The Measurement Problem Is the “Measurement” Problem

Arne Hansen and Stefan Wolf

(Dated: October 11, 2018)

Physics builds on two tenets: On the one hand, statements are expressed in formal languages. On the other, these statements are to be tested against experience. Observers are the nexus between experience and the account thereof. Whether this very account can be formalized—that is, exhaustively represented in a formal language—can be doubted, as we argue. Such an incommensurability of accounts of experience and formal languages has repercussions on how to approach the measurement problem and issues regarding self-reference in quantum mechanics: If there is no privileged language of experience, the possibility of closing the theory to the end of the observer is in doubt. It also means that physics cannot be reduced to mere data compression or statistical learning within some given language—instead, physics plays an active role in establishing language (and meaning).

I. INTRODUCTION

In the attempt to close quantum theory (or any other physical theory, for that matter) to the end of the observer—to incorporate an observer into the formal language of the theory—, one encounters problems: When observing an observer, one is faced with the measurement problem [1, 2]. Two manifestations thereof are the Wigner’s-friend experiment [3–5] and Schrödinger’s cat [6]:

(MP1) Wigner measures his friend who, in turn, measures another system. The friend supposedly obtains a definite result as he “performs a measurement” while being, at the same time, in a superposition of states corresponding to two different results.

(MP2) Schrödinger’s cat is in a similarly precarious situation, being in a superposition of “alive” and “dead,” thus contradicting the intuition of mutual exclusion of “alive” versus “dead.”

Both Wigner’s friend and Schrödinger’s cat are represented in the formal language of quantum mechanics despite carrying some “classical” (distinguishable) information. Similarly, when one considers self-measurement scenarios, as in [7], the observer himself gets assigned a state, i.e., a symbol from the formal language, that he then tries to access in a measurement—as if Wigner had been his own friend. In order to obtain a formal contradiction it is, in both cases, crucial to associate an account of experience (i.e., the statement to have observed a certain value) with symbols in a formal language. If the existence of such a formal account of experience is in doubt, then the formal contradiction is, too. Doubts regarding the possibility of an exhaustive formal account of experience root in the intricate relations between language, meaning, experience, and the role of the observer herein (see Figure 1).

The outline of the remainder of this article is as follows: In Section II we characterize the epistemological role of the observer and isolate the crucial qualification of a measurement result as having been “observed.” In Section III we review arguments against the possibility of a reduction of such a predicate to atomic rules of a formal language. The resulting scepticism has consequences on how one regards the concepts of states, systems, and the role of the Born rule in quantum mechanics, as discussed in Section IV. In Section V we examine the measurement problem and self-measurement issues from the perspective developed in the preceding sections.

Figure 1. At the core of our considerations is the tension between “meaning” and “experience,” and how it affects the measurement problem in quantum mechanics.

1 The example of Schrödinger’s cat is by now rather trite. Furthermore, it has a anthropocentric smack, similar to Wigner’s reference to “consciousness” as a necessary requirement for being an observer [6].
II. THEORIES, SENTENCES, EXPERIENCE

The starting point of our considerations are the following two characteristics which we regard as necessary (albeit not sufficient) for doing physics:

(C1) Physics strives for a formal description of the world.  

(C2) Experience serves as its final, normative authority.  

Concerning Characteristic (C2), Within physics, one rarely refers to experience but rather to observations. We take an observation to be a special kind of experience, e.g., verifiable in some sense. Hence, any conclusion valid for experiences applies to observations. In the following we attempt, despite the doubts discussed in Section IIIE to establish a notion of formal description and to isolate the account of observation. In Section III we address the question whether the program of formalization can be carried through to include the account observation. In contrast to, e.g., [8], we do not “de-emphasize the role of language,” but rather return to the case of the linguistic turn.

A formal language is a set of sentences $P \subset S^*$, with $S^*$ being the Kleene closure (the set of all finite strings or concatenations) of an alphabet $S$, that are syntactically correct with respect to a set of rules $R$. The relation between observations and a formal language $T = (S, R, P)$ is of the following kind:  

If I have observed $x$, I deem a formal language $T$ which forbade the observation of $x$ untenable.

If, for instance, in two subsequent identical quantum measurements, one observed different values, quantum mechanics, $T_{qm} = (S_{qm}, R_{qm}, P_{qm})$, would be contradicted: There are no quantum states and measurement operators that could, within the postulates of quantum mechanics, account for the corresponding result $(x_1, x_2)$ with $x_1 \neq x_2$. The elements in $S_{qm}$ together with rules in $R_{qm}$ do not allow to conclude that $x$ may be observed for either there is no such sentence in $P_{qm}$ or an associated probability weight is zero.

Let $T = (S, R, P)$ be the formal language of some theory. In order to formally characterize the sentences that falsify $T$, we now consider statements restricted to a context: We assume a formal language

\begin{align*}
T_{con} = (S_{con}, R_{con}, P_{con}) \text{ whose syntactically correct sentences } p \in P_{con} \text{ refer to possible results observable for a given context, i.e., experimental setup. Furthermore, we assume that the formal language } T \text{ can be restricted to some } T' \text{ such that the corresponding sentences } P' \text{ are the subset of } P_{con} \text{ of sentences that } T \text{ can account for. For } T \text{ to be falsifiable in a context } T_{con}, \text{ the set of sentences } P' \text{ has to be a proper subset of } P_{con}. \text{ We can derive a formal language } T_{fal} \text{ from } T' \text{ and } T_{con} \text{ with all sentences about the experimental context that contradict } T \text{ as illustrated in Figure 2 If we considered a sentence in } P_{fal} \text{ true, then } T \text{ would be falsified for the given context. In the previous example of two identical subsequent quantum measurements, the result } (x_1, x_2) \text{ with } x_1 \neq x_2 \text{ corresponds to a sentence in } P_{fal}. \text{ Falsification refers to theories, including semantic concepts beyond a formal language, rather than to the formal language directly. The semantic concepts are delegated to the condition “I have observed } x_1, \text{” which we now turn to.}

Ultimately, sentences are to be gauged by experience according to Characteristic (C2) Let $v_O : P_{con} \to \{true, false\}$ be a function—the so-called verification function—, for which $v_O(p) = true$ if and only if the observer $O$ has observed $p$. More specifically, if $v_O(p) = true$ then $O$ deems some apparatus fit to produce values in the context $\mathcal{M}$, and $O$ is certain to have obtained the value $p$. The verification function establishes whether the condition “I have observed $p$” is satisfied or not. Thus, for $O, T$ is falsified for the context $P_{con}$ if there exists $p \in P_{fal}$ with $v_O(p) = true$.

The reasoning about a formal language $T$ is independent of the particular observer—it transcends single observers: Any observer, upon knowing the formal language $T$, can conclude for all sentences $p \in P_{con}$ whether they are in $P_{fal}$ or not and, hence, whether they falsify $T$ or not. The rules $R$ are, therefore, required not to

---

2 This does not mean to interpret the description. At this point we do not imply, for instance, whether or not the description approximates some realistic truth; it is rather a methodological constraint. Also, scientific realism allows for a revision in view of suitable evidence.

3 This restriction implies, if you will, that evidence is sensory evidence.

4 Tarski similarly characterizes “formalized language” in [3] and remarks the additional structure for “formalized deductive sciences,” where the rules are specified by axioms and deductive rules.

5 Popper in [10] refers to “empirical-scientific systems.”
depend on observations, qualified by a—subjective, as argued below—verification function. A theory in this sense is not statistical learning. Therefore, our approach differs from [11], and from revision theories of truth [12].

Can the observer be included into the formal language? Can the verification function be reduced to “atomic” (i.e., not further reducible) symbols and thus gain a similar observer-independent status? Or, are there parts in an account of experience that defy a deduction from a finite set of rules? In Section III these questions are addressed.

III. IRREDUCIBLE NATURAL LANGUAGE

In the following, we argue that accounts of experience cannot be exhaustively expressed in a formal language: In a first step, we examine how the limits on formal languages limit a formal account of experience (III A). After discussing these structural concerns, we review arguments against semantic atomism and an “immediacy” in the account of experience as maintained with sense data in classical empiricism (III B), before turning to entailing consequences (III C III E).

In analogy to an observation by Putnam⁶ it should be noted that the subsequent arguments do not constitute a proof of impossibility but are, nonetheless, reasons for concern. The following considerations are incomplete and touch aspects merely superficially.

A. The limits of formal languages

Self-reference imposes limitations on formal languages. Problems arising from self-reference crystallize, e.g., in the Liar’s antinomy:

This sentence is false.

The sentence is self-contradictory because a statement is true if and only if the claim that the statement be true is true: This particular unquotation notion of truth—illustrated by: “Snow is white” is true if and only if snow is white—is called Schema T [14]: For a truth predicate T and with ⟨·⟩ denoting the name of a sentence, it can be written as

\[ \phi \leftrightarrow T(\phi), \quad \forall \text{ sentences } \phi. \]

With the theorem on the undefinability of truth, Tarski showed that any formal language extending first-order arithmetic with a truth predicate containing Schema T allows for such a contradiction. Self-reference, together with a negation⁷ thwarts the unification of different linguistic contexts as a consistent truth predicate requires a meta-language.

The verification function above serves as a predicate. If it is formalized in a theory extending first-order arithmetic, we require it to contain the Schema T, and no sentences of the formal language are excluded from arising from observation, then there is a liar’s antinomy. There are three escape routes: (1) Either nature miraculously removes all problematic sentences, and leaves us with an incomplete formal language in which certain syntactically correct sentences are excluded by assumption, or (2) we can run into glitches in our experience that defy a deduction from a finite set of rules, or (3) we have to abandon Schema T and thereby an unquotation conception of truth. While these considerations do not logically exclude the formalization of the verification function, they taint attempts to logically reduce accounts of experience to atoms.

Similarly, if a theory strives for universality and, thus, for explaining itself, then it allows to formulate a Curry antinomy [17]—even if formulated in natural language as long as it allows for modus ponens, contraction, and tautologies.

B. Semantics and experience

A central argument against an exhaustive formalizability of accounts of experience derives from the observation that they have semantic implications: Meaning and experience are intricately intertwined (see Figure 3). If we are to examine how, within some language, one can account for experience, we have to consider how experience plays into establishing meaning. In [18], Wittgenstein examines the roots of meaning by considering language games (“Sprachspiele”) in which individuals establish the meaning of (first) words. For a child, that has no medium to establish meaning from explanation⁸, the acquisition of language reduces to trimming⁹. This process, in turn, relies on observation. There is an issue of self-reference

---

⁶ “Reichenbach, Carnap, Hempel, and Sellars gave principled reasons why a finite translation of material-thing language into sense-datum language was impossible. Even if these reasons fall short of a strict mathematical impossibility proof, they are enormously convincing […] In the same spirit, I am going to give principled reasons why a finite empirical definition of intentional relations and properties in terms of physical/computational relations and properties is impossible—reasons which fall short of a strict proof, but which are, I believe, nevertheless convincing.” [12 §5]

⁷ There is an apparent analogy to Gödel’s first incompleteness theorem. In fact, the latter can be proven by a reduction to Tarski’s theorem [15]. In the context of spacetime causality, Gödel’s closed time-like curves [16] allow for a grandfather’s paradox, similarly combining self-reference and negation.

⁸ “Man muss schon etwas wissen (oder können), um nach der Be- nennung fragen zu können. Aber was muss man wissen?” [18, §30]

⁹ “Das Lehren der Sprache ist hier [für das Kind] kein Erklären, sondern ein Abrichten.” [18, §5]
account of experience

meaning

Figure 3. The circular dependency of meaning and the account of experience, eventually, calls into question any reduction to atoms.

At the very root of meaning—or at the very root of any account of experience for that matter: Whenever one attempts to reduce language to some atomic propositions or first words, one is faced with a problem of circular dependence.

Sense data and the informant model

In a first conception one might take the given in experience to be an ordinary judgement of perception, such as “I see a screen in front of me.” In [12], this is called Naive Epistemological Realism (NER). If one assumes an equivalence of experience [13] NER does not allow to distinguish a dream or hallucinatory experience from other, subjectively equivalent experiences. Without the possibility to qualify experiences, the reliability of experience would be lost: A dream or hallucinatory experience could then not be told apart from other experiences. Thus, if experience is taken to be propositional, it cannot be propositional about objective facts, but merely about sense data [14]. The observer is the neutral medium for “(mind-independent) facts” [15]. In [12], Gupta argues for an equivalence between sense-datum theories and an informant model. On the one hand, sense-datum theories build on an informant model, on the other:

Once we accept the informant model of experience—that is, once we accept the idea that epistemological role of experience is to reveal facts about the world—we commit ourselves to the propositional given. And this commitment inexorably drives us, in light of the phenomenological features of experience, to the sense-datum theory. [12, §2C]

Thus, the subsequent arguments against sense-datum theories are also arguments against the idea that our experience reduces to an apprehension of pre-existent information, some given facts.

Objections to reductionism

There has been ample criticism of models attempting to reduce accounts of experience or semantics, as sense-datum theories do. In the following, a few of the arguments are sketched.

a. Wittgenstein. If one joins the dots of the Tractatus logico-philosophicus [20] (see also [21]), a dense network of relations between terms emerges, but no ultimate explanation. Wittgenstein exposes the “misunderstanding of the logic of our language” [20] indirectly. He concludes:

My propositions are elucidatory in this way: he who understands me finally recognizes them as senseless, when he has climbed out through them, on them, over them. (He must so to speak throw away the ladder, after he has climbed up on it.) He must surmount these propositions; then he sees the world rightly. [21, §6.53]

b. Semantic holism. Quine attacks a dogma of reductionism—specified as “the belief that each meaningful statement is equivalent to some logical construct upon terms which refer to immediate experience” [22]. In a first step, he argues for a “confirmation holism”—based on the observation “that experience can confirm or refute only a whole system of knowledge” [22, 14]

If a conflict with experimental evidence occurs, it is not logically determined which statements are to be rejected. It may be reasonable to change even fundamental hypotheses of physics subsequent to the results of experiments. [23]

10 “Something is given in each experience; that is, each individual experience makes a rational contribution to knowledge.” [12, §2B, Existence of the given]

11 And on that screen: I see “I see . . . in front of me” in front of me.

12 “Subjectively identical experiences make identical epistemic contribution. More precisely, if e and e’ are subjectively identical experiences of an individual, then the given in e is identical to the given in e’.” [12, §2B, Epistemic equivalence of subjectively identical experience]

13 “The given in experience does not yield anything false or erroneous; in particular, it does not yield a false proposition” [12, §2B, Reliability of all experience]

14 “According to the sense-datum theory, the self is directly and immediately aware of its sense-data. The self’s relationship to its sense-data is not mediated by any process that might affect its apprehension. In particular, none of the various factors that distort our perceptions of ordinary things is present here. The relationship of a self to its sense-data is transparent, direct, and unmediated. The sense-data are just what they seem to be. […] The sense-datum theory preserves an element of the naive picture that in experience we make a direct perceptual contact, with public, physical objects and with (some of) their properties and relations. The theory retains the idea of direct perceptual contact but introduces new subjective entities—sense-data—to be the objects of this contact.” [12, §2A]

15 The idea does not only originate from Quine; the latter rather develops Duhem’s holism further [23].
By means of a confirmation theory of meaning, this entails a holisticism: “If a statement cannot be confirmed in isolation, it does not have meaning in isolation either” [23]. Quine maintains, however, a privileged semantic context building on a concept of “same concurrent stimulation,” similar to sense data: “observation sentences” form the “intersubjective tribunal” to test theoretic hypotheses [24].

c. Representation and reference. Putnam argues “that the understanding of that [inner] expression—one’s understanding of one’s own thoughts—is not an occurrence but an ability” [14 §1]. We can establish understanding, reference, and meaning—they are not a priori given in a specific representation. The ant’s incidental “picture of Churchill” in the sand constitutes one of Putnam’s arguments against the existence of exhaustive criteria that determine reference or representation: Similarity to the features of Churchill is neither necessary nor sufficient to refer to Churchill (see [14 §1]). Magritte’s “Treachery of Images” exposes similar ambiguities: Foucault distinguishes in his discussion of Magritte’s references to a pipe [25] similitude and resemblance, and regards the painter to bring “the former into play against the latter” [25 §5]. Putnam is lead by such considerations to the question:

If lines in the sand, noises, etc., cannot ‘in themselves’, represent anything, then how is it that thought forms can ‘in themselves’ represent anything? Or can they? How can thought reach out and ‘grasp’ what is external? [19 §1]

d. No privileged language. The above is one of Putnam’s arguments against unacquired, innate, non-contextual semantic structures, an underlying lingua mentis that allows to deduce semantics if deciphered correctly [15 §18]. Two of Gonseth’s “four principles” (see [27]), at the core of his “open philosophy,” reflect a similar stance: The revision principle says “that every position and every scientific statement, including statements of logic, can be revised” [23]. The principle of duality aims “to bring together reason and experience” [23] within an “interplay between general statements up to logical laws and particular laws and particular statements down to statements that describe single facts or events. Changes in the periphery of the particular can have repercussions up to the center of the general” [23].

Sellars argues, “as a first step in a general critique of the entire framework of givenness” [24 §1]: Sense-datum theories are faced with an inconsistent triad, stemming from a concept of sensation as “inner episodes […] without any prior learning or concept formation” [20 §7] and “inner episodes which are non-inferential knowings that certain items are, for example, red or C# [the musical note] and that these episodes are the necessary conditions of empirical knowledge as providing the evidence for all other empirical propositions” [24 §7].

Gupta draws a similar conclusion:

The connections of our words to the world depend on experience, on view and, of course, on contingent features of the world. A particular vocabulary may have a tidy semantics under one set of worldly circumstances but may fail to do so under a different set. No vocabulary is guaranteed to have a tidy semantics by experience. No vocabulary has a privileged status [12 §5D, emphasis added].

C. Theoretical diversity

Paul Feyerabend argues in [27] that theories cannot be understood, let alone challenged, from within themselves: Theories are often grasped in contrast to other, competing ones. Data that can effectively falsify a theory is often gained through competing theories. In light of the previous discussion (see [11B]), it seems evident: Not only do theories depend on observations; what is considered to be an observation depends on the available theories. If there is no privileged language, then any language is to be contested. Thus, abuse of language is crucial to progress and discovery [20].

D. Physics vs. statistical learning

If there is no privileged language, there is no privileged account of experience. Not only does this bar us from

16 “An observation sentence is one on which all speakers of the language give the same verdict when given the same concurrent stimulation.” [24 p. 86f]
17 “Resemblance presupposes a primary reference that prescribes and classes. […] Resemblance serves representation, which rules over it; similitude serves repetition, which ranges across it.” [25 §5]
reducing semantics to “atomic” statements, it also yields flexibility as to what one qualifies as observations.

Reification

Learning algorithms as referred to in [11] build on a fixed set of data relying, in turn, on a fixed semantics that specifies what is to be counted as an observation. Within physics one can—according to Feyerabend, one must—question any underlying semantics: Physical theories feed back into the semantic foundation. If physics determines what counts as data in the first place, it cannot be reduced to statistical learning. Similarly, physics cannot be regarded as mere data compression: Any ontological statements derived from a notion of information rely on a privileged language that qualifies privileged data—leading to a reification in terms of information.

Informational structuralism

Quantum Bayesianism is an observer-centered, yet axiomatic approach building on the concept of information: Embracing the observer and the measurement as “primitive” [31], instead of removing them from the theory, seems justified in light of the above discussion. If any account of experience is necessarily subjective, then a subjective theory seems reasonable. (In fact, we take a similar position in the subsequent discussion on quantum mechanics.)

When regarding information as the “latent antibody” [31] against the problems of quantum mechanics, it is the hope of an ultimate reduction to information-theoretic principles and atomic information, one is left with a semantically problematic reification as above. A more structuralist perspective [31], guided by questions like “how much information?” [22] rather than by “information about what?” seems less exposed to the objections raised above.

E. Consequences for the verification function

In view of the above arguments, assuming experience to be non-trivially and irreducibly dependent on subjective, observer-related factors seems to be a viable stance. This entails that the verification function cannot be formalized.

Given the initial characteristics of physics, [C1] and [C2] there is a dialectic at the core of physics:

Whereas physical theories crucially rely on formal languages, they are to be measured against an inherently informal account of experience.22

The initial characterization of formal languages as observer-transcendent, as well as the separation of the verification function, can be questioned with the preceding arguments—reflecting Wittgenstein’s reservations towards a division of object and meta-language [21]. How can we talk about, or refer to, formal languages without our natural language? And how can natural language circumvent the problem of first words without experience? Despite this criticism of the initially drawn picture of formal languages: The latter serves to carve out the issue that attempts to formalize or reduce fail—at the latest when we arrive at the account of experience that will constitute our verdict about scientific theories. In the end, also this text is only a language game.

IV. SYSTEMS, STATES, AND THE BORN RULE

Among physicists, an informant model of experience, assuming the mind-independent existence of facts, is prevalent. This, in turn, has effects on the use and meaning of terms. In the following, terms central to quantum mechanics will briefly be discussed.

A. State and system

As Wittgenstein observes, the meaning of terms is specified and modified while—not prior to—being used. In this sense, the words “state” and “system” are not as clear and static as often insinuated in scientific practice. This foundation for explanatory constructs might be shakier than it appears at first sight.

Whereas in classical mechanics, a system and its state are both characterized by directly measurable quantities, the matter gets more intricate in quantum mechanics:

22 “Der Widerstreit [zwischen der tats¨achlichen Sprache und unserer Forderung nach der Kristallklarheit der Logik] wird unertr¨aglich; die Forderung droht nun zu etwas Leerem zu werden. — Wir sind auf Glatteis geraten, wo die Reibung fehlt, also die Bedingungen in gewissem Sinne ideal sind, aber wir eben deshalb auch nicht gehen k¨onen. Wir wollen gehen; dann brauchen wir die Reibung. Zur¨uck auf den rauhen Boden!” [18, §107] — Gonseth, with his principle of duality, makes this dialectic an integral part of his philosophy of science.

23 “That the scientific method is fundamentally objective is a notion deeply rooted in Western tradition.”

24 “As Wittgenstein often pointed out, a philosophical problem is typically generated in this way: certain assumptions are made which are taken for granted by all sides in the subsequent discussion.”

25 Van Fraassen, in [31], emphasizes the change of the use of words like “atom”, “electron” or “field” to conclude: “Thus, scientific revolutions, and even evolutions, embarrass the standard scientific realist.”
Grete Hermann refers to quantum states as “new symbols that express the mutual dependency of the determinability of different measurements”\(^{26}\). It seems reasonable to emphasize the semiotic character of the state: Symbols of a formal language \(T\), though they might be called states, are, a priori, not endowed with any further meaning than to serve as signs\(^{27}\). Gleason’s theorem\(^ {28}\) sheds a new light onto the quantum state and shifts the semiotic character to measurements represented by sets of orthogonal projectors on a (finite-dimensional) Hilbert space: The theorem states that any measure \(\mu\) for projectors on a Hilbert space of dimension greater than two, satisfying an additivity constraint for orthogonal projectors,

\[
\mu\left(\sum_i P_i\right) = \sum_i \mu(P_i)
\]
as well as the constraints

\[
\mu(0) = 0 \quad \mu(1) = 1
\]
is of the form

\[
\mu(P) = \text{Tr}(P \rho)
\]

with \(\rho\) being a positive trace-1 operator, i.e., a density matrix. A theory that represents measurements with sets of orthogonal projectors as above cannot bear a measure \(\mu\) with a range \(\{0, 1\}\), as expected from a model assigning definite and non-contextual values to its measurement operators\(^ {27, 28}\). The way back to a simple association of states and measurement results as in classical mechanics is barred by non-locality\(^ {29, 30}\) and contextuality\(^ {10}\): “Classical” information is inadequate and insufficient for quantum mechanics.

### B. Born rule

As demanded in Section\(^ {11}\) any physical theory has to yield assertions as to which results are not expected to be observed. In classical mechanics, measurable entities have a one-to-one correspondence to states. The situation in quantum mechanics is more intricate, as there is no immediate correspondence between observed entities and state symbols: The Born rule bridges between these incommensurable realms. At first sight, the need of such a bridge seems unfortunate as it manifests the separation of a realm of observable entities from the realm of states. Together with a model of the measurement process, the Born rule leads to issues such as the measurement problem. On a closer look, however, fundamental theories seem to require a formal framework that connects to information: The core of Popper’s argument for a fundamental indeterminism in classical mechanics (\(C\)) in\(^ {11}\) evolves around the observation that the only means of extracting information from a system in classical mechanics—without going beyond classical mechanics in the measurement process—involves introducing untraceable disturbances. The underlying assumption is: In order to extract any information, there has to be an interaction\(^ {25}\). The problem in classical mechanics is usually tamed by describing the measurement in another theory \(T’\): For instance, optical measurement devices may determine the position of a system otherwise described by classical mechanics. The disturbance due to the interaction captured in \(T’\) may be assumed to be small. Then the error one has to tolerate before falsifying \(C\) or \(T’\) is small. (In contrast to this, Popper’s observation of a fundamental indeterminism relates to necessarily large errors.) In this light, the possibility of measuring an entity “without in any way disturbing a system”\(^ {23}\) is not a feature of classical mechanics alone—optics (or another external theory) is necessary to reduce the errors.

In summary, a fundamental theory (not relying on other theories to capture an interaction necessary to extract information) has to model the emergence of information—potentially exposing it to a measurement problem.

### V. THE MEASUREMENT PROBLEM

The above considerations have repercussions on the measurement problem. In the proceeding, we illustrate the problem with the Wigner’s-friend experiment. A discussions of Maudlin’s reading\(^ {1}\) of the problem can be found in Appendix\(^ {A}\) Breuer’s approach\(^ {2}\) to self-reference issues in quantum mechanics in is examined in Appendix\(^ {B}\).

The measurement problem roots in the irreconcilability of distinguishability of information and linearity in quantum theory\(^ {2}\). The problem can be illustrated with a Wigner’s-friend experiment as depicted in Figure\(^ {4}\) Employing references to states—despite the above

\(^{26}\) “Im Gegensatz dazu [Zustände der klassischen Physik] braucht der quantenmechanische Formalismus zur Zustandsbeschreibung neuartige Symbole, die die gegenseitige Abhängigkeit in der Bestimmbarkeit verschiedener Größen zum Ausdruck bringt.”\(^ {34}\)

\(^{27}\) “There is no quantum world. There is only an abstract quantum mechanical description. It is wrong to think that the task of physics is to find out how Nature is. Physics concerns what we can say about Nature.” [Bohr as quoted in\(^ {52}\)]

\(^{28}\) Bohr anticipated this observation: “Indeed the finite interaction between object and measuring agencies conditioned by the very existence of the quantum of action entails—because of the impossibility of controlling the reaction of the object on the measuring instruments if these are to serve their purpose—the necessity of a final renunciation of the classical ideal of causality and a radical revision of our attitude towards the problem of physical reality”\(^ {52}\).
criticism——, the problem can be put as follows: A source emits a system in a state

$$|\phi\rangle = \frac{|0\rangle + |1\rangle}{\sqrt{2}} \in \mathcal{H}_S.$$  

This state is then measured by an observer, called Wigner’s friend and modelled by a quantum system with Hilbert space $\mathcal{H}_F$, in the basis $\{|0\rangle, |1\rangle\}$. Finally, Wigner himself measures the joint system $\mathcal{H}_S \otimes \mathcal{H}_F$ in a basis

$$\left\{ \frac{|0\rangle_S|0\rangle_F + |1\rangle_S|1\rangle_F}{\sqrt{2}}, \frac{|0\rangle_S|0\rangle_F - |1\rangle_S|1\rangle_F}{\sqrt{2}}, \ldots \right\}.$$  

Within Everett’s relative-state formalism $Q$ of quantum mechanics, the joint system $\mathcal{H}_S \otimes \mathcal{H}_F$ after the friend’s measurement is in a state

$$V(|\phi\rangle_S) = \frac{1}{\sqrt{2}}(V(|0\rangle_S) + V(|1\rangle_S))$$

$$= \frac{1}{\sqrt{2}}(|0\rangle_S \otimes |0\rangle_F + |1\rangle_S \otimes |1\rangle_F),$$

where $V$ is the isometry modelling the measurement of the friend. Thus, Wigner’s final measurement yields the eigenvalue, corresponding to the first basis vector with probability 1.

Besides the relative-state formalism $Q$, one might consider the scenario in a formalism $Q_C$ with a “collapse.” Within $Q_C$, a system is either isolated and evolves unitarily according to the Schrödinger equation, or it interacts with its environment. A measurement is such an interaction and entails a collapse to the eigenvector associated with the measurement result. In $Q_C$, the measurement of the friend reduces to a unitary within the system under consideration by Wigner: Environment is a subjective concept, depending on what an observer considers as the system to be measured. The system associated with $\mathcal{H}_S \otimes \mathcal{H}_F$ measured by Wigner is isolated from his perspective as long as he measures the entire joint system: The friend’s “measurement” is not an interaction with the environment relative to Wigner, but an interaction within an isolated system. Thus, $Q_C$ yields predictions on the outcome of Wigner’s final measurement identical to those of $Q$.

In a third formalism with an objective collapse $Q_{OC}$, the joint system $\mathcal{H}_S \otimes \mathcal{H}_F$ collapses, after the interaction modelled by the isometry $V$ above conditioned on the obtained result. Importantly, this collapse is happening independently of the observer, not merely subjectively—that is, it has to be considered also by Wigner (similar to GRW [10]). For Wigner, who does not know the result of the friend’s measurement, the entangled state $V(|\phi\rangle)$ collapses to a mixture

$$\rho = \frac{1}{2}(|0\rangle_0\langle 0| + |1\rangle_1\langle 1|),$$  

and Wigner measures either of two first vectors in the basis above with equal probability.

So, the question is: Does a measurement within a closed system induce a collapse as modelled in $Q_{OC}$? The Wigner’s-friend setup allows to empirically test this question and distinguish $Q_{OC}$ from $Q/Q_C$.

The precise meaning of the term “measurement” is crucial in the above considerations: In $Q$, any measurement is primarily a unitary, entangling the observed system with a memory system which includes the observer into the framework. Even though a symbol in the formal language is assigned a tag “the observer’s memory,” there is no simple correspondence to an “observer” in a discourse of ordinary language surrounding an experiment. The Born rule is then applied to the memory system of the respective observer, after tracing out all other systems. In $Q_C$, the measurement is a notion relative to the system that is to be measured. Any interaction that involves a part of the environment relative to this system can be considered a measurement and induces a collapse. On the hand, a system is called isolated if there are no such interactions: Then, the evolution is a unitary operator. As long as the perception of an “isolated system” on one side and a “measurement” or “interaction with the environment” on the other are clearly separated and mutually exclusive, this is a consistent framework. Note that the friend’s measurement is not a measurement relative to Wigner.

If $Q$ and $Q_C$ were falsified in a Wigner’s-friend experiment, and we were left with $Q_{OC}$, the situation would be intricate: The relative character of the two other formalisms is lost, as there is an “objective collapse.” Then, an interaction with the environment or an associated dissipation of information is not a necessary requirement for a collapse. An isolated system would then show a non-unitary evolution. If the friend shared his result with Wigner, he would dissipate information into Wigner’s environment, and, thus, we would again be in a case consistent with $Q$ and $Q_C$. But can we establish that a measurement has happened without revealing the result? One might assume that the friend’s memory was

29 Here, we do not refer to the many-worlds interpretation of quantum mechanics. We want to emphasize not to confuse the formalism with an interpretation [15].

30 This relativity is reflected in the partial trace in $Q$, which is relative to the memory of the respective observer, and in the unitary entangling the observed system with the observers memory.
in an initial state $|\Delta\rangle$ orthogonal to both $|0\rangle$ and $|1\rangle$ and there was a unitary operator $U$ with

$$U : \mathcal{H}_M \otimes \mathcal{H}_S \to \mathcal{H}_M \otimes \mathcal{H}_S$$

$$|\Delta\rangle \otimes |k\rangle \mapsto |k\rangle \otimes |k\rangle \quad \forall k = 1, \ldots, k.$$ 

for an orthonormal basis $\{|k\rangle\}_k$. Then, a positive operator-valued measurement (POVM) could determine whether the memory was still in the initial state or not without revealing the actual result. If we were to build a consistent theory, then any other unitary of the same form as $U$ should induce a collapse. With this, quantum mechanics as we know it would eventually—collapse.

In conclusion, the meaning of “measurement” is crucial to both $Q$ and $Q_C$: Different uses of the term—formal ones on the level of the theory, ordinary ones, different relative ones—are not to be simply equated. The measurement as an account of observation—and thus of experience—does not have a direct correspondence to symbols in a formal language: The measurement problem is a semantic confusion.

VI. CONCLUSION

Leibniz’ reservation against space-time forming a fixed stage has its linguistic analogue: Wittgenstein’s observation on the intricate and circular dependency of meaning and experience lead him to conclude that meaning derives from the use of language. These considerations on the plasticity of language have been extended by, e.g., Quine’s arguments for semantic holism or Putnam’s reflections on reference and representation, and lead, eventually, to doubting the existence of a privileged language—a “semantic stage”—for accounts of experience: Meaning arises along the discourse, not prior to it. There is, consequently, no objective language to exhaustively represent an observer’s account of experience: The observer is external to the formal language of any physical theory.

There are different, incommensurable linguistic contexts. Associations across these contexts—for instance, “observer” reduced to “system” or “measurement” as sensory perception reduced to “measurement” as part of a formalism—are light-footed extensions of the terms’ use in physics. In the face of the intricate relation between language and experience, as well as the normative authority of experience, it is debatable to “interchangeably use the words ‘experience’, ‘observation,’ and ‘state of the observer’” [11]. If an observer is measured, one can say something—but not necessarily reproduce his account of sensory evidence.

In summary: If semantic reductionism has limits, then so does scientific reductionism. It is in the context of the measurement problem and issues of self-reference that one runs into these limits.

In light of the absence of an underlying privileged language, Feyerabend’s call for a diversity of theories gets underlined.

Physics is to shape meaning—not consume it.

Appendix A: Maudlin’s reading

Maudlin in [1] reads the measurement problem as the inconsistency of the following three “claims”:

1.A The wave-function of a system is complete, i.e., the wave function specifies (directly or indirectly) all the physical properties of a system.

1.B The wave-function always evolves in accord with a linear dynamical equation (e.g., the Schrödinger equation).

1.C Measurements of, e.g., the spin of an electron always (or at least usually) have determinate outcomes, i.e., at the end of the measurement the measuring device is either in a state which indicates spin up (and not down) or down (and not up).

To show the inconsistency, Maudlin considers, in addition to a two-dimensional observed system, a measurement apparatus. The argument is then: By linearity, the apparatus should be in a superposition of its pointer states “up” and “down” if the measured system is in a superposition with respect to the measurement basis (by 1.A and 1.B). According to 1.C, on the contrary, the pointer of the apparatus should be exclusively in a state “up” or “down.”

31 Wigner already remarked on the imprecise use of terms: “Most importantly, he [the quantum theorist] has appropriated the word ‘measurement’ and used it to characterize a special type of interaction by means of which information can be obtained on the state of a definite object. […] On the other hand, since he is unable to follow the path of the information until it enters his, or the observer’s, mind, he considers the measurement completed as soon as a statistical relation has been established between the quantity to be measured and the state of some idealized apparatus. He would do well to emphasize his rather specialized use of the word ‘measurement’” [2].

32 The debate about a fundamental absolute space-time appears in a new light if Reichenbach’s principle is confronted with Bell non-locality, supporting the scepticism often attributed to Leibniz and not shared by many physicists throughout history—most notably Mach.
The commitment to the above “claims” can, however, be questioned as discussed below. Thus, for running into Maudlin’s contradiction, one has to take a specific stance, namely assuming the sufficient representation of accounts by formal symbols possible. The resulting categorization of interpretations—by the choice of which claim to drop—is similarly subjective.

The completeness claim \[1.A\] does not specify what is to be considered a “physical property.” Is it “what can be measured”? Or “what can be assigned a symbol in the formal language of a physical theory”? It seems we are faced with similar problems as with what is to be considered a “physical system.” For the inconsistency to arise, accounts of experience are to be regarded as a “physical property.” The last claim, \[1.C\], does only state that measurements have determinate results, but it specifies these in terms of states of a measuring device. If one takes the requirement of “determinate measurement results” to be the capability to meaningfully assert “I have observed ‘up’ and not ‘down’” (or vice versa)—that is, to attribute “empirical content” to such a statement—it does not necessarily follow that the state of some apparatus is exclusively in a correspondent state “up,” or “down.” One may include an apparatus into the formal framework and assume that then, the apparatus is being measured. Assuming the interaction between the observed system and the apparatus to be an entangling unitary means that the result of a measurement of the system and the result of a measurement of the apparatus have correlated results.

In a similar manner, further apparatuses “between” the observed system and the observer, who then reports on his experience, might be included. One can even go as far as to assign a quantum state to the brain or memory of the observer—as we do above in connection with the relative-state formalism. There are, however, doubts as to whether the assigned state—or any symbol in any other formal language—exhaustively captures the meaning of an account as the one above. If one follows, e.g., Quine’s arguments on semantic holism, or Putnam’s reflections on reference, such a “representational completeness [of the wave-function]” \[1\] seems out of reach: There is then a gap for any formal language due to issues of semantics. This semantic gap is wider than what a Born rule can bridge.

The second claim, \[1.B\], states the linearity of quantum mechanics and refers to the Schrödinger equation, as an example for such an evolution. The Schrödinger equation does not hold unconditionally, but merely under the restriction to closed or isolated systems. The claim that “the traditional theory did not [...] state in clear physical terms, the conditions under which the non-linear evolution takes place” \[1\] cannot be sustained if “isolated systems” is enough of a “clear physical term.” As argued above, the distinction between closed systems and systems interacting with their environment, e.g., during a measurement, is crucial in avoiding inconsistencies.

There is yet another intricacy: If the system is isolated, then, according to the Schrödinger equation, the system evolves unitarily. A system that interacts with its environment, i.e., that is not isolated, evolves linearly according to some CPTP map. This is the case for the formalism \(Q_{OC}\) above: There is a CPTP map so that

\[V(|\varphi\rangle_S) \mapsto \rho,\]

where \(\rho\) is the density matrix in \(\mathcal{H}_\mathcal{Q}\). The divergence of the measurement probabilities for Wigner in \(Q_{OC}\) from the ones in \(Q\) and \(Q_C\) occurs already with a non-unitary, merely linear, evolution.

In light of the discussion in the previous chapters, a “new physics” that provides a “real solution” \[1\], maybe even a realistic solution, seems forlorn a hope.

**Appendix B: Quantum self-reference**

In \[7\], Breuer investigates problems of self-reference in quantum mechanics. The approach relies on incorporating propositions and semantics into the formal language of quantum mechanics, and thus stands in contrast to the argumentation in Section \[III\] above. Subsequently, the steps towards such an incorporation are examined in greater detail.

In a first step, the framework of propositions \(P\), corresponding to sentences about an experimental context we discuss in Section \[III\] is incorporated into \(T\).

Propositions about physical systems can be reformulated by saying “The state of the system has this and that property.” So instead of speaking of propositions, we can equally well speak about sets of states: to each proposition there corresponds the set of states for which the proposition is true. \[2\]

Propositions can be expressed in some formal language \(T^{\text{con}}\) as done in Section \[II\] As such, there is little to object to incorporating \(T^{\text{con}}\) and \(T\) into some \(T'\). The reduction of \(T^{\text{con}}\) into \(T\) is, however, problematic. Let us take \(S\) to be the set of state symbols. Then, the reduction proposed above can be regarded as a function \(f: P^{\text{con}} \to \mathcal{P}(S)\), assigning each proposition a set of states. To speak “equally well” about sets of states, we require \(f\) to be injective. The set of falsifying propositions, \(f^{-1}(\emptyset)\), has then a cardinality of one. This poses a caveat to falsifiability: If single sentences have no inherent meaning, then how can one meaningfully assert that the theory was contradicted?

One could allow for ordinary language to fill the void. This is not an option in the context of \[7\], as ordinary language is meant to be reduced to \(T\) as well.

---

33 The partial trace of an isometry \(V': |\varphi\rangle_S \mapsto |\varphi\rangle_S G\) modelling a second measurement of the friend in the same basis with a memory outside the control of Wigner, yields such a CPTP map.
So good experiments serve to at least partially constitute the semantics of physical theories. In this sense, observation is a semantic concept. [1]

In light of the circular dependency of the account of experience and semantics discussed above, observation is a semantic concept. An observation, however, is neither to be equated with an experiment nor with a formalism of “measurement” within $T$, for reasons discussed in Section [11]. Thus, the formal language of quantum mechanics is not semantically closed, as concluded in the following statement.

Tarski (1956, 1969) calls a language semantically closed if it contains (1) semantic concepts and (2) expressions referring to its own propositions. The language of a physical theory can be closed semantically: If apparatus and object system, as well as their interaction, can be described by the theory, then the semantic concept of observation can be introduced into the language of the theory. [2]

In conclusion: One may doubt whether the reduction of the linguistic context, including the observer and his account of experience, to the formalism of quantum mechanics is feasible. Consequently, an important premise for the arguments in [7] is in question.
