Abstract.

Nonlinear saturation of toroidal Alfvén eigenmode (TAE) via ion induced scatterings is investigated in the short-wavelength gyrokinetic regime. It is found that the nonlinear evolution depends on the thermal ion $\beta$ value. Here, $\beta$ is the plasma thermal to magnetic pressure ratio. Both the saturation levels and associated energetic-particle transport coefficients are derived and estimated correspondingly.
1. Introduction

In burning plasmas of next generation devices such as ITER \[1\], energetic particles (EP), e.g., fusion-alpha particles, contribute significantly to the total power density and, consequently, could drive shear Alfvén wave (SAW) instabilities \[2–6\]. SAW instabilities, in turn, can lead to enhanced EP transport, degradation of plasma performance and, possibly, damaging of plasma facing components \[7–9\]. Due to equilibrium magnetic field geometries and plasma nonuniformities, SAW instabilities manifest themselves as EP continuum modes (EPM) \[5\] and/or various discretized Alfvén eigenmodes (AE); e.g., the well-known toroidal Alfvén eigenmode (TAE) \[10\]. The EP anomalous transport rate is related to TAE amplitude and spectrum \[11\], and thus, in-depth understanding of the nonlinear dynamics of TAE is crucial for assessing the performance of future burning plasmas \[6–8\].

Most numerical investigations on TAE nonlinear dynamics focused on EP phase space dynamics induced by a single-toroidal-mode-number TAE \[12–16\]. There are some literatures on the effects of mode couplings on the TAE nonlinear dynamics \[17–25\]. Hahm et al. \[18\] studied the TAE downward spectral cascading and eventually saturation induced by nonlinear ion Compton scattering. The nonlinearly saturated spectrum and overall electromagnetic perturbation amplitude are derived, and the resulting bulk ion heating rate was also obtained in a later publication \[26\]. References \[19\] and \[20\] meanwhile, demonstrated and analyzed TAE saturation via enhanced continuum damping due to nonlinearly narrowed SAW continuum gap. The spontaneous excitation of axisymmetric zero frequency zonal structures (ZFZS) via modulational instability is investigated in Ref. \[22\] and further extended to include the important effects of resonant EPs \[24\] and the fine-scale radial structures \[25\]. Recently, a new decay channel of TAE into a geodesic acoustic mode (GAM) and a kinetic TAE (KTAE) is proposed and analyzed \[27\]. It is shown that this nonlinear decay process can lead to effective TAE saturation and thermal ion heating via GAM Landau damping; i.e., an effective $\alpha$-channeling process \[28, 29\]. All the various nonlinear processes described so far may play similar important roles in situations of practical interest, depending on the plasma parameters. This makes the analysis complicated, since the various processes must be accounted for on the same footing. Furthermore, plasma conditions in present day machines and next generation devices are different, and correspond to different dominant nonlinear processes that must be considered in practical applications. Clarifying these issues is one aim of the present work and will be addressed in the following.

The theory presented in Ref. \[18\] considered that there exists many TAEs ($O(n^2q)$), with $n$ being the characteristic toroidal mode number of most unstable TAE and $q$ the safety factor), located at different radial positions with slightly shifted frequencies due to local equilibrium parameters. Furthermore, a low-$\beta$ regime was assumed, i.e., $\beta \ll \epsilon^2$, such that, in each triad interaction, a pump TAE decay into another TAE within the toroidicity induced SAW continuum gap and an electrostatic fluctuation near the ion sound wave (ISW) frequency range. Here, $\beta$ is the plasma thermal to magnetic pressure ratio, and $\epsilon \equiv r/R_0$ is the inverse aspect ratio, with $r$ and $R_0$ being the minor and major radii of the torus. More specifically, we note that TAEs are characterized by parallel wavenumber $|k_\parallel| \approx 1/(2qR_0)$, and, thus, two counter-propagating TAEs with radially overlapped mode structures can couple and generate an ISW fluctuation with a much lower frequency and $|k_\parallel| \approx 1/(qR_0)$. As the TAEs cascades toward lower frequencies, the wave energy is, eventually, absorbed
via enhanced continuum damping near the lower SAW accumulation point. The
original theory [18] adopted the nonlinear drift kinetic approach and considered
the long wavelength MHD limit with \( \omega/\Omega_{ci} \gg k_\perp^2 \rho_i^2 \) which corresponds to
\( (T_i/T_E)/(q^2\varepsilon) \ll \omega/\Omega_{ci} \) for TAEs excited by well-circulating EPs. The corresponding
nonlinear couplings are due to the parallel ponderomotive force from the \( \mathbf{b} \cdot \mathbf{\delta J} \times \mathbf{\delta B} \)
nonlinearity. Here, \( \Omega_{ci} \) is the ion gyro-frequency, \( k_\perp \) is the perpendicular wavenumber,
\( \rho_i \) is the ion Larmor radius, \( T_E \) and \( T_i \) are the EP and bulk ion temperature, \( \mathbf{b} \) is
the unit vector along the equilibrium magnetic field, and \( \mathbf{\delta J} \) and \( \mathbf{\delta B} \) are the perturbed
TAE current and magnetic field, respectively. In next generation devices and plasmas
of fusion interest, however, plasma parameters are such that the short wavelength
\( k_\perp^2 \rho_i^2 > \omega/\Omega_{ci} \) regime applies [6, 30], and, one needs, instead, to adopt the nonlinear
gyrokinetic approach [30]. This consideration is the primary motivation for the present
analysis.

In the present work, we generalize the drift-kinetic theory of TAE saturation
via ion induced scattering [18] to the fusion plasma relevant short wavelength regime
using nonlinear gyrokinetic theory [31]. Both low- and high- \( \beta \) regimes are considered.
In the lower \( \beta \) limit, our analysis, following closely that of Ref. [18] shows that in
the gyrokinetic regime, the nonlinear coupling coefficients are much bigger than those
predicted in Ref. [18]. As a consequence, our theory predicts lower levels of TAE
saturation and EP transport. In the higher-\( \beta \) limit, since the nonlinear coupling
is maximized for ISW frequency larger than the TAE frequency mismatch with the
SAW continuum, the physics picture becomes different. That is, the TAE decays
directly into an ISW fluctuation and a propagating lower kinetic TAE (LKTAE) [32].

\[ \delta \phi = \delta \phi_0 + \delta \phi_1 + \delta \phi_S, \]
\[ \delta \psi \equiv \mathbf{\omega} \cdot \mathbf{\delta A}_\parallel / (c k_\parallel) \]

The rest of the paper is organized as follows. In Sec. 2 the theoretical model is
given, which is then used to derive the nonlinear parametric dispersion relation in Sec. 3
The nonlinear TAE spectrum evolution and the saturation level in the lower-\( \beta \) limit
are derived in Sec. 4.1. The TAE saturation level in the higher-\( \beta \) limit, meanwhile, is
derived in Sec. 4.2. Corresponding EP transport rates in both regimes are evaluated
in Sec. 5 based on the quasilinear approach. Finally, a conclusion is given in Sec. 6.

2. Theoretical model

To investigate the nonlinear TAE spectrum evolution, we adopt the standard nonlinear
perturbation theory, and consider a toroidal Alfvén mode (TAM) \( \Omega_0 = (\omega_0, \mathbf{k}_0) \)
interacting with another TAM \( \Omega_1 = (\omega_1, \mathbf{k}_1) \) and generating an ISW fluctuation
\( \Omega_S = (\omega_S, \mathbf{k}_S) \). Here, TAMs represent SAW instabilities in the TAE frequency range,
strongly affected by toroidal effects [32][33], including TAE, KTAE, as well as EPM.
Thus, the nonlinear equations derived in Sec. 3 can be applied to both TAE spectral
energy transfer in the lower-\( \beta \) limit, where \( \Omega_0 \) and \( \Omega_1 \) correspond, respectively, to test and
background TAEs; and TAE decaying into LKTAE in the higher-\( \beta \) limit, where
\( \Omega_1 \) and \( \Omega_0 \) correspond, respectively, to the pump TAE and LKTAE sideband\( \S \). The scalar potential \( \delta \phi \) and parallel vector potential \( \delta \mathbf{A}_\parallel \) are used as the field variables,
and one has, \( \delta \phi = \delta \phi_0 + \delta \phi_1 + \delta \phi_S \), with the subscripts 0, 1 and S denoting \( \Omega_0 \), \( \Omega_1 \) and
\( \Omega_S \), respectively. Furthermore, \( \delta \psi \equiv \mathbf{\omega} \cdot \mathbf{\delta A}_\parallel / (c k_\parallel) \) is introduced as an alternative field

\[ \S \] To be more precise, \( \omega/\Omega_{ci} \gg k_\perp \rho_i^2 \), as we shown in Sec. 3.3.

\[ \S \] Note that, in this work, \( \Omega_1 \) and \( \Omega_0 \) correspond to the pump and sideband waves, contrary to usual
notations.
variable, and one has \( \delta \psi = \delta \phi \) in the ideal MHD limit. Without loss of generality, \( \Omega_0 = \Omega_1 + \Omega_2 \) is adopted as the frequency/wavenumber matching condition. For effective spectral transfer by ion induced scattering, we have \( |\omega_0| \sim O(v_{\text{id}}/qR_0) \); i.e., the ISW fluctuation frequency is comparable to thermal ion transit frequency. Therefore, \( \Omega_0 \) and \( \Omega_1 \) are counter-propagating TAMs, with \( \omega_0 \simeq \omega_1 \) and \( k_{\|,0} \simeq -k_{\|,1} \). Here, \( k \equiv (nq - m)/(qR_0) \) is the wavenumber parallel to equilibrium magnetic field.

For high-\( n \) TAMs, we adopt the following ballooning mode representation in the \((r, \theta, \phi)\) field-aligned flux coordinates [34]:

\[
\delta \phi_0 = A_0 e^{i(n_0 \phi - m_0 \theta - \omega t)} \sum_j e^{-ij \theta} \Phi_0(x - j) + c.c.,
\]

\[
\delta \phi_1 = A_1 e^{i(n_1 \phi - m_1 \theta - \omega t)} \sum_j e^{-ij \theta} \Phi_1(x - j + \delta_1) + c.c..
\]

Here, \( m = \hat{m} + j \) with \( \hat{m} \) being the reference poloidal mode number, \( x = n_0q - \hat{m}_0 \simeq n_0q(r_0)(r - r_0) \), \( r_0 \) is the TAE localization position with \( |n_0q(r_0) - \hat{m}_0| \simeq 1/2 \), \( \Phi \) is the fine radial structure associated with \( k_1 \) and magnetic shear, \( \delta_1 \equiv (n_1 - n_0)q + \hat{m}_0 - \hat{m}_1 \mp 1 \) is a small normalized radial shift accounting for possible misalignment of TAM radial mode structure and \( A \) is the mode amplitude. The ISW \( \Omega_S \), on the other hand, can be written as

\[
\delta \phi_S = A_S e^{i(n_S \phi - m_S \theta - \omega t)} \Phi_S.
\]

\( \Phi_S \) is determined by \( \Phi_0 \) and \( \Phi_1 \) [34]. Noting that, for ISM, the corresponding typical distance between mode rational surfaces is much wider than that of TAEs, i.e., \( 1/|n_Sq'(r_S)| \gg 1/|n_0q'(r_0)|, 1/|n_1q'(r_1)| \) as noted earlier \( n_S \ll n_0, n_1 \), we typically have \( |n_Sq(r_S) - m_S| \simeq 1 \) and \( |\delta_1| \ll 1 \).

The governing equations describing the nonlinear interactions among \( \Omega_0, \Omega_1 \) and \( \Omega_S \), can then be derived from quasi-neutrality condition

\[
\frac{n_0 e^2}{T_i} \left( 1 + \frac{T_i}{T_e} \right) \delta \phi_k = \sum_s \langle q J_k \delta H_k \rangle_s, \quad (1)
\]

and nonlinear gyrokinetic vorticity equation

\[
\frac{\rho^2}{4 \pi \omega_k^2} \frac{\partial}{\partial l} \frac{k^2}{B} \frac{\partial}{\partial \theta} \delta \psi_k + \frac{\rho^2}{T_i} \langle (1 - J_k^2) F_0 \rangle \delta \phi_k - \sum_s \left\langle \frac{q}{\omega_k} J_{k,\omega_d} \delta H_k \right\rangle_s
\]

\[
= -i \frac{\rho}{B_0 \omega_k} \sum_{k = k + k'} \hat{B} \cdot k' \times k' \left[ \frac{\rho^2}{4 \pi \omega_k^2} \frac{\partial}{\partial k'_{\perp}} \frac{\partial}{\partial k_{\perp}} \delta \psi_k \frac{\partial}{\partial \psi_{k'}} \frac{\partial}{\partial k''_{\perp}} \delta \psi_{k''} \right. \right. 
\]

\[
\left. \left. + \langle c(J_k J_{k'} - J_{k'} J_k) \delta \mathcal{L}_k \delta \mathcal{H}_{k'} \rangle \right\rangle . \quad (2)
\]

Here, \( J_k \equiv J_0(k_{\perp} \rho) \) with \( J_0 \) being the Bessel function of zero index, \( \rho = v_\perp/\Omega_e \), \( \Omega_e \) is the cyclotron frequency, \( F_0 \) is the equilibrium particle distribution function, \( \sum_s \) is the summation on different particle species, \( \omega_d = (v_{\perp}^2 + 2v_{\parallel}^2)/(2\Omega_e R_0) \), \( k_{\perp} \sin \theta + k_{\parallel} \cos \theta \) is the magnetic drift frequency, \( l \) is the length along the equilibrium magnetic field line, \( \delta \mathcal{L}_k \equiv \delta \phi_k - k_{\|} v_{\|} \delta \psi_k/\omega_k \), and other notations are standard. The dominant nonlinear terms in the vorticity equation are Maxwell and Reynolds stresses; i.e., the first and

|| The \( \mp \) sign is to be chosen according to the leading order value of \((n_1 - n_0)q + \hat{m}_0 - \hat{m}_1 \) being \( \pm 1 \) according to the parallel wave number matching condition.
second terms on the right hand side of equation (2), respectively. Furthermore, \langle \cdots \rangle indicates velocity space integration and \delta H is the nonadiabatic particle response, which can be derived from nonlinear gyrokinetic equation [31]:

\[
\left( -i\omega + v_{\parallel} \partial_t + i\omega_d \right) \delta H_k = -i\omega_k \frac{q}{m} QF_0 J_k \delta L_k \\
- \frac{e}{B_0} \sum_{k = k' + k''} \mathbf{b} \cdot k'' \times k' J_{k'} \delta L_{k'} \delta H_{k''}.
\] (3)

Here, \( QF_0 = (\omega \partial - \omega_s) F_0 \) with \( E = \frac{v^2}{2} \), \( \omega_s F_0 = \mathbf{k} \cdot \mathbf{b} \times \nabla F_0 / \Omega_c \) is related to the expansion free energy. In this work, we assume that the TAE drive is from EPs while neglect the pressure gradient of bulk plasmas. On the other hand, for EPs we assume \( QF_{0,E} \approx -\omega_s E F_{0,E} \) for EP drive strong enough to drive TAE unstable [36].

3. Parametric decay instability

In this section, the equations describing the nonlinear evolution of \( \Omega_0 \) due to interactions with \( \Omega_1 \) are derived. They are very closely related to those of Ref. [30] for parametric decay of KAWs in uniform plasmas, with differences due to the peculiar features associated with the toroidal geometry. The derivation follows the standard procedure of a nonlinear perturbation theory. At the leading order, linear particle responses to TAMs and ISW are derived, which are then used at the next order in the small amplitude expansion to derive the nonlinear equations describing ion sound mode generation by beating of \( \Omega_0 \) and \( \Omega_1 \). Finally, the equations describing nonlinear evolution of \( \Omega_0 \) due to the \( \Omega_S \) and \( \Omega_i \) coupling is derived.

Separating \( \delta H_{k,s} = \delta H_{k,s}^L + \delta H_{k,s}^NL \), the linear particle responses to the electrostatic ISW can be derived noting the \( \omega_s \sim O(v_i/(qR_0)) \) ordering for effective ion induced scattering. One obtains

\[
\delta H_{L,e}^S = 0, \tag{4}
\]

\[
\delta H_{L,i}^S = e T_e F_0 \frac{\omega_S}{\omega_S - k_{\parallel,S} v_{\parallel}} J_S \delta \phi_S. \tag{5}
\]

Small magnetic drift orbit width ordering (\( |\omega_{d,e}| \ll |v_i/(qR_0)| \)) and \( |\omega_{s,S}| \ll |\omega_S| \) are also used here. Linear particle responses to the high-\( n \) TAMs can also be derived noting the \( k_{\parallel,T} v_{Te} \gg \omega_T \gg k_{\parallel,T} v_i \gg \omega_{d,i,\omega_d,e} \) ordering. At the leading order one obtains

\[
\delta H_{L,e}^T = - e T_e F_0 \delta \psi_T, \tag{6}
\]

\[
\delta H_{L,i}^T = e T_i F_0 J_T \delta \phi_T. \tag{7}
\]

Equations (4) to (7) are used below in the nonlinear analysis at the next order in the small amplitude expansion.

3.1. Nonlinear ion sound wave fluctuation generation

The predominantly electrostatic ISW fluctuation generation can be derived from quasi-neutrality condition, with the nonlinear particle responses derived from nonlinear

More precisely, the Reynolds stress is recovered from the long wavelength limit of the second term on the right hand side of equation [2] [6].
gyrokinetic equation. For electrons with \( k_{||,S} v_e \gg \omega_S, \omega_{d,S} \), the nonlinear gyrokinetic equation becomes

\[
v_{||} \partial_t \delta H_{S,e}^{NL} = - \frac{e}{B_0} \sum \left( \hat{b} \cdot \mathbf{k}' \times \mathbf{k}' \hat{L}_k \delta H_{S,e} \right) = - \frac{\check{\Lambda}}{T_e} F_0 v_{||} \left( \frac{k_{||,1} v_{||}}{\omega_{1,\tau}} - k_{||,0} \right) \delta \phi_0 \delta \psi_1 \cdot,
\]

with \( \check{\Lambda} \equiv (e/B_0) \hat{b} \cdot \mathbf{k}_0 \times \mathbf{k}_1 \cdot \), and the superscript “\(*\)” in the subscripts denoting the corresponding quantity of the complex conjugate component. Noting that \( \omega_{1,\tau} \approx -\omega_0 \), \( k_{||,1,\tau} \approx k_{||,0} \), and that \( k_{||,S} \approx 2k_{||,0} \), one then has

\[
\delta H_{S,e}^{NL} = - \frac{\check{\Lambda}}{\omega_0 T_e} F_0 \delta \psi_0 \delta \psi_1 \cdot.
\]

Nonlinear ion response to \( \Omega_S \), on the other hand, can be derived, noting the \( \omega_S \approx k_{||,S} v_{i\tau} \gg \omega_{d,S} \) ordering

\[
\delta H_{S,i}^{NL} = - \frac{\check{\Lambda}}{\omega_0 T_i} F_0 \frac{k_{||,S} v_{||}}{\omega_S - k_{||,S} v_{||}} J_0 J_1 \delta \phi_0 \delta \phi_1 \cdot.
\]

Substituting \( \delta H_{S,i} \) and \( \delta H_{S,e} \) into quasi-neutrality condition, one then obtains the nonlinear \( \Omega_S \) equation

\[
\partial_t \delta \phi_S = i \frac{\check{\Lambda}}{\omega_0} \beta_1 \delta \phi_0 \delta \phi_1 \cdot.
\]

Here, \( \check{\Lambda} \equiv 1 + \tau + \tau \Gamma_S \xi_S Z(\xi_S) \) is the linear dispersion function of \( \Omega_S \), with \( \tau \equiv T_e/T_i \), \( \Gamma_S \equiv (J_0^2 F_0/n_0) \), \( \xi_S \equiv \omega_S/(k_{||,S} v_{i\tau}) \) and \( Z(\xi_S) \) being the well known plasma dispersion function, defined as

\[
Z(\xi_S) \equiv \frac{1}{\sqrt{\pi}} \int_{-\infty}^{\infty} e^{-y^2} \frac{\xi_S}{y} dy.
\]

Furthermore, \( \beta_1 \equiv \sigma_0 \sigma_1 + \tau \check{F}_1 (1 + \xi_S Z(\xi_S)) \), with \( \check{F}_1 \equiv (J_0 J_1 \sigma_0 F_0/n_0) \), \( \sigma_k \equiv 1 + \tau - \tau \Gamma_k \), and \( \sigma_k \neq 1 \) corresponding to breaking of ideal MHD constraint and generation of finite parallel electric field by kinetic effects, which is typically not important for TAEs in the SAW continuum gap, while, on the other hand, is crucial for LKTAEs. The \( \sigma_T \)’s, with the subscript “\( T \)” denoting TAMs, are systematically kept in this paper to be consistent with the notations of Ref. [30] where the equations presented in Sec. 3 are originally derived for parametric decay of KAWs with arbitrary perpendicular wavenumber in uniform plasmas.

3.2. Nonlinear TAM equations

Nonlinear particle responses to \( \Omega_0 \), can be derived similarly. Noting that \( \Omega_S \) could be heavily ion Landau damped, the linear behavior \( \sim \delta \phi_S \) can be of the same order of the formally nonlinear response \( \sim \delta \phi_0 \delta \phi_1 \cdot \). Thus, one needs to include both linear and nonlinear responses while deriving the nonlinear particle responses to \( \Omega_0 \), which can be readily derived as \( [30] \)

\[
\delta H_{0,e}^{NL} = - \frac{\check{\Lambda}^2}{\omega_0^2} \frac{e}{T_e} F_0 \sigma_0^2 \sigma_0 |\delta \phi_1|^2 \delta \phi_0, \tag{11}
\]

\( ^{\dagger} \) Please, note the slightly different normalization used here and in Ref. [30] mostly connected with the definition of \( \Lambda \).
\[ \delta H_{0,i}^{NL} = \frac{i \hat{\Lambda} e}{\omega_0} F_0 \left[ k_{||S}\nu_l - \omega - k_{||S}\nu_l \right] J_1 J_S \delta \phi_2 \delta \phi_1 \]
\[ - i (\hat{\Lambda}/\omega_0) J_1^2 J_0 \delta \phi_1^2 \delta \phi_0. \]

Substituting equations (11) and (12) into the quasi-neutrality condition, equation (11), one has
\[ \delta \psi_0 = \left( \sigma_0 + \sigma_0^{(2)} \right) \delta \phi_0 + D_0 \delta \phi_1 \delta \phi_S, \]
in which,
\[ \sigma_0^{(2)} \equiv \hat{\Lambda}^2 \left[ - \sigma_1^2 \sigma_0 + \tau \hat{F}_2 (1 + \xi_S Z(\xi_S)) \right] |\delta \phi_1|^2 / \omega_0^2, \]
\[ D_0 \equiv i \hat{\Lambda} \hat{F}_1 [1 + \xi_S Z(\xi_S)] / \omega_0, \]
\[ \hat{F}_2 \equiv \langle J_0^2 (F_0/\nu_0) \rangle. \]

The nonlinear vorticity equation of \( \Omega_0 \), is
\[ \left[ 1 - \frac{\Gamma_0 + \alpha_0^{(2)}}{\omega_0^2} \delta \phi_0 - \frac{k_{||0}^2 V_A^2}{\omega_0^2} \delta \phi_0 \right] = \frac{D_2}{b_0} \delta \phi_1 \delta \phi_S, \]
with
\[ \alpha_0^{(2)} \equiv \hat{\Lambda}^2 \left( \hat{F}_2 - \hat{F}_1 \right) (1 + \xi_S Z(\xi_S)) |\delta \phi_1|^2, \]
\[ D_2 = - i \hat{\Lambda} \left[ \hat{F}_1 (1 + \xi_S Z(\xi_S)) - \Gamma_0 \xi_S Z(\xi_S) - \hat{\Gamma}_1 \right] / \omega_0. \]

Substituting equation (13) into equation (14), one then obtains the nonlinear eigenmode equation of \( \Omega_0 \):
\[ (\varepsilon_0 + \varepsilon_0^{NL}) \delta \phi_0 = - \left( D_2 \omega_0^2 / b_0 + k_{||0}^2 V_A^2 D_0 \right) \delta \phi_1 \delta \phi_S. \]

Here, \( \varepsilon_0 \equiv \varepsilon_T(\Omega_0) \) is the linearized wave operator of \( \Omega_0 \), with \( \varepsilon_T \) defined as \( \varepsilon_T \equiv k_{||0}^2 V_A^2 \sigma_T - (1 - \Gamma_T) \omega_T^2 / \nu_T \), and \( \varepsilon_0^{NL} \equiv - \alpha_0^{(2)} / b_0 + k_{||0}^2 V_A^2 \sigma_0^{(2)}. \) The TAM eigenmode dispersion relation can then be derived noting the \( V_A^2 \propto 1 - 2\xi_0 \cos \theta \) dependence on poloidal angle \( \theta \) with \( \xi_0 = 2(r/R_0 + \Delta') \) and \( \Delta' \) being Shafranov shift. Meanwhile, \( \sigma^{(2)} \) and \( \alpha^{(2)} \) correspond, respectively, to the contribution of nonlinear particle response to ISW on ideal MHD constraint breaking and Reynolds stress.

The right hand side of equation (15) can be simplified using the expressions of \( \varepsilon_k \) and \( \sigma_k \), and one has
\[ (\varepsilon_0 + \varepsilon_0^{NL}) \delta \phi_0 = \frac{i \omega_0 \hat{\Lambda} \beta_2}{b_0 \tau_0} \delta \phi_1 \delta \phi_S, \]
with \( \beta_2 \equiv \beta_1 / \sigma_0 - \varepsilon_S. \) Substituting equation (11) into (16), we obtain
\[ (\varepsilon_0 + \varepsilon_0^{NL}) \delta \phi_0 = \frac{\hat{\Lambda}^2 \beta_1 \beta_2}{b_0 \tau_0 \varepsilon_S} |\delta \phi_1|^2 \delta \phi_0. \]

Equation (17) describes the nonlinear evolution of \( \Omega_0 \) due to the nonlinear interactions with \( \Omega_1 \). Ion Compton scattering related to ion Landau damping of the ISW
fluctuation may play an important role for TAE saturation, and consistently, we rewrite the coefficients explicitly as functions of $\varepsilon_S$:

$$\varepsilon_0^{NL} = \frac{\hat{\Lambda}^2}{b_0} |\delta \phi_1|^2 \left( \hat{G}_1 + \hat{G}_2 \varepsilon_S \right),$$

with

$$\hat{G}_1 = (1 - \Gamma_0) \sigma_1^2 - \sigma_S \hat{G}_2,$$
$$\hat{G}_2 = \left( \hat{F}_2 - \hat{F}_1 - (1 - \Gamma_0) \tau \hat{F}_2 / \sigma_0 \right) / (\tau \Gamma_S).$$

On the other hand,

$$\frac{\beta_1 \beta_2}{\tau \varepsilon_S} = \hat{H}_1 + \hat{H}_2 \varepsilon_S + \hat{H}_3 \varepsilon_S,$$

with

$$\hat{H}_1 = \left( \sigma_0 \sigma_1 - \hat{F}_1 \sigma_S / \Gamma_S \right) \left( 2 \hat{F}_1 / \Gamma_S - \sigma_0 \right) / (\tau \sigma_0),$$
$$\hat{H}_2 = \hat{F}_1 \left( \hat{F}_1 / \Gamma_S - \sigma_0 \right) / (\tau \sigma_0 \Gamma_S),$$
$$\hat{H}_3 = \left( \sigma_0 \sigma_1 - \hat{F}_1 \sigma_S / \Gamma_S \right)^2 / (\tau \sigma_0).$$

The nonlinear $\Omega_0$ eigenmode dispersion relation, can then be derived, by multiplying both sides of equation (17) with $\Phi_0^\ast$, noting that $\varepsilon_S$ varies much slower than $|\Phi_0|^2$ and $|\Phi_1|^2$ in radial direction, and averaging over the radial length $1/(n_0 q') \ll \delta \ll 1/(n_S q')$. One then has

$$\left( \hat{\varepsilon}_0 - \Delta_0 |A_1|^2 - \chi_0 \varepsilon_S |A_1|^2 \right) \Delta_0 = -\hat{C}_0 |A_1|^2 A_0,$$  \hspace{1cm} (18)

in which, $\hat{\varepsilon}_0$ is the linear $\Omega_0$ eigenmode dispersion relation, defined as $\hat{\varepsilon}_0 = \int |\Phi_0|^2 \varepsilon_0 dr$. The coefficients, $\Delta_0$, $\chi_0$ and $\hat{C}_0$, corresponding respectively to nonlinear frequency shift, ion Compton scattering and shielded-ion scattering, are given as

$$\Delta_0 = \langle \langle \hat{\Lambda}^2 (\hat{G}_1 - \hat{H}_1) / b_0 \rangle \rangle,$$
$$\chi_0 = \langle \langle \hat{\Lambda}^2 (\hat{G}_2 - \hat{H}_2) / b_0 \rangle \rangle,$$
$$\hat{C}_0 = \langle \langle \hat{\Lambda}^2 \hat{H}_3 / b_0 \rangle \rangle,$$

with

$$\langle \langle \cdots \rangle \rangle = \int (\cdots) |\Phi_0|^2 |\Phi_1|^2 dr$$  \hspace{1cm} (22)

accounting for the contribution of TAE fine scale mode structures. Note that, because of this, equation (22) takes into account the selection rule on mode numbers that can be most effectively coupled via $\delta_1$; that is, the small normalized radial shift that accounts for the possible misalignment of TAM pump and decay modes. The one-to-one correspondence to $\Delta_0^{(2)}$, $\chi_0^{(2)}$ and $C_0$ of Ref. 30 are straightforward. $\chi_0$ can be further simplified, and yields

$$\chi_0 = \langle \langle \hat{\Lambda}^2 \left( \hat{F}_2 - \hat{F}_1^2 / \Gamma_S \right) / (\tau b_0 \sigma_0 \Gamma_S) \rangle \rangle,$$  \hspace{1cm} (23)

which is positive definite from Schwartz inequality [30].
3.3. Parametric decay instability

Equation (18) can be considered as the equation describing nonlinear parametric decay of a pump TAE $\Omega_1$ into TAE/LKTAE $\Omega_0$ and ISW $\Omega_S$ daughter waves $[30, 38]$, and we immediately obtain the nonlinear parametric dispersion relation

$$\left( \hat{E}_0 - \Delta_0 |A_1|^2 - \chi_0 \hat{E}_{S} |A_1|^2 \right) = -\frac{\hat{C}_0}{\hat{E}_S} |A_1|^2, \quad (24)$$

which can be solved for the condition of $\Omega_1$ spontaneous decay. The low- and high-$\beta$ regimes, will be discussed, respectively, in sections 3.3.1 and 3.3.2.

3.3.1. Low-$\beta$ limit: ion Compton scattering induced TAE cascading  

In the low-$\beta$ ($\beta \ll \epsilon^2$) limit, equation (24) describes the pump TAE ($\Omega_1$) decay into a sideband TAE ($\Omega_0$) in the SAW continuum gap and an ISW ($\Omega_S$), as shown in Fig. 1. Since $\Omega_S$ could be heavily ion Landau damped, depending on plasma parameters such as $\tau$, two parameter regimes with distinct decay mechanisms shall be discussed separately.

For typical tokamak parameters with $\tau \sim O(1)$, $\Omega_S$ is heavily ion Landau damped, and becomes a quasi-mode. One obtains, from the imaginary part of equation (24),

$$\gamma + \gamma_0 = \frac{|A_1|^2}{\partial_{\omega_0} \hat{E}_{0,R}} \left( \frac{\hat{C}_0}{|E_S|^2} + \chi_0 \right) \hat{E}_{S,I}. \quad (25)$$

In deriving equation (25), $\hat{E}_0 \simeq i(\gamma + \gamma_0)\partial_{\omega_0} \hat{E}_{0,R}$ expansion is taken, with $\gamma_0 \equiv -\hat{E}_{0,I}/\partial_{\omega_0} \hat{E}_{0,R}$ being the damping rates of $\Omega_0$, and the subscript “R” and “I” denoting real and imaginary parts. The two terms on the right hand side of equation (25) correspond to, respectively, the shielded-ion and nonlinear ion Compton scatterings, and $\hat{E}_{S,I}$ is the imaginary part of $\Omega_S$ dispersion function. Noting that $\hat{C}_0$ and $\chi_0$ are both positive definite, and that $\hat{E}_{S,I} = \sqrt{\pi} \tau \Gamma S \xi_S \exp(-\xi_S^2)$ with $\xi_S = (\omega_0 - \omega_1)/(|k_{||} v_{it}|)$, we then have, the parametric instability $\gamma > 0$ requires $\omega_1 > \omega_0$, i.e., the parametric decay can spontaneously occur only when the pump TAE frequency is higher than that of the sideband. Thus, the parametric decay
process leads to, power transfer from higher to lower frequency part of the spectrum, i.e., downward spectrum cascading [18, 30]. The threshold condition, is again, given by \( \gamma = 0 \) for nonlinear drive via ion induced scattering to overcome \( \Omega_0 \) dissipation.

For \( \tau \gg 1 \), on the other hand, \( \Omega_S \) is weakly damped, and both \( \Omega_S \) and \( \Omega_0 \) are normal modes of the system. Consequently the higher order term \( \Delta_0 \) and \( \chi_0 \) can be neglected. The resonant decay process can be analyzed following the standard approach, and will be neglected here.

### 3.3.2. High-\( \beta \) limit: TAE decay into LKTAE

In the high-\( \beta \) (\( \beta \geq \epsilon^2 \)) limit, the sideband \( \Omega_0 \) is a propagating LKTAE in the lower continuum, as shown in Fig. 2. Equations (10) and (16) can be directly applied here, while noting that \( \hat{E}_0 \) in equation (16) is now the LKTAE eigenmode dispersion relation, which can be written as [32,39]

\[
\bar{\hat{E}}_0 \delta \phi_0 = -\frac{\pi k_0^2 \rho_i^2 \omega_A^2}{2^{2\xi+1} b_0 \Gamma^2 (\xi + 1/2)} \left[ \frac{2\sqrt{2}\Gamma(\xi + 1/2)}{\delta \Gamma(\xi)} + \delta W_f \right],
\]

with the bar (\( \bar{\cdot} \)) denoting high-\( \beta \) limit. Furthermore, \( \Gamma(\xi) \) and \( \Gamma(\xi + 1/2) \) are Euler gamma functions, \( \xi \equiv 1/4 - \Gamma_+ \Gamma_-/(4\sqrt{\Gamma_- s^2 \rho_K^2}) \), \( \Gamma_+ \equiv \omega^2/\omega_A^2 (1 \pm \varepsilon_0) - 1/4 \), \( \omega_A^2 \equiv V_F^2/(q^2 R_0^2) \), \( \delta \equiv 1/(2\sqrt{\Gamma_- s^2 \rho_K^2}) \), \( s \equiv r \delta r/q \) is the magnetic shear, \( \delta W_f \) playing the role of a potential energy, and \( \rho_K^2 \equiv (k_0^2 \rho_i^2/2) [3/4 + \tau(1 - i\delta_0)] \) denotes kinetic effects associated with finite ion Larmor radii and electron Landau damping.

Note that, ISW frequency is higher for \( T_e \gg T_i \) and in this “high-\( \beta \) limit”, resonant decay into weakly ion Landau damped ISW is preferred. Neglecting higher order terms associated with \( \Omega_S \), equations (10) and (16) can be simplified as:

\[
\tilde{\delta}_{S} \delta \phi_S = \frac{\Lambda}{\omega_0} \sigma_0 \sigma_1 \delta \phi_0 \delta \phi_1^*,
\]

\[
\tilde{\delta}_0 \delta \phi_0 = \frac{\omega_0 \Lambda}{b_0} (\Gamma_S - \Gamma_1) \delta \phi_1 \delta \phi_S.
\]

The parametric dispersion relation for a pump TAE (\( \Omega_1 \)) decaying into an ISW (\( \Omega_S \)) and an LKTAE (\( \Omega_0 \)) is then

\[
\tilde{\delta}_S \tilde{\delta}_0 = -\langle \sigma_0 \sigma_1 \Lambda^2 (\Gamma_S - \Gamma_1)/b_0 \rangle |A_1|^2,
\]
which can be solved following the standard procedure of resonant decay instabilities, and yields:

\[
(\gamma + \gamma_0)(\gamma + \gamma_S) = \frac{\langle (\sigma_0 \sigma_1 \lambda^2 (\Gamma_S - \Gamma_1)/b_0) \rangle |A_1|^2}{\partial_{\omega_0} \delta_{0,R} \partial_{\omega_S} \delta_{S,R}}.
\] (29)

Note that short radial scale averaging in equation (29) introduces selection rules for the decay mode number, similar to the discussion following equation (22) above.

4. TAE nonlinear saturation due to ion induced scattering

As discussed in Sec. 3.3, spontaneous power transfer from \(\Omega_1\) to \(\Omega_0\) leads to the TAE scattering to the lower frequency fluctuation spectrum in the low-\(\beta\) limit, and to LKTAE in the high-\(\beta\) limit. In both cases, nonlinear saturation of the TAE fluctuation spectrum is eventually achieved. The TAE nonlinear saturation process and the resulting saturation level in low- and high-\(\beta\) limit, are analyzed in sections 4.1 and 4.2.

4.1. Low-\(\beta\) limit: spectral transfer due to ion induced scattering

In a realistic burning plasma with typical toroidal mode number \(n \geq O(10)\) and finite \(q\), many \((\sim O(n^2q))\) TAEs are excited by EPs with comparable linear growth rate [40]. Each TAE, can thus, interact with the turbulence “bath” of background TAEs, leading to nonlinear saturation and spectrum transfer, as illustrated in Fig. 3 and discussed in Ref. [18]. In the rest of section 4.1 we will investigate the TAE spectrum evolution, following closely the analysis of Ref. [18]. The wave kinetic equation describing the spectrum evolution is derived in section 4.1.1 which is then solved in section 4.1.2 for the saturated spectrum and overall magnetic perturbation amplitude.

4.1.1. Nonlinear wave-kinetic equation for TAE spectrum evolution

The above discussed nonlinear TAE spectral transfer, can be described by wave kinetic equation. Equation (18) describing the test TAE \(\Omega_0\) interacting with a background TAE \(\Omega_1\), can be generalized as

\[
\hat{E}_{k_1} A_{k_1} = \sum_{k_1} \left( \Delta_0 + \chi_0 \delta_S - \hat{C}_0 \delta_S \right) |A_{k_1}|^2 A_{k_1},
\] (30)

with the subscript “\(k_1\)” denoting background TAEs, and the summation over \(k_1\) denoting all the background TAEs within strong interaction region, i.e., counter-propagating and radially overlapping with \(\Omega_k\), and the frequency difference \(|\omega_k - \omega_{k_1}|\) comparable with ion transit frequency \((|v_i/(qR_0)|)\). In equation (30), the \(k\) subscript denotes a generic test TAE, and \(\sum_{k_1}\) runs on all background modes, including \(k\) itself. Furthermore, consistent with equation (25), we have neglected the nonlinear frequency shift. Multiplying equation (30) by \(A_{k_1}\), and taking the imaginary part, we then obtain the wave kinetic equation describing TAE nonlinear evolution due to interaction with turbulence bath of TAEs:

\[
(\partial_t - 2\gamma_{L,k}) I_k = \frac{2}{\partial_{\omega_k} \delta_{k,R} \partial_{\omega_S} \delta_{S,R}} \sum_{k_1} \frac{1}{k_{1z}^2} \left( \frac{\hat{C}}{|\delta_S|^2} + \chi_0 \right) \delta_{S,i} I_{k_1} I_k,
\] (31)
with $I_k \equiv |\nabla A_k|^2$ and $\gamma_{L,k} \equiv -\hat{E}_{k,I}/(\partial_\omega \hat{E}_{k,R})$ being the linear growth/damping rate of $\Omega_k$.

Denoting TAEs with their eigenfrequencies, i.e., $I_k \to I_\omega$, the summation over “$k_1$” can be replaced by integration over “$\omega$”, given many background TAEs within the strong interaction range with $\Omega_\omega$ (continuum limit):

$$(\partial_t - 2\gamma_L(\omega)) I_\omega = \frac{2}{\partial_\omega \hat{E}_{\omega,R}} \int_{\omega_L}^{\omega_M} d\omega' V(\omega, \omega') I_{\omega'} I_\omega,$$

with $I_\omega = \sum_k I_k \delta(\omega' - \omega_k)$ being the continuum version of $I_k$, $\omega_M$ being the highest frequency for TAE to be linearly unstable, $\omega_L$ being the lowest frequency for $I_{\omega_L} > 0$ as shown in Fig. 3 and one has $\omega_M - \omega_L \simeq O(\epsilon)\omega_T$, comparable with the TAE gap width. Furthermore $\omega_L$ is linearly stable, and is driven nonlinearly. On the other hand, the integration kernel $V(\omega, \omega')$ is defined as

$$V(\omega, \omega') \equiv \frac{1}{k_{\perp,\omega'}^2} \left( \frac{\hat{C}}{|\phi_S|^2} + \chi_0 \right) \hat{E}_{S,i}.$$

### 4.1.2. Nonlinear saturation spectrum and magnetic fluctuation level

The nonlinear saturation condition can then be obtained from $\partial_t I_\omega = 0$ as:

$$\gamma_L(\omega) = -\frac{1}{\partial_\omega \hat{E}_{\omega,R}} \int_{\omega_L}^{\omega_M} d\omega' V(\omega, \omega') I_{\omega'}.$$

Noting that, for burning plasmas with most unstable TAEs characterized by toroidal mode number $n \gtrsim O(10)$, and that $|\omega_M - \omega_L| \gg |v_i/(qR_0)|$ for the process to be important, $I_{\omega'}$ varies in $\omega'$ much slower than $V(\omega, \omega')$. Expanding $I_{\omega'} = I_\omega - \omega_S \partial_\omega I_\omega$, the integral equation then becomes a differential equation, and we have

$$\gamma_L(\omega) = -\frac{1}{\partial_\omega \hat{E}_{\omega,R}} \int_{\omega - \omega_M}^{\omega - \omega_L} d\omega S V(\omega_S) (I_\omega - \omega_S \partial_\omega I_\omega)$$

$$= -\frac{1}{\partial_\omega \hat{E}_{\omega,R}} [U_0 I_\omega - U_1 \partial_\omega I_\omega].$$

(34)
Here, \( U_0 \) and \( U_1 \) are defined as, respectively,
\[
U_0 = \int_{-\omega-M}^{-\omega-L} d\omega_S V(\omega_S), \quad (35)
\]
\[
U_1 = \int_{-\omega-M}^{-\omega-L} d\omega_S \omega_S V(\omega_S). \quad (36)
\]

For the ion Compton scattering process to be important, one requires \( \omega_M - \omega_L \gg v_{\text{th}}/(qR_0) \), which corresponds to \( \beta \ll \epsilon_r^2 \). Noting that \( V(\omega_S) \propto \delta S_i \) is an odd function of \( \omega_S \) varying on the scale of \( v_{\text{th}}/(qR_0) \), \( U_0 \) becomes vanishingly small as \( |\omega - \omega_L|, |\omega - \omega_M| \gg v_{\text{th}}/(qR_0) \). Equation (34) can then be replaced by roughly, 0 and intensity over the fluctuation population zone, and we have
\[
I_\omega \simeq \int d\omega \partial_\omega \delta_\omega, R \frac{\gamma_L(\omega)}{U_1(\omega)} \simeq I_M(\omega_M) = \frac{1}{U_1} \int_\omega^\omega M \gamma_L(\omega) \partial_\omega \delta_\omega, R d\omega, \quad (37)
\]
with \( I_M(\omega_M) \equiv I_\omega(\omega = \omega_M) \). Note that, in equation (37), we have imposed boundary condition at \( \omega = \omega_M \), and \( U_1 \) is moved out of the integration due to the fact that \( \delta S_i \parallel \omega \) and, thus, \( V(\omega_S) \) decays exponentially with \( |\omega_S| \); thus, \( U_1(\omega) \) is essentially constant under the integration sign. For \( |\omega - \omega_L|, |\omega - \omega_M| \gg v_{\text{th}}/(qR_0) \), the integral limits in equation (34) can be replaced by \( \pm \infty \), and we have
\[
U_1 \simeq \int d\omega \partial_\omega \delta_\omega, R \frac{\gamma_L(\omega)}{U_1(\omega)} \simeq \frac{\pi^{3/2}}{2k_1^2} \left( \frac{\hat{C}}{|\delta S|^2} + \chi_0 \right) k_{\|,S}^2 v_{\text{th}}^2. \quad (38)
\]
The value of \( I_\omega \) at \( \omega_M \), \( I_M(\omega_M) \), on the other hand, can be determined noting that for \( |\omega - \omega_M| \ll |k_{\|,S} v_{\text{th}}| \), the lower and upper integral limits of equations (35) and (36), can be replaced by roughly, 0 and \( \infty \), and one has
\[
U_0(\omega_M) \simeq \int d\omega_S \delta S_i, \quad U_1(\omega_M) \simeq \int d\omega_S \delta S_i, \quad (39)
\]
\[
I_M(\omega_M) \simeq \frac{1}{U_1} \left( \frac{\hat{C}}{|\delta S|^2} + \chi_0 \right) k_{\|,S}^2 v_{\text{th}}^2. \quad (40)
\]
\[
I_M(\omega_M) \simeq \frac{2k_{\|,S} v_{\text{th}} \omega_M \gamma_L(\omega_M)}{U_1} - \frac{1}{U_1} \int_0^\omega_M \gamma_L(\omega) \partial_\omega \delta_\omega, R d\omega. \quad (41)
\]
The overall TAE intensity at saturation, can be derived by integrating the intensity over the fluctuation population zone, and we have
\[
I_S \equiv \int_{-\omega_L}^{\omega_M} I_\omega d\omega \simeq \frac{\pi^{3/2}}{U_1} \int_{-\omega_L}^{\omega_M} (\omega - \omega_L) \partial_\omega \delta_\omega, R d\omega \simeq \frac{\gamma_L}{U_1} \omega_{\text{eff}}^2. \quad (42)
\]
with $\epsilon_{\text{eff}} \equiv 1 - \omega_M/\omega_L \sim O(\epsilon)$ following Ref. [18]. In deriving equation (39), we replaced the TAE linear growth rate $\gamma_L$ with its spectrum averaged value, $\gamma_L(\omega) \approx \gamma_L$, which is validated by the fact that, for burning plasma relevant parameter regimes, a broad TAE spectrum with comparable linear growth rate can be driven unstable [6, 11]. In deriving the final expression of equation (39), $\partial_\omega$ $\Omega_{\omega R} \sim -2\omega$ is used. The contribution of $I_M$ is of order $\gamma_L(\omega_M)k_{\parallel SVU}/((\omega_M - \omega)\gamma_L)$ smaller than the other term, and is neglected.

The saturation level of the magnetic fluctuations, can then be obtained, noting $|\delta B_r|^2 = |k_0 A_{\parallel}|^2 = |c k_0|/(\omega k_0)|^2 I_S$,

$$
|\delta B_r|^2 \approx \frac{e^2 e^2 \epsilon_{\text{eff}}}{2\pi^{3/2}} \frac{\omega_T \gamma_L k^2}{(C/|\delta S|^2 + \chi_0) \Omega^2 T_{\text{ci}}^2 \rho^2}
$$

(40)

with $|k_{0,T}/k_{0,r}| \approx \epsilon$ for TAEs in the inertial layer assumed. For $b \lesssim 1$, one has

$$
\dot{C}_0 \sim \chi_0 \sim \frac{e^2}{B_0^2} \tau k^2 \rho^2 b
$$

(41)

and $|\delta S| \sim O(1)$, and thus,

$$
\frac{\delta B_r}{B_0} \sim \frac{e^4 \epsilon_{\text{eff}}}{2\pi^{3/2}} \frac{\gamma_L \omega^2 T_{\text{ci}}^2}{\Omega^2 T_{\text{ci}}^2 \rho^2}.
$$

(42)

The saturation level, $\delta B_r/B_0$, is smaller than the prediction of Ref. [18] by $\epsilon(\omega/\Omega_{ci})/(k_0^2 \rho^2)$ due to the enhanced coupling in the kinetic regime [30]. Noting that, for most unstable modes driven by EPs, one has typically, $k_0 \rho_{\text{ci}} \sim O(1)$ [5], which gives $k_0^2 \rho^2 \sim (T_i/T_E)/q^2$, with $\rho_{\text{ci}} \sim (T_E/T_i)^{1/2} \rho_{\text{ci}}$, being the EP magnetic drift orbit width and $T_E$ being the characteristic EP energy. Thus, the saturation level predicted in the present work applies as $T_i/(c T_E q^2) \gg \omega/\Omega_{ci}$; while the expression given by Ref. [18] can be used in the opposite limit. The saturation level given in equation (42), can then be simplified and yield the following scaling

$$
\frac{\delta B_r}{B_0} \sim \frac{m_i}{8\pi^{3/2} e^2 \mu_0 \omega_T T_i^2} \frac{\gamma_L T_E^2}{q^2 N_0^{-1} \epsilon^6 R_0^{-2}}
$$

$$
\sim 1.2 \times 10^{15} A_m q^2 N_0^{-1} \epsilon^6 R_0^{-2} \frac{T_E^2 \gamma_L}{T_i \omega_T}.
$$

(43)

with $A_m = m_i/m_p$ being the mass ratio of thermal ion to proton, and $N_0$ being the thermal plasma density. For typical burning plasmas parameters, the saturation level can be estimated as $|\delta B_r/B_0| \sim 10^{-4} - 10^{-3}$. In obtaining the above saturation level, ITER like parameters are used, i.e., $B_0 \sim 5$ Tesla, $T_E \sim 3.5$ MeV, $T_i \sim 10$ KeV, $R_0 \sim 6$ m, $N_0 \sim 10^{20} m^{-3}$, $q \sim 3$, $\epsilon \sim 1/6 - 1/3$ and $\gamma_L/\omega_T \sim 10^{-2}$.

4.2. High-$\beta$ limit: TAE saturation via coupling to KTAE

In high-$\beta$ limit, the pump TAE decays into an ISW and a small scale LKTAE in the continuum. The resulting TAE saturation level, can be derived following the analysis of Ref. [27] where TAE decay into GAM and LKTAE is analyzed. For the simplicity of discussion, following the discussion of section 3.3.2, we assume $\Omega_S$ is weakly ion Landau damped. The equation for the feedback of $\Omega_0$ and $\Omega_S$ to the unstable pump TAE $\Omega_1$, is derived as

$$
\vec{E}_1 \delta \phi_1 = \frac{\omega}{b_1} \hat{\Lambda}(\Gamma_S - \Gamma_0) \delta \phi_0 \delta \phi_S^*.
$$

(44)

* Here, for simplicity of discussion while without loss of generality, well circulating EPs are assumed.
The magnitudes of \( \hat{\alpha} \) for simplicity of discussion, well-circulating EPs with small drift orbit (49) in both low- and high-\( \beta \) limit, can be applied to derive the ion heating rate from ion Compton scattering rate (nonlinear Landau damping) and the EP transport coefficient in the corresponding parameter regime. As an application, presented in Sec. 5 is an estimation of EP transport coefficient using quasilinear transport theory and assuming well circulating EPs with relatively small magnetic drift orbit width. The ion heating rate is not derived here, while interested readers may readily derive it following the procedure of Ref. 26 using the saturated TAE amplitude given in equations (40) and (41).

5. Consequences on EP transport

The EP transport coefficient, can be estimated from quasilinear transport theory [11]. For simplicity of discussion, well-circulating EPs with small drift orbit (\( k_0 \rho_{d,E} \lesssim 1 \)) is assumed, while a more general approach is presented in Refs. 43–45. Considering transport time scale is much longer than the characteristic EP transit time and spatial
scale is much larger than resonant EP magnetic drift orbit width, the quasilinear equation for EP equilibrium distribution function evolution is

\[
\partial_t F_{0,E} = -\frac{e}{B_0} \sum_{k = k' + k''} \mathbf{b} \cdot k'' \times k' J_k \delta L_k \delta H_{k''},
\]

with \((\cdot, \cdot)\) denoting bounce averaging, \(k = k' + k'' = k_0 \mathbf{\hat{r}}\) selecting phase space zonal structure modulations in the radial direction, and \(\delta H\) being the linear EP response to \(k''\), consistent with the quasilinear ordering. For well circulating EPs, \(\delta H_k\) can be derived by transforming into drift orbit center coordinates, and one obtains

\[
\delta H_k = -\frac{e}{m} Q_k F_0 J_k \delta L_k \sum_{l, p} J_l(\hat{\lambda}_k) J_p(\hat{\lambda}_k) e^{-i(l-p)(\theta - \theta_{\text{tr}})} \frac{J_k(\hat{\lambda}_k)}{\omega_k - k_{||} v_{||} + l \omega_{tr}},
\]

(53)

with \(\hat{\lambda}_k = k_{\perp} \hat{v}_d / \omega_{tr}\) denoting finite drift orbit width effects, and \(\theta_{\text{tr}} \equiv \tan^{-1}(k_{\perp} / k_\theta)\). Substituting equation (53) into equation (52), one then has,

\[
\partial_t F_{0,E} = i \frac{e}{B_0} \frac{e}{m} k_\theta \frac{\partial}{\partial r} \left[ \frac{1}{\omega_k - k_{||} v_{||} + l \omega_{tr}} - \frac{1}{\omega_k^* - k_{||} v_{||} + l \omega_{tr}} \right] \frac{J_k^2(\hat{\lambda}_k)}{Q_k F_0}.
\]

Noting that

\[
\left( \frac{1}{\omega_k - k_{||} v_{||} + l \omega_{tr}} - \frac{1}{\omega_k^* - k_{||} v_{||} + l \omega_{tr}} \right) = -2i \pi \delta(\omega_k - k_{||} v_{||} + l \omega_{tr})
\]

and that \(\delta L_k \simeq (1 - k_{||} v_{||} / \omega_k) \delta \phi_k\), one then has

\[
\partial_t N_{0,E} \simeq -\partial_r D_{\text{Res}} \partial_r N_{0,E}, \tag{54}
\]

with \(N_{0,E}\) being the equilibrium EP density, and the resonant EP radial diffusion rate given as

\[
D_{\text{Res}} \equiv \left\langle 2 \pi \sum_l |\delta V_{E,l,t}|^2 J_l^2(\hat{\lambda}_k) \delta(\omega - k_{||} v_{||} + l \omega_{tr}) \frac{F_0}{N_{0,E}} \right\rangle,
\]

(55)

and \(|\delta V_{E,l,t}|^2 \equiv e^2 k_0^2 J_k^2 |\delta \phi_k|^2 |2l^2 \omega_{tr}^2 / (B_0^2 \omega_{tr}^2)|\) being the resonant EP radial electric-field drift velocity. For EPs with small magnetic drift orbits, \(k_\theta \rho_{d,E} \lesssim 1\), \(l = \pm 1\) transit harmonic resonances dominate, and the EP radial transport coefficient is very similar to that describing zero frequency zonal flow generation by EP driven TAEs \([24]\) (equation (10) therein), with the underlying mechanism that zonal structures are linearly un-damped structures related to nonlinear equilibria. It is also straightforward to find out that, \(J_l^2(\hat{\lambda}_k) \delta(\omega - k_{||} v_{||} + l \omega_{tr})\) is proportional to the linear growth rate of TAE, and this reflects the fundamental property that resonant particle transport and wave-particle power transfer (resonant excitation) are intimately related \([6]\).

The circulating EP transport coefficient induced by the saturated TAE spectrum in the short wavelength \(k_0^2 \rho_{d,E}^2 / \epsilon \gg \omega / \Omega_{ci}\) limit, can be derived by substituting

\[\text{for the derivation of equation (53), interested readers may refer to Ref. [24] and references therein.}\]
equations (40) or (49) into equation (55). Noting $|\delta\phi|^2 = \omega^2 \delta B_r^2 / (c^2 k^2 V_0^2)$, one then obtains

$$D_{\text{Res}} \approx \frac{1}{4} \frac{V_A}{k_{||,0}} \left| \frac{\delta B_r}{B_0} \right|^2 .$$

(56)

In deriving the EP diffusion rate, equation (56), resonant EP transit time, $\omega_{tr,\text{Res}}^{-1}$, is taken as the de-correlation time. Substituting equation (43) into (56), one then has, the scaling law for TAE induced EP diffusion rate in the low-$\beta$ limit

$$D_{\text{Res}} \sim 1 \times 10^{31} A_m^{1/2} \epsilon^{-6} q^{-3/2} N_0^{-3/2} R_0^{-1} \frac{T_e^2}{T_i} \frac{n_i}{T_e} \omega_T .$$

(57)

For ITER-like parameters, the circulating EP diffusion rate can be estimated as $D_{\text{Res}} \sim 1 - 10^2 m^2/s$, for $\epsilon \sim 1/6 - 1/3$. Note that, this coefficient is valid for circulating particles in the lower-$\beta$ limit, as ion induced scattering is the dominant mechanism for TAE nonlinear saturation. The corresponding result for the higher-$\beta$ limit, meanwhile, can be obtained similarly from equation (56) with $\delta B_r$ given by equation (49), and one has $D_{\text{Res}} \sim 1 m^2/s$. For potential predictive applications, calibration using results from large scale simulations [47] and/or test particle simulations [48] is required, and this will be carried out in a future publication.

6. Conclusions and Discussions

In conclusion, the TAE saturation in the burning plasma related short wavelength limit ($k_0^2 \rho_i^2 / \epsilon \gg \omega / \Omega_{ci}$) is analyzed, using nonlinear gyrokinetic equation. In the low-$\beta$ limit, with $\beta \ll \epsilon^2$, a TAE may decay into another TAE with lower frequency due to ion induced scattering. The nonlinear equation describing a test TAE nonlinear evolution due to interacting with a background TAE is derived, which is then generalized to including all the background TAEs that are strongly interacting with the test TAE for burning plasmas with most unstable TAEs characterized by typically $n \gtrsim 10$ [6–8,41].

It is shown that the damping of the generated ISW due to ion induced scattering plays a key role in the nonlinear decay process, and the spontaneous decay requires that the secondary generated TAEs have a lower frequency, leading to the downward TAE spectral transfer and finally saturation due to enhanced coupling to SAW continuum. The wave kinetic equation describing TAE spectral transfer is derived from the imaginary part of the nonlinear TAE equation, which is then solved for the nonlinear saturated spectrum. In the high-$\beta$ limit, with $\beta \gg \epsilon^2$, the TAE may directly decay into a lower KTAE in the continuum, and the corresponding parametric dispersion relation as well as result TAE saturation level is also derived. The related EP transport coefficient is derived using quasilinear transport theory [11], assuming, as illustration, well circulating EPs with small drift orbits, that the transport time scale is slower than particle transit time, and that the corresponding spatial scale is longer than EP magnetic drift orbit.

For the processes discussed in this paper to occur and dominate over other mechanisms, several constraint on plasma parameters are required. First, $k_0^2 \rho_i^2 / \epsilon \gg \omega / \Omega_{ci}$ for the nonlinear coupling in the kinetic regime to dominate over that due to parallel ponderomotive force. Second, for the process discussed in Sec. 3.3.1 to occur, $\beta \ll \epsilon^2$ is required for the high frequency secondary SAW mode due to this nonlinear ion induced scattering process to be a gap TAE. This $\beta \ll \epsilon^2$ regime is also assumed for solving the wave-kinetic equation for the saturated TAE spectrum. Meanwhile,
for the process discussed in Sec. 3.3.2 to be dominant, $\beta \gg \epsilon^2$ is required for the high frequency sideband to be a LKTAE with the frequency lower than the lower accumulational point frequency of toroidicity induced gap.

As a final remark, the nonlinear ion induced scattering discussed here, has a cross-section comparable to other processes in the short wavelength limit, e.g., ZFZS generation and/or decaying into a GAM and a kinetic TAE (KTAE). Thus, the TAE saturation can be quite sensitive to the threshold condition of different channels; i.e., it depends on the considered plasma parameter regime and, typically, multiple nonlinear physics processes are responsible for it.
