ eigenbasis, $J_z|m\rangle = m| m\rangle$ for $J = N/2$, where $N$ is total number of atoms and $m$ is half the population difference. We begin with a separable, coherent spin state $|\alpha(\theta, \phi)\rangle$, defined by

$$|\alpha(\theta, \phi)\rangle = e^{i\phi J_x} e^{i\theta J_y} |N/2\rangle \quad (13)$$

where

$$C_m^J(\theta) = \left( \frac{2J}{J+m} \right)^{1/2} \cos(\theta/2)^{-J-m} \sin(\theta/2)^{J+m}. \quad (14)$$

Evolving this state under $\hat{H}_{OAT}$ results in a non-linear rotation of each $J_z$ component about the $J_z$ axis by twisting angle $\chi t$, as illustrated in Fig. 1(b-e). For small interaction times $\chi t$, the resultant nonclassical state has significantly modified noise properties, and leads to spin squeezing, Fig. 1c). At larger times, the state becomes non-Gaussian, as illustrated in Fig. 1(d,i). At time

$$t_{cat} = \frac{\pi}{2\chi}, \quad (15)$$

noting that for any integers $J$ and $m$ \[11\],

$$e^{-im^2\pi/2} = \frac{e^{-i\pi/4}}{\sqrt{2}} (1 + (-1)^J e^{i(J+m)\pi}) \quad (16)$$

such that

$$e^{-i\hat{J}_z^2\pi/2} |\alpha(\theta, \phi)\rangle = \frac{e^{-i\pi/4}}{\sqrt{2}} \sum_{m=-J}^J C_m^J(\theta) (1 + i(-1)^J e^{i(J+m)\pi}) e^{-i(J+m)\phi} |m\rangle$$

$$= \frac{e^{-i\pi/4}}{\sqrt{2}} \left( \sum_{m=-J}^J C_m^J(\theta) e^{-i(J+m)\phi} |m\rangle + i(-1)^J \sum_{m=-J}^J C_m^J(\theta) e^{-i(J+m)(\phi + \pi)} |m\rangle \right)$$

$$= \frac{e^{-i\pi/4}}{\sqrt{2}} \left( |\alpha(\theta, \phi)\rangle + i(-1)^J |\alpha(\theta, \phi + \pi)\rangle \right). \quad (17)$$

When we choose $\theta = \pi/2$ (as in Fig. 1), the state is an equal superposition of the maximal and minimal eigenstates of $\hat{J}_y$ (Fig. 1k). This state is characterised by its large quantum Fisher information (QFI) with respect to the pseudo-spin operator $\hat{J}_y$: $F_Q = 4\text{Var}(J_y) = N^2$. That is, for pure state $|\psi\rangle$ under evolution $|\psi(t)\rangle = e^{-i\hat{H}_Q t} |\psi(0)\rangle$,

$$F_Q = 4\text{Var}(J_y) = N^2$$

FIG. 1. (a-e) Single-mode $Q$-functions of $N = 20$ atoms ($Q/Q_{\text{max}}$ with $Q(\theta, \phi) = |\langle \alpha(\theta, \phi)|\Psi(t)\rangle|$), showing evolution under one-axis twisting for the state $|\Psi(t)\rangle = \exp(-i\hat{J}_y^2\chi t)|\alpha(\pi/2, \pi/2)\rangle$. (f-j): the corresponding probability distributions in the $\hat{J}_y$ eigenbasis. The system is prepared entirely in a single component ($|\Psi(0)\rangle = |N/2\rangle$ (a,f), before a $\pi/2$ pulse places the state on the equator of the Bloch sphere ($|\Psi(t)\rangle = e^{-i\hat{J}_y^2\chi t}|N/2\rangle = |\alpha(\pi/2, \pi/2)\rangle$) (b,g). Using this as the initial state, the one-axis twisting interaction [Eq. $\hat{J}_y$] creates a nonclassical state (c,h), and quickly reaches the over-squeezed regime (d,i). Eventually, after $t_{cat} = \pi/2\chi$ the state becomes a spin-cat state in the $J_y$ basis (e,j).
exp(i\(\hat{J}_z\Omega\))\(\psi\)'s, the parameter \(\Omega\) may be estimated with Heisenberg-limited sensitivity \(\Delta \Omega = 1/\sqrt{F_Q} = 1/N\) [52–54]. If the scattering lengths of the two components are asymmetric, evolution under the full Hamiltonian Eq. (1) may result in drift in the \(J_x, J_y\) plane. Rather than manually accounting for this drift, it is simpler to calculate the QFI by finding the maximum eigenvalue of the collective-covariance matrix,

\[
F_{i,j} = 2\langle \hat{J}_i \hat{J}_j + \hat{J}_j \hat{J}_i \rangle - 4\langle \hat{J}_i \rangle \langle \hat{J}_j \rangle.
\] (18)

where \(i, j = x, y, z\) [55]. The QFI of the state \(|\psi(t)\rangle = e^{-iJ_z^2|\alpha(\pi/2, 0)\rangle}\) as a function of time is shown in Fig. 2. The QFI initially increases rapidly, before quickly reaching a plateau at \(F_Q = N^2/2\). At \(\chi t = \pi/2\), the state briefly revives to a cat state, and the QFI peaks at \(F_Q = N^2\). Throughout this paper, we refer to this peak as the “cat peak”, and take it as the signature of a cat-like state.

### III. ONE-DIMENSIONAL MULTI-MODE MODEL

In cases with small atom-number and very tightly confined potentials, such as [15], the motional dynamics of the condensate are negligible and the single-mode approximation [Eq. (2) and Eq. (3)] is sufficient to model the evolution of quantum correlations in the system. However, there are cases when the multimode dynamics cause a break-down of the single mode approximation, and we must model the system in a way that accounts for both the quantum correlations and multimode dynamics. The truncated Wigner (TW) method [56, 62] has been used successfully to model spin-squeezing in the presence of significant multimode dynamics [15, 47, 48, 63–67]. However, the truncation of third order terms in the Fokker-Planck equation limits the dynamics to states with positive Wigner functions [68], and therefore cannot be used to model the creation of spin-cat states, which display significant negativity [2]. Fig. 2 compares a single-mode TW simulation to the exact calculation. While TW simulation agrees quite well for times less than \(\chi t \sim \pi/2\), it does not describe the revival of the state and the associated cat peak. Other phase-space methods also fail, such as positive-P [69, 71], which is restricted to evolution times much less than \(t_{\text{cat}}\) due to the exponential divergence of stochastic trajectories, or number-phase Wigner [72, 73], which is negative for coherent-spin states. We circumvent these issues by employing the method of Sinatra and Castin [59, 74, 75], which is described in depth in Appendix A. Briefly, the idea is to expand the state in the number basis, and then evolve the wavefunction for each number component within the Hartree-Fock approximation. In this way it is possible to capture both multi-mode dynamics and quantum correlations. We define a new Fock space with bosonic annihilation operators

\[
\hat{a}_{\phi_{a,m}} = \int d\mathbf{r} d\mathbf{r} \hat{\phi}_{a,m}(\mathbf{r}, t) \hat{\psi}_a(\mathbf{r})
\] (19)

\[
\hat{b}_{\phi_{b,m}} = \int d\mathbf{r} d\mathbf{r} \hat{\phi}_{b,m}(\mathbf{r}, t) \hat{\psi}_b(\mathbf{r}),
\] (20)

which are used to construct a set of dynamic basis states, labeled by their projection along the \(J_z\) axis, \(m\)

\[
| m; \phi_{a,m}(\mathbf{r}, t), \phi_{b,m}(\mathbf{r}, t) \rangle = e^{-i\mathcal{A}_m(t)/\hbar} \left( \begin{array}{c} \hat{\phi}_{a,m}^{\dagger} \nonumber \hat{\phi}_{b,m}^{\dagger} \\ \sqrt{n_a} \\ \sqrt{n_b} \end{array} \right) \left( \begin{array}{c} \alpha \nonumber \phi_m \end{array} \right) |0\rangle,
\] (21)

with \(n_a = N/2 + m, n_b = N/2 - m\), and we implicitly assume a fixed total number \(n_a + n_b = N\). The approximation in this method is that each number-component is well described by a single wavefunction. Although this ansatz assumes a Hartree product state for each number component, it is able to capture quantum correlations between number components that may arise from subsequent dynamics.

We consider a harmonically trapped BEC, where the trapping frequency \(\omega\) along the \(x\) axis is small compared to the \(y\) and \(z\) directions. The dynamics in the transverse dimensions are therefore integrated out resulting in an effective one dimensional (1D) system, with modified interaction strengths \(g_{ij}\). In practice, \(g_{ij}\) is determined by the degree of transverse confinement. However, in a 1D model, the dynamics are entirely determined by the magnitude of the chemical potential, \(\mu_0\), relative to the non-interacting ground-state energy \(\hbar \omega/2\). Thus, the relevant parameter is the dimensionless chemical potential \(\mu = \mu_0/\hbar \omega\). As such, we adjust \(\tilde{g}_{ij}\), such that the chemical potential matches the chemical potential of the 3D system we wish to emulate. Working in dimensionless oscillator units \(\tau = \omega t\) and \(\xi = x\sqrt{\hbar M/\hbar}\), assuming a Hamiltonian of the form Eq. (1), the (unity-normalised) mode-function \(\phi_{j,m}(\xi, \tau)\) and phase factors \(\mu_m(\tau)\) that define the states Eq. (21) evolve in time under the equa-
FIG. 3. Mean-field dynamics of $|\phi_{a,m}|^2/|\phi_{\text{max}}|^2$ (a-c) and $|\phi_{b,m}|^2/|\phi_{\text{max}}|^2$ (d), labelled by $m = (n_a - n_b)/2$ with, $N = 100$, $\kappa = 0$ and $\lambda = 1$. (a) When the chemical potential is close to the single-particle ground state energy the system is well described by a single-mode treatment, i.e. the dynamics are almost identical for populations $a,b$ and for all number components $m$. (b) A larger chemical potential gives rise to breathing dynamics shown here for the $m = 0$ number component, which is different for each $m$ (c) and between populations (d). In the case of symmetric dynamics ($\lambda = 1$), we have $\phi_{a,m}(\xi,\tau) = \phi_{b,-m}(\xi,\tau)$.
IV. EFFECT OF MULTIMODE DYNAMICS ON THE QFI

Figure 4 shows the QFI, calculated via Eq. (18), with $\dot{J}_x = (\dot{J}_+ + \dot{J}_-) / 2$, $\dot{J}_y = -i(\dot{J}_+ - \dot{J}_-) / 2$, and

$$\dot{J}_+ = \int d\xi \dot{\psi}_a(\xi) \psi_b^*(\xi),$$

$$\dot{J}_- = \int d\xi \dot{\psi}_b(\xi) \psi_a^*(\xi).$$

(31)

(32)

When $\mu = 0.6$, we see excellent agreement with the single mode model. However, despite a clearly defined cat peak with maximum amplitude $F_0 = N^2$ the time taken for this revival is large; $t_{\text{cat}} \approx 1570/\mu$ for $\mu = 0.6$. Increasing $\mu$ significantly decreases $t_{\text{cat}}$, however the peak QFI is diminished, eventually disappearing completely.

We can understand the scaling of $t_{\text{cat}}$ with $\mu$ by considering the shape of $|\phi_0(\xi)|^2$. In the regime where $\mu \gg \hbar \omega$, the ground state is well approximated by the Thomas-Fermi (TF) solution [76]

$$|\phi_0(\xi)|^2 = \frac{\mu - \frac{1}{2} \xi^2}{N g_0}$$

for $\xi^2 < 2\mu$, and 0 otherwise, and

$$g_0 = \frac{4\sqrt{2}\mu^2}{3N}$$

(33)

(34)

is chosen to enforce the normalisation of $|\phi_0(\xi)|^2$. We note that this equivalent to choosing a particular value of $g_0$ to determine $\mu$.

Inserting this into Eq. (8) and Eq. (10), with $\phi_0(\xi) = \phi_b(\xi) = \phi_0(\xi)$ gives the twisting rate of the TF initial state

$$\chi_{\text{TF}} = (1 + \lambda - 2\kappa) \frac{2\mu}{5N},$$

(35)

FIG. 4. The quantum Fisher information of a maximally non-linear ($\kappa = 0$), symmetric ($\lambda = 1$) condensate with $N = 100$ as a function of evolution time for several $\mu$. Times $\tau_{\text{cat}}$ were taken directly from numerics by finding the peak, except for $\mu = 200.0$ which was estimated from Eq. (35) and Eq. (15). The times are $\tau_{\text{cat}} = 1570, 5735, 0.9817$ for $\mu = 0.6, 32.08, 200.0$, respectively. Chemical potential $\mu$ is in units of $\hbar \omega$.

and therefore

$$\tau_{\text{cat}} = \omega t_{\text{cat}} = \frac{5\pi N}{4\mu(1 + \lambda - 2\kappa)}.$$  

Subsequent dynamics in the twisting rate $\chi(\tau)$ occur when $\lambda, \kappa \neq 1$. For symmetric scattering lengths ($\lambda = 1$) the excitation spectrum of the two component TF ground-state agree well with the 1D single component result presented in the appendix of Ref. [77], which finds oscillating excitations with period

$$T_n = \frac{2\pi}{\sqrt{\frac{\pi}{2}(n + 1)}}.$$  

(37)

Breathing motion is the $n = 2$ excitation, ($T_2 \approx 3.63$) which agrees well with the dynamics observed in Figure 3. Figure 5 compares $\chi_{\text{TF}}$ to $\chi(\tau)$ calculated via Eq. (5) using the mean-field wavefunctions, obtained by setting $m = 0$ in Eq. (22), i.e $\phi_j(\xi, \tau) = \phi_{j0}(\xi, \tau)$. In the TF regime we observe breathing oscillations in $\chi(\tau)$ with period $T_2 \approx 3.63$, and find good agreement between $\chi(\tau)$ and $\chi_{\text{TF}}$ at $\tau = 0$. As $\mu$ approaches the single-particle energy $E_0 = \frac{1}{2}$, the multi-mode dynamics vanish, but so does the effective twisting rate $\chi(\tau)$.

Although Eq. (36) neglects dynamics (Figure 8 explores deviations from this formula that arise due to multi-mode dynamics), it is suggestive that $t_{\text{cat}}$ could be reduced by increasing $\mu$. However, in absolute terms, the time scale (in SI units) generally depends on $\mu$ and so one must be careful comparing $\tau_{\text{cat}}$, and a full 3D simulation would be needed to compare a fairly single-mode and
highly multi-mode regime. The 1D and 3D interaction strengths are related by some area $A_1$, $g_{1D} = g_{3D}/A_1$, and so one could vary $\mu$ by adjusting $A_1$ but keeping $\omega$ fixed. In this case, so long as the TF approximation holds, $\mu_{TF} \propto g_{1D}^{2/3}$, and $t_{cat}$ would be reduced by relaxing $A_1$, which supports multi-mode dynamics.

Figure 4 reveals a trade-off between this speed-up and the maximum QFI the state reaches, as clearly the multi-mode dynamics have a deleterious effect on the QFI, especially around $t_{cat}$. To explore the cause of this, consider $F_Q = 4\text{Var}(\hat{J}_y)$, which is the optimal generator at $t_{cat}$ for symmetric interactions ($\lambda = 1$). It is convenient to decompose the QFI into terms that depend on the 0th, 1st and 2nd order overlaps respectively [7]

$$F = 4\text{Var}(\hat{J}_y) = F_0 + F_1 + F_2,$$  

where

$F_0 = \langle \hat{J}_+\hat{J}_- \rangle + \langle \hat{J}_-\hat{J}_+ \rangle$  

$F_1 = -4\langle \hat{J}_y \rangle^2$  

$F_2 = -\langle \hat{J}_+\hat{J}_- \rangle - \langle \hat{J}_-\hat{J}_+ \rangle$.  

suppressing the $\tau$ dependence, expressing $F_0$, $F_1$ and $F_2$ in terms of Eq. (27) gives

$$\gamma_{jk}^{\mu}(m, \tau) = \int d\xi \phi_{j,m}(\xi, \tau)\phi_{k,m-m'}(\xi, \tau),$$

and to decompose the QFI into terms that depend on the $m = 0$ term the most to $F_2$ [c.f. Eq. (43c)].

$$F_0 = N + 2 \sum_{n_a=1}^{N-1} \frac{N!}{(n_a-1)!(n_b-1)!} [c_a^{2n_a}c_b^{2n_b}] \gamma_0^{ab}(m)^2$$  

$$F_1 = -\text{Im} \left( \sum_{n_a=1}^{N} \frac{N!}{(n_a-1)!(n_b)!} [c_a^{2(n_a-1)}c_b^{2n_b}c_a^{2n_a}c_a^{2n_a}] / h [\gamma_1^{ab}(m)]^{n_a-1} \gamma_2^{bb}(m)^{n_b} \right)^2$$  

$$F_2 = -\sum_{n_a=2}^{N} \frac{N!}{(n_a-2)!(n_b)!} [c_a^{2(n_a-2)}c_b^{2n_b}c_a^{2n_a}] [\gamma_2^{ab}(m)^2 \gamma_2^{aa}(m)^{n_a-2} \gamma_2^{bb}(m)^{n_b} - c.c.]$$

combined to deduce $0 \leq F_2 \leq N^2/2$. The terms $F_1$ and $F_2$ initially decay, and reach $\sim 0$ at approximately $\tau = 0.1t_{cat}$. At $\tau = t_{cat}$, $F_2$ experiences a revival to the maximum value, which is responsible for the cat peak. The decay of the overlaps is responsible for the decreased QFI in the multimode regime. As such, the QFI at $t_{cat}$ is independent of $\gamma_1^{bb}(m)$.

In the multimode regime, the decreased QFI is primarily determined by the decay of $|\gamma_{jk}^{\mu}(m, \tau)|^2$. Figure 6 (bottom row) shows the magnitude of the overlaps to the power of $n_b$ as this directly appears in Eq. (43c), $\gamma_0^{bb}(0)$.
\( \gamma_{bb}(0) \) and \( \gamma_{0b}^{bb}(0) \) for the symmetric number component \( (m = 0) \), which has the largest weighting in Eq. (27). The second-order overlap is reduced more than the first or zeroth-order overlaps, and as the first-order overlaps already do not contribute, this indicates that poor second-order overlaps are primarily responsible for the reduction in maximum QFI.

\[
\gamma_{bb}(0) \quad \text{and} \quad \gamma_{0b}^{bb}(0) \quad \text{for the symmetric number component} \quad (m = 0), \quad \text{which has the largest weighting in Eq. (27). The second-order overlap is reduced more than the first or zeroth-order overlaps, and as the first-order overlaps already do not contribute, this indicates that poor second-order overlaps are primarily responsible for the reduction in maximum QFI.}
\]

V. SPEED LIMITS ON CAT EVOLUTION TIME

Having determined that multi-mode dynamic can have a deleterious effect on the peak QFI, we performed many simulations such as those depicted in Figures 4 and 7. The results are collected in Figure 8. As condensates with asymmetric interactions always perform more poorly than symmetric ones for otherwise fixed parameters, we focus on symmetric systems \( (\lambda = 1) \). In particular we collate the maximum QFI and the corresponding time \( \tau_{\text{cat}} \) as a function of chemical potential. The maximum QFI is compared to \( F_Q = N^2/2 \), which is approximately the QFI of a twin-Fock state \( (\text{TFS}) |TFS\rangle = |N/2, N/2\rangle \), which has \( N/2 \) atoms in both components. This QFI which is quickly reached under one-axis twisting (see for instance Figures 2, 4) and serves as a threshold - if the maximum QFI is close to the TFS QFI there is little point bothering with the comparatively large \( \tau_{\text{cat}} \).

The top row of Figure 8 reveals that, as \( \mu \) increases and moves the system away from the single-mode regime, there are certain values of \( \mu/N \) that support the creation of states with QFI approaching \( F_Q = N^2 \). Crucially, this is true even in the presence of significant multi-mode dynamics. After scaling out the total number \( N \), for a particular value of \( \kappa \) these values of \( \mu/N \) are predicted by studying the period, \( T \), of the (maximally weighted) overlap \( |\gamma_{ab}^{jk}(m = 0)| \), which we previously deduced is primarily responsible for the decay in QFI. The bottom row of Figure 8 shows the time at which the maximum QFI occurs (empty squares, not necessarily \( t_{\text{cat}} \)), compared to the period of \( |\gamma_{ab}^{jk}(0)| \). Values of \( \mu \) with \( \tau_{\text{cat}} \) [Eq. (36), in Figure 8 plotted as a solid black line] that give rise to cat peaks significantly above the \( N^2/2 \) threshold (dashed magenta line). The take-home result of this plot is this: for a symmetric condensate far from the single-mode regime, given an \( N \) and \( \kappa \), it is not possible to use OAT to generate a state with QFI comparable to a spin-cat state faster than \( T \), and \( \mu \) should be chosen such that \( t_{\text{cat}} \) is an integer multiple of \( T \).

VI. CONCLUSION

We have investigated the creation of spin-cat states from non-linear atomic interactions in a two-level 1D trapped Bose-Einstein condensate. Starting from a simple analytic treatment within the Thomas-Fermi approximation, we deduce that working in a multi-mode regime should produce a larger twisting rate, and thus faster evolution toward a spin-cat state in absolute terms. Using the method of Sinatra and Castin we find that multi-mode dynamics have a deleterious effect on the maximum QFI, as a result of poor overlap between the mode functions of the different spatial components, especially the second order overlaps \( \gamma_{ab}^{jk} \). In particular we find that condensates with asymmetric interactions are more suscepti-
FIG. 8. (top row) For a symmetric condensate $\lambda = 1$, the maximum QFI is displayed for a range of parameters. The QFI is compared to $F_Q = N^2/2$ (dashed magenta), which is quickly (relative to $\tau_{\text{cat}}$) reached under OAT. (bottom row) For $N = 100$, we display the time at which the maximum QFI occurs (not necessarily $t_{\text{cat}}$). This is compared to the TF result (Eq. (36), solid black), and deviations from this curve indicate that the corresponding maximum QFI is not associated with a cat peak. The dashed cyan lines are integer multiples of the period of $|\gamma^a_{jk}|^2 (m = 0)$.

Appendix A: The Method of Sinatra and Castin

In this appendix we will present the method of Sinatra and Castin, and derive a number of useful results which we use throughout this paper.

1. Example: Single component system

For simplicity, we will first present the method as it applies to a single-component field $\hat{\psi}(r)$. In Section A3 we present the generalisation to a two-component system represented by the fields $\hat{\psi}_a(r), \hat{\psi}_b(r)$. The idea behind the method is to expand the state in the number basis, and then evolve each number state within a single-mode (or Hartree-Fock) approximation. Quantitatively, this is done by defining a Bosonic annihilation operator

$$\hat{a}_\phi = \int d\phi^*(r) \hat{\psi}(r). \quad (A1)$$

which destroys a particle with mode function $\phi(r)$ (normalized to unity). From the canonical commutation relations $[\hat{\psi}(r), \hat{\psi}^*(r')] = \delta(r - r')$ it follows that

$$[\hat{a}_\phi(r), \hat{a}^*_\phi(r')] = \int d\phi^*(r) \varphi(r). \quad (A2)$$
It is possible to use the mode-annihilation operator Eq. (A1) to construct a set of number-like states. To start with, the mode-annihilation operator Eq. (A1) acts on the vacuum in the standard way,

\[ \hat{a}_\phi |0\rangle = 0. \]  

(A3)

Thus, we can define the basis states

\[ |n; \phi_n\rangle = \left( \frac{\hat{a}_\phi^{\dagger}}{\sqrt{n!}} \right)^n |0\rangle, \]  

(A4)

which each have their own mode function \( \phi_n(r) \). This is conceptually similar to the usual single-mode approximation, with the key difference that each number component has its own wavefunction (or mode function). Associating each number state with a unique mode function means that superpositions of these states can exhibit spatial dynamics. The utility of this picture is that if written in this basis, \( |\psi(t)\rangle \) can be evolved in time by simply evolving each mode function \( \phi_n(r, t) \), i.e. in this picture the basis states are time dependent. Essentially the full multi-mode problem is recast as a single mode problem with spatial dynamics accounted for separately by \( \phi_n(r, t) \), which can significantly reduce the numerical difficulty of constructing and evolving the full state. Thus we have retained a multi-mode description of the system, within the approximation that each number component is well described by a single wavefunction. As a counter-example, another n-particle state is

\[ |\bar{n}\rangle = \frac{1}{\sqrt{n!}} \left( \hat{a}_{\phi_{n-1}}^{\dagger} \right)^{n-1} \hat{a}_\phi^{\dagger} |0\rangle, \]  

(A6)

which cannot be expressed in the form of Eq. (A4) if \( \phi_1 \neq \phi_{n-1} \).

Making use of Eq. (A3) and applying commutator Eq. (A2) m times with the identity

\[ [\hat{A}, \hat{B}^n] = n \hat{B}^{n-1} [\hat{A}, \hat{B}], \]  

(A7)

(which holds for any two operators \( \hat{A}, \hat{B} \) that both commute with \( [\hat{A}, \hat{B}] \)), the overlap of the basis states is

\[ \langle m; \phi_m(r') |n; \phi_n(r) \rangle = \delta_{m,n} \left( \int dr \phi_m^*(r) \phi_n^*(r) \right)^m. \]  

(A8)

Although the mode functions \( \phi_n(r) \) are non-orthogonal, they are normalised to unity. Importantly, this implies that the states \( |n; \phi_n(r)\rangle \) are orthogonal, and normalised so long as \( m = m' \) and \( n = n' \), which justifies the expansion Eq. (A5).

2. Equations of motion for a single component field.

Here we will derive equations of motion for the mode functions \( \phi_n(r, t) \), and then discuss how these may be used to calculate expectation values.

For brevity, in this section we will suppress the \( n \) index on the mode functions \( \phi_n(r, t) \). Consider a single component system evolving under the Hamiltonian

\[ \hat{H} = \int dr \hat{\psi}^\dagger(r) \hat{H}_0 \hat{\psi}(r) + \frac{g}{2} \int dr \hat{\psi}^\dagger(r) \hat{\psi}(r) \hat{\psi}(r), \]  

(A9)

with single-particle Hamiltonian \( \hat{H}_0 \). Assuming the coefficients \( c_n \) are stationary, then the dynamics are entirely governed by the basis states \( |n, \phi(r, t)\rangle \), which evolve under the Schrödinger equation

\[ i\hbar \frac{\partial}{\partial t} |n; \phi(r, t)\rangle = \hat{H} |n; \phi(r, t)\rangle. \]  

(A10)

Using the definition Eq. (A4) with Eq. (A1), the left-hand side (LHS) of the Schrödinger equation is

\[ i\hbar \frac{\partial}{\partial t} |n; \phi(r, t)\rangle = i\hbar n \left( \hat{a}_\phi^{\dagger} \right)^{n-1} \left( \int dr \frac{\partial \phi(r, t)}{\partial t} \hat{\psi}^\dagger(r) \right) |0\rangle. \]  

(A11)

However the right-hand side (RHS) is a little more effort, so we split the RHS into the single-particle term and the interaction term. To proceed, the commutators

\[ \left[ \hat{\psi}(r), \hat{a}_{\phi(r', t)}^{\dagger} \right] = \phi(r, t) \]  

(A12)

\[ \left[ \hat{a}_{\phi(r, t)}, \hat{\psi}^\dagger(r') \right] = \phi^*(r', t) \]  

(A13)

will be needed, along with the commutator identity Eq. (A7). The single particle term is

\[ \int dr \hat{\psi}^\dagger(r) \hat{H}_0 \hat{\psi}(r) |n; \phi(r', t)\rangle \]  

(A14)

\[ = \left( \frac{n}{\sqrt{n!}} \right)^n \int dr \hat{\psi}^\dagger(r) \hat{H}_0 \phi(r, t) \left( \hat{a}_{\phi(r', t)}^{\dagger} \right)^{n-1} |0\rangle, \]

and the interaction term is

\[ \frac{g}{2} \int dr \hat{\psi}^\dagger(r) \hat{\psi}(r) \hat{\psi}(r) |n; \phi(r', t)\rangle \]  

(A15)

\[ = \frac{gn(n-1)}{2\sqrt{n!}} \int dr \hat{\psi}^\dagger(r) \hat{\psi}(r) \phi(r, t)^2 \left( \hat{a}_{\phi(r', t)}^{\dagger} \right)^{n-2} |0\rangle. \]

Equating the LHS and the RHS of the Schrödinger equation, and multiplying through on the left by the inverse of \( \hat{a}_\phi \) \( n-2 \) times, we obtain
\[
\left( \hat{a}_{\phi}^\dagger (r, t) + \int d\mathbf{r} \hat{\psi}^\dagger (\mathbf{r}) g(\mathbf{r}, t) \right) |0\rangle = 0, \quad (A19)
\]

where we have defined:

\[
f(t) = \int d\mathbf{r} \phi^* (\mathbf{r}, t) \left( i\hbar \frac{\partial \phi (\mathbf{r}, t)}{\partial t} - \hat{H}_0 \phi (\mathbf{r}, t) \right), \quad (A20)
\]

\[
g(r, t) = i\hbar \frac{\partial \phi (\mathbf{r}, t)}{\partial t} - \hat{H}_0 \phi (\mathbf{r}, t) - g(n-1)|\phi(\mathbf{r}, t)|^2 \phi(\mathbf{r}, t). \quad (A21)
\]

Eq. (A19) implies,

\[
\int d\mathbf{r} \hat{\psi}^\dagger (\mathbf{r}) g(\mathbf{r}, t) = -\hat{a}_{\phi}^\dagger f(t)
\]

\[
= - \int d\mathbf{r} \hat{\psi}^\dagger (\mathbf{r}) f(t) \phi(\mathbf{r}, t), \quad (A22)
\]

where the second line follows from the definition of \( \hat{a}_{\phi} \) [Eq. (A1)]. Equating the integrands we can conclude that \( g(\mathbf{r}, t) = -f(t)\phi(\mathbf{r}, t) \), which can be re-written as

\[
i\hbar \frac{\partial \phi_n (\mathbf{r}, t)}{\partial t} = \left( \hat{H}_0 - f_n(t) + g(n-1)|\phi_n(\mathbf{r}, t)|^2 \right) \phi_n(\mathbf{r}, t). \quad (A24)
\]

Notice we have re-labelled \( f(t) \) and the mode functions with the \( n \) index. This equation is strikingly similar to the time-dependent Gross-Pitaevskii equation (GPE), but with a dynamic offset to the energy given by \( f_n(t) \). Substituting Eq. (A24) into Eq. (A20) reveals that \( f_n(t) \) depends only on the non-linear term,

\[
f_n(t) = \frac{g}{2} (n-1) \int d\mathbf{r} |\phi_n(\mathbf{r}, t)|^4. \quad (A25)
\]

In principle, Eq. (A24) fully determines the dynamics of \( \phi_n(\mathbf{r}, t) \), i.e. one must solve the equation of motion for each \( \phi_n(\mathbf{r}, t) \), computing \( f_n(t) \) at each time step via Eq. (A25). It is tidier to define the rotated field

\[
\tilde{\phi}_n (\mathbf{r}, t) = \phi_n (\mathbf{r}, t) e^{-iA_n(t)}/\sqrt{n}, \quad (A26)
\]

with

\[
A_n(t) = -n \int_0^t f_n(t')dt'. \quad (A27)
\]

To summarise, the time-evolved basis state is

\[
|n; \phi_n(\mathbf{r}, t)\rangle = e^{-iA_n(t)/\hbar} \left( \int d\mathbf{r} \tilde{\phi}_n(\mathbf{r}, t) \tilde{\psi}^\dagger (\mathbf{r}) \right)^n |0\rangle, \quad (A28)
\]

where \( \tilde{\phi}_n(\mathbf{r}, t) \) evolve under a set of GPE-like equations

\[
i\hbar \frac{\partial \tilde{\phi}_n (\mathbf{r}, t)}{\partial t} = \left( \hat{H}_0 + g(n-1)|\tilde{\phi}_n(\mathbf{r}, t)|^2 \right) \tilde{\phi}_n(\mathbf{r}, t), \quad (A29)
\]

and \( A_n(t) \) are computed by integrating

\[
\frac{dA_n(t)}{dt} = -\frac{g}{2} n(n-1) \int d\mathbf{r} |\tilde{\phi}_n(\mathbf{r}, t)|^4. \quad (A30)
\]

For a single field containing \( N \) atoms, the full state \( |\psi(t)\rangle \) can be constructed by solving \( N \) coupled differential equations Eq. (A29) and Eq. (A30). However, this may still be a challenging numerical task if \( N \) is large, particularly in higher numbers of spatial dimensions. Fortunately, for some states it may be sufficient to consider a subset of the full system. Additionally, in Ref. [74] the authors present a number of approximation methods which are less computationally demanding, however these methods are not employed in this work and as such they will not be discussed any further. Here, we will calculate some observables in terms of \( \tilde{\phi}_n(\mathbf{r}, t) \) and \( A_n(t) \). For simplicity, we drop the tilde notation, with the understanding that \( \phi_n(\mathbf{r}, t) \) is the solution to Eqs. (A29) rather than Eq. (A24) with Eq. (A25).

### 3. Generalisation to two fields

In the previous section we presented the case of a single field mainly for pedagogical reasons. In this section we present the formalism as it applies two fields \( \tilde{\psi}_a, \tilde{\psi}_b \). In analogy with Eq. (A1), the relevant (dynamic) basis states are

\[
|n; \phi_{a,n}(\mathbf{r}, t), \phi_{b,n}(\mathbf{r}, t)\rangle = e^{-iA_{n}(t)/\hbar} \left( \frac{\hat{a}_{\phi_{a,n}}^\dagger}{\sqrt{n_a!}} \right)^{n_a} \left( \frac{\hat{b}_{\phi_{b,n}}^\dagger}{\sqrt{n_b!}} \right)^{n_b} |0\rangle, \quad (A32)
\]
with $n = (n_a, n_b)$, and
\begin{align}
\hat{\alpha}_{\phi_a, n} &= \int dr \phi_{\alpha, n}^*(r, t) \hat{\psi}_a(r) \\
\hat{b}_{\phi_b, n} &= \int dr \phi_{\beta, n}^*(r, t) \hat{\psi}_b(r).
\end{align}
(A33)
(A34)

Consider the two-component Hamiltonian
\begin{equation}
\mathcal{H} = \sum_{j = a,b} \hat{\psi}_j^+(r) \hat{H}_0 \hat{\psi}_j(r) + \sum_{j,k = a,b} \frac{g_{jk}}{2} \int dr \hat{\psi}_j^+(r) \hat{\psi}_k^+(r) \hat{\psi}_j(r) \hat{\psi}_k(r).
\end{equation}
(A35)
(A36)

Following a similar procedure to the previous Section, one can derive the equations of motion for the mode functions $\phi_{\alpha, n}(r, t)$, $\phi_{\beta, n}(r, t)$ and phase factor $A_n(t)$ (suppressing the $r$ and $t$ dependence),
\begin{equation}
\frac{i}{\hbar} \frac{\partial \phi_{\alpha, n}}{\partial t} = \left( \hat{H}_0 + g_{aa}(n_a - 1)|\phi_{\alpha, n}|^2 + g_{ab}n_b |\phi_{\beta, n}|^2 \right) \phi_{\alpha, n}
\end{equation}
(A37)
\begin{equation}
\frac{i}{\hbar} \frac{\partial \phi_{\beta, n}}{\partial t} = \left( \hat{H}_0 + g_{bb}(n_b - 1)|\phi_{\beta, n}|^2 + g_{ab}n_a |\phi_{\alpha, n}|^2 \right) \phi_{\beta, n}
\end{equation}
(A38)
\begin{equation}
\frac{dA_n}{dt} = - \sum_{j = a,b} \frac{g_{jj}}{2} n_j(n_j - 1) \int dr |\phi_{j, n}|^4 - g_{ab}n_an_b \int dr |\phi_{\alpha, n}|^2 |\phi_{\beta, n}|^2.
\end{equation}
(A39)

Once these equations have been solved, expectation values of normally ordered moments (such as those presented in Section [A3]) can be evaluated making use of the following identities,
\begin{align}
\hat{\psi}_a(r)|n; \phi_{\alpha, n'}(r', t), \phi_{\beta, n'}(r', t)\rangle &= \sqrt{n_a} \phi_{\alpha, n'}(r, t)|n_a - 1, n_b; \phi_{\alpha, n'}(r', t), \phi_{\beta, n'}(r', t)\rangle \\
\hat{\psi}_b(r)|n; \phi_{\alpha, n'}(r', t), \phi_{\beta, n'}(r', t)\rangle &= \sqrt{n_b} \phi_{\beta, n'}(r, t)|n_a, n_b - 1; \phi_{\alpha, n'}(r', t), \phi_{\beta, n'}(r', t)\rangle
\end{align}
(A40)
(A41)

with the overlap
\begin{equation}
(m; \phi_{\alpha, n'}(r', t), \phi_{\beta, n'}(r', t)|n; \phi_{\alpha, n'}(r, t), \phi_{\beta, n'}(r, t)\rangle
\end{equation}
(A42)
\begin{equation}
= \left( \int dr \phi_{\alpha, n'}^*(r, t) \phi_{\alpha, n'}(r, t) \right)^{n_a} \times \left( \int dr \phi_{\beta, n'}^*(r, t) \phi_{\beta, n'}(r, t) \right)^{n_b} e^{[A_{n'}(t) - A_{n}(t)]/\hbar} \delta_{m, n'}.
\end{equation}

Note that $\delta_{m, n} = \delta_{m_a, n_a} \delta_{m_b, n_b}$ and also that typically $n$, $n'$ are not independent (for instance $n'_a = n_a \pm 1$, and likewise for $m$, $m'$).

4. SU(2) expectation values

In the main text we are interested in employing this formalism to calculate the expectation values of observables associated with the SU(2) algebra. If we impose the constraint $n_a + n_b = N$, then all two-level basis states Eq. (A31) have conserved total number $N$, which can now be labelled with a single index $m = (n_a - n_b)/2$. This is the notation used in the main text [Eq. (2)] These states are the multi-mode analogue of Dicke states. We note that for any SU(2) state summing over $m$ is equivalent to summing over $n_a$, but we continue to use the latter for notation for clarity.

We study the time-evolution of coherent-spin states of $N$ atoms, i.e.
\begin{equation}
|\psi(t)\rangle = \frac{1}{\sqrt{N!}} \left( c_a |\phi_a\rangle + c_b |\phi_b\rangle \right)^N |0\rangle
\end{equation}
(A43)
\begin{equation}
= \sum_{n_a = 0}^N \sqrt{\frac{N!}{n_a!n_b!}} (c_a)^{n_a} (c_b)^{n_b} \times
\end{equation}
(A44)
\begin{equation}
\times |m; \phi_{\alpha, n}(r, t), \phi_{\beta, m}(r, t)\rangle.
\end{equation}

The coefficients $c_a, c_b$ describe the initial coherent-spin state with $|c_a|^2 + |c_b|^2 = 1$, and initial condition $\phi_a = \phi_b$.

Observables that commute with the total number are conserved, and can be simply evaluated with respect to the initial coherent-spin state Eq. (A43), for instance $\langle \hat{N}_a \rangle = N/2$, $\langle \hat{N}_a^2 \rangle = N^2/4$, etc. In general expectation values of normally-ordered observables can be evaluated by making use of Eq. (A40) and Eq. (A41), with the overlap Eq. (A42). In terms of the mode-overlaps
\begin{equation}
\gamma_{jmk}(m, t) = \int dr \phi_{j, m}(r, t) \phi_{k, m'}^*(r, t),
\end{equation}
(A45)
we have
\[
\langle \hat{J}_+ \rangle = \int d\mathbf{r} (\hat{\psi}_a(\mathbf{r}) \hat{\psi}_b^\dagger (\mathbf{r}))
\]
\[
= \sum_{n_a=1}^{N} \frac{N!}{(n_a - 1)!n_b!} |c_a|^{2(n_a - 1)} |c_b|^{2n_b} c_d^* c_e e^{i[A_{m-1}(t) - A_{m}(t)]/\hbar} \gamma_a^{gb}(m, t) [\gamma_1^{ab}(m, t)]^{n_a - 1} [\gamma_1^{bb}(m, t)]^{n_b}.
\]

Up to conjugates and ordering, there are four unique moments which are needed to study one-axis twisting. The relevant higher order moments are (see also Ref. [74], Appendix A):

\[
\langle \hat{J}_+ \hat{J}_- \rangle - \langle \hat{N}_b \rangle = \int \int d\mathbf{r} d\mathbf{r}' (\hat{\psi}_a(\mathbf{r}) \hat{\psi}_b(\mathbf{r}) \hat{\psi}_a^\dagger (\mathbf{r}') \hat{\psi}_b^\dagger (\mathbf{r}'))
\]
\[
= \sum_{n_a=2}^{N-1} \frac{N!}{(n_a - 2)!n_b!} |c_a|^{2(n_a - 2)} |c_b|^{2n_b} c_d^* c_e^2 e^{i[A_{m-2}(t) - A_{m}(t)]/\hbar} \gamma_a^{gb}(m, t) \gamma_1^{ab}(m, t)^{n_a - 2} [\gamma_1^{bb}(m, t)]^{n_b}
\]

\[
\langle \hat{N}_a \hat{J}_+ \rangle - \langle \hat{J}_+ \rangle = \int \int d\mathbf{r} d\mathbf{r}' (\hat{\psi}_a(\mathbf{r}) \hat{\psi}_b(\mathbf{r}) \hat{\psi}_a^\dagger (\mathbf{r}') \hat{\psi}_b^\dagger (\mathbf{r}'))
\]
\[
= \sum_{n_a=1}^{N-1} \frac{N!}{(n_a - 1)!n_b!} |c_a|^{2(n_a - 1)} |c_b|^{2n_b} c_d^* c_e e^{i[A_{m-1}(t) - A_{m}(t)]/\hbar} \gamma_a^{gb}(m, t) \gamma_1^{ab}(m, t)^{n_a - 1} [\gamma_1^{bb}(m, t)]^{n_b}
\]

\[
\langle \hat{N}_a \hat{J}_- \rangle - \langle \hat{J}_- \rangle = \int \int d\mathbf{r} d\mathbf{r}' (\hat{\psi}_a(\mathbf{r}) \hat{\psi}_b(\mathbf{r}) \hat{\psi}_a^\dagger (\mathbf{r}') \hat{\psi}_b^\dagger (\mathbf{r}'))
\]
\[
= \sum_{n_a=1}^{N} \frac{N!}{(n_a - 1)!n_b!} |c_a|^{2n_a} |c_b|^{2n_b} c_d^* c_e e^{i[A_{m+1}(t) - A_{m}(t)]/\hbar} \gamma_1^{gb}(m, t) [\gamma_1^{ab}(m, t)]^{n_a} [\gamma_1^{bb}(m, t)]^{n_b - 1}.
\]
