Uniform Convergence of Gradients for Non-Convex Learning and Optimization

Dylan J. Foster Ayush Sekhari Karthik Sridharan
{djfoster, sekhari, sridharan}@cs.cornell.edu

Abstract

We investigate 1) the rate at which refined properties of the empirical risk—in particular, gradients—converge to their population counterparts in standard non-convex learning tasks, and 2) the consequences of this convergence for optimization. Our analysis follows the tradition of norm-based capacity control. We propose vector-valued Rademacher complexities as a simple, composable, and user-friendly tool to derive dimension-free uniform convergence bounds for gradients in non-convex learning problems. As an application of our techniques, we give a new analysis of batch gradient descent methods for non-convex generalized linear models and non-convex robust regression, showing how to use any algorithm that finds approximate stationary points to obtain optimal sample complexity, even when dimension is high or possibly infinite and multiple passes over the dataset are allowed.

Moving to non-smooth models we show—in contrast to the smooth case—that even for a single ReLU it is not possible to obtain dimension-independent convergence rates for gradients in the worst case. On the positive side, it is still possible to obtain dimension-independent rates under a new type of distributional assumption.

1 Introduction

The last decade has seen a string of empirical successes for gradient-based algorithms solving large scale non-convex machine learning problems (Krizhevsky et al., 2012; He et al., 2016). Inspired by these successes, the theory community has begun to make progress on understanding when gradient-based methods succeed for non-convex learning in certain settings of interest (Jain and Kar, 2017). The goal of the present work is to introduce learning-theoretic tools to—in a general sense—improve understanding of when and why gradient-based methods succeed for non-convex learning problems.

In a standard formulation of the non-convex statistical learning problem, we aim to solve

\[
\begin{align*}
\text{minimize} & \quad L_D(w) := \mathbb{E}_{(x,y) \sim D} \ell(w; x, y), \\
\end{align*}
\]

where \( w \in \mathcal{W} \subseteq \mathbb{R}^d \) is a parameter vector, \( D \) is an unknown probability distribution over the instance space \( \mathcal{X} \times \mathcal{Y} \), and the loss \( \ell \) is a potentially non-convex function of \( w \). The learner cannot observe \( D \) directly and instead must find a model \( \bar{w} \in \mathcal{W} \) that minimizes \( L_D \) given only access to i.i.d. samples \( (x_1, y_1), \ldots, (x_n, y_n) \sim D \). Their performance is quantified by the excess risk \( L_D(\bar{w}) - L^* \), where \( L^* = \inf_{w \in \mathcal{W}} L_D(w) \).

Given only access to samples, a standard (“sample average approximation”) approach is to attempt to minimize the empirical risk \( \bar{L}_n(w) := \frac{1}{n} \sum_{i=1}^{n} \ell(w; x_i, y_i) \). If one succeeds at minimizing \( \bar{L}_n \), classical statistical
learning theory provides a comprehensive set of tools to bound the excess risk of the procedure. The caveat is that when \( \ell \) is non-convex, global optimization of the empirical risk may be far from easy. It is not typically viable to even verify whether one is at a global minimizer of \( \tilde{L}_n \). Moreover, even if the population risk \( L_D \) has favorable properties that make it amenable to gradient-based optimization, the empirical risk may not inherit these properties due to stochasticity. In the worst case, minimizing \( L_D \) or \( \tilde{L}_n \) is simply intractable. However, recent years have seen a number of successes showing that for non-convex problems arising in machine learning, iterative optimizers can succeed both in theory and in practice (see Jain and Kar (2017) for a survey). Notably, while minimizing \( \tilde{L}_n \) might be challenging, there is an abundance of gradient methods that provably find approximate stationary points of the empirical risk, i.e. \( \| \nabla \tilde{L}_n(w) \| \leq \varepsilon \) (Nesterov, 2013; Ghadimi and Lan, 2013; Reddi et al., 2016; Allen-Zhu and Hazan, 2016; Lei et al., 2017). In view of this, the present work has two aims: First, to provide a general set of tools to prove uniform convergence results for gradients, with the goal of bounding how many samples are required to ensure that with high probability over samples, simultaneously over all \( w \in W \), \( \| \nabla L_D(w) \| \leq \| \nabla \tilde{L}_n(w) \| + \varepsilon \); Second, to explore concrete non-convex problems where one can establish that the excess risk \( L_D(\tilde{w}) - L^* \) is small a consequence of this gradient uniform convergence. Together, these two directions yield direct bounds on the convergence of non-convex gradient-based learning algorithms to low excess risk.

Our precise technical contributions are as follows:

- We bring vector-valued Rademacher complexities (Maurer, 2016) and associated vector-valued contraction principles to bear on the analysis of uniform convergence for gradients. This approach enables norm-based capacity control, meaning that the bounds are independent of dimension whenever the predictor norm and data norm are appropriately controlled. We introduce a “chain rule” for Rademacher complexity, which enables one to decompose the complexity of gradients of compositions into complexities of their components, and makes deriving dimension-independent complexity bounds for common non-convex classes quite simple.

- We establish variants of the Gradient Domination condition for the population risk in certain non-convex learning settings. The condition bounds excess risk in terms of the magnitude of gradients, and is satisfied in non-convex learning problems including generalized linear models and robust regression. As a consequence of the gradient uniform convergence bounds, we show how to use any algorithm that finds approximate stationary points for smooth functions in a black-box fashion to obtain optimal sample complexity for these models—both in high- and low-dimensional regimes. In particular, standard algorithms including gradient descent (Nesterov, 2013), SGD (Ghadimi and Lan, 2013), Non-convex SVRG (Reddi et al., 2016; Allen-Zhu and Hazan, 2016), and SCSG (Lei et al., 2017) enjoy optimal sample complexity, even when allowed to take multiple passes over the dataset.

- We show that for non-smooth losses dimension-independent uniform convergence is not possible in the worst case, but that this can be circumvented using a new type of margin assumption.

**Related Work** This work is inspired by Mei et al. (2016), who gave dimension-dependent gradient and Hessian convergence rates and optimization guarantees for the generalized linear model and robust regression setups we study. We move beyond the dimension-dependent setting by providing norm-based capacity control. Our bounds are independent of dimension whenever the predictor norm and data norm are sufficiently controlled (they work in infinite dimension in the \( \ell_2 \) case), but even when the norms are large we recover the optimal dimension-dependent rates.

Optimizing the empirical risk under assumptions on the population risk has begun to attract significant attention (e.g. Gonen and Shalev-Shwartz (2017); Jin et al. (2018)). Without attempting a complete survey,
we remark that these results typically depend on dimension, e.g. Jin et al. (2018) require \( \text{poly}(d) \) samples before their optimization guarantees take effect. We view these works as complementary to our norm-based analysis.

**Notation** For a given norm \( \| \cdot \| \), the dual norm is denoted \( \| \cdot \|_* \). \( \| \cdot \|_p \) represents the standard \( \ell_p \) norm on \( \mathbb{R}^d \) and \( \| \cdot \|_\sigma \) denotes the spectral norm. \( \mathbf{1} \) denotes the all-ones vector, with dimension made clear from context. For a function \( f : \mathbb{R}^d \to \mathbb{R} \), \( \nabla f(x) \in \mathbb{R}^d \) and \( \nabla^2 f(x) \in \mathbb{R}^{d \times d} \) will denote the gradient and the Hessian of \( f \) at \( x \) respectively. \( f \) is said to be \( L \)-Lipschitz with respect to a norm \( \| \cdot \| \) if \( |f(x) - f(y)| \leq L \| x - y \| \) \( \forall x, y \). Similarly, \( f \) is said to be \( H \)-smooth w.r.t norm \( \| \cdot \| \) if its gradients are \( H \)-Lipschitz with respect to \( \| \cdot \| \), i.e. \( \| \nabla f(x) - \nabla f(y) \|_* \leq H \| x - y \| \) for some \( H \).

## 2 Gradient Uniform Convergence: Why and How

### 2.1 Utility of Gradient Uniform Convergence: The Why

Before introducing our tools for establishing gradient uniform convergence, let us introduce a family of losses for which this convergence has immediate consequences for the design of non-convex statistical learning algorithms.

**Definition 1.** The population risk \( L_D \) satisfies the \((\alpha, \mu)\)-Gradient Domination condition with respect to a norm \( \| \cdot \| \) if there are constants \( \mu > 0, \alpha \in [1, 2] \) such that

\[
L_D(w) - L_D(w^*) \leq \mu \| \nabla L_D(w) \|_\alpha \quad \forall w \in \mathcal{W},
\]

where \( w^* \in \arg \min_{w \in \mathcal{W}} L_D(w) \) is any population risk minimizer.

The case \( \alpha = 2 \) is often referred to as the Polyak-Łojasiewicz inequality (Polyak, 1963; Karimi et al., 2016). The general GD condition implies that all critical points are global, and is itself implied (under technical restrictions) by many other well-known conditions including one-point convexity (Li and Yuan, 2017), star convexity and \( \tau \)-star convexity (Hardt et al., 2018), and so-called “regularity conditions” (Zhang et al., 2016); for more see Karimi et al. (2016). The GD condition is satisfied—sometimes locally rather than globally, and usually under distributional assumptions—by the population risk in settings including neural networks with one hidden layer (Li and Yuan, 2017), ResNets with linear activations (Hardt and Ma, 2017), phase retrieval (Zhang et al., 2016), matrix factorization (Liu et al., 2016), blind deconvolution (Li et al., 2018), and—as we show here—generalized linear models and robust regression.

The GD condition states that to optimize the population risk it suffices to find a (population) stationary point. What are the consequences of the statement for the learning problem, given that the learner only has access to the empirical risk \( \hat{L}_n \) which itself may not satisfy GD? The next proposition shows, via gradient uniform convergence, that GD is immediately useful for non-convex learning even when it is only satisfied at the population level.

**Proposition 1.** Suppose that \( L_D \) satisfies the \((\alpha, \mu)\)-GD condition. Then, for any \( \delta > 0 \), with probability at least \( 1 - \delta \) over the draw of the data \( \{(x_t, y_t)\}_{t=1}^n \), every algorithm \( \hat{w}^{\text{alg}} \) satisfies

\[
L_D(\hat{w}^{\text{alg}}) - L^* \leq 2 \mu \left( \| \nabla \hat{L}_n(\hat{w}^{\text{alg}}) \|_\alpha + \mathbb{E} \sup_{w \in \mathcal{W}} \| \nabla \hat{L}_n(w) - \nabla L_D(w) \|_\alpha + c \left( \frac{\log(1/\delta)}{n} \right)^{\frac{\alpha}{2}} \right),
\]  

where the constant \( c \) depends only on the range of \( \| \nabla \ell \| \).
Note that if $\mathcal{W}$ is a finite set, then standard concentration arguments for norms along with the union bound imply that $\mathbb{E}\sup_{w \in \mathcal{W}} \| \nabla \bar{L}_n(w) - \nabla L_D(w) \| \leq O\left( \sqrt{\log|\mathcal{W}| / n} \right)$. For smooth losses, if $\mathcal{W} \subset \mathbb{R}^d$ is contained in a bounded ball, then by simply discretizing the set $\mathcal{W}$ up to precision $\varepsilon$ (with $O(\varepsilon^{-d})$ elements), one can easily obtain a bound of $\mathbb{E}\sup_{w \in \mathcal{W}} \| \nabla \bar{L}_n(w) - \nabla L_D(w) \| \leq O\left( \sqrt{d / n} \right)$. This approach recovers the dimension-dependent gradient convergence rates obtained in Mei et al. (2016).

Our goal is to go beyond this type of analysis and provide dimension-free rates that apply even when the dimension is larger than the number of examples, or possibly infinite. Our bounds take the following “norm-based capacity control” form: $\mathbb{E}\sup_{w \in \mathcal{W}} \| \nabla \bar{L}_n(w) - \nabla L_D(w) \| \leq O\left( \frac{C(\mathcal{W})}{n} \right)$ where $C(\mathcal{W})$ is a norm-dependent, but dimension-independent measure of the size of $\mathcal{W}$. Given such a bound, any algorithm that guarantees $\| \nabla \bar{L}_n(\hat{w}\text{alg}) \| \leq O\left( \frac{1}{n} \right)$ for a $(\alpha, \mu)$-GD loss will obtain an overall excess risk bound of order $O\left( \frac{\mu}{n^{0.5 \alpha}} \right)$. For $(1, \mu_1)$-GD this translates to an overall $O\left( \frac{\mu_1}{\sqrt{n}} \right)$ rate, whereas $(2, \mu_2)$-GD implies a $O\left( \frac{\mu_2}{n} \right)$ rate. The first rate becomes favorable when $\mu_1 \leq \sqrt{n} \cdot \mu_2$ which typically happens for very high dimensional problems. For the examples we study, $\mu_1$ is related only to the radius of the set $\mathcal{W}$, while $\mu_2$ depends inversely on the smallest eigenvalue of the population covariance and so is well-behaved only for low-dimensional problems unless one makes strong distributional assumptions.

An important feature of our analysis is that we need to establish the GD condition only for the population risk; for the examples we consider this is easy as long as we assume the model is well-specified. Once this is done, our convergence results hold for any algorithm that works on the dataset $\{(x_t, y_t)\}_{t=1}^n$ and finds an approximate first-order stationary point with $\| \nabla \bar{L}_n(\hat{w}\text{alg}) \| \leq \varepsilon$. First-order algorithms that find approximate stationary points assuming only smoothness of the loss have enjoyed a surge of recent interest (Ghadimi and Lan, 2013; Reddi et al., 2016; Allen-Zhu and Hazan, 2016; Allen-Zhu, 2018a), so this is an appealing proposition.

### 2.2 Vector Rademacher Complexities: The How

The starting point for our uniform convergence bounds for gradients is to apply the standard tool of symmetrization—a vector-valued version, to be precise. To this end let us introduce a normed variant of Rademacher complexity.

**Definition 2** (Normed Rademacher Complexity). Given a vector valued class of function $\mathcal{F}$ that maps the space $\mathcal{Z}$ to a vector space equipped with norm $\| \cdot \|$, we define the normed Rademacher complexity for $\mathcal{F}$ on instances $z_{1:n}$ via

$$\mathcal{R}_{\| \cdot \|}(\mathcal{F}; z_{1:n}) := \mathbb{E}_z \sup_{f \in \mathcal{F}} \left\| \sum_{t=1}^n \varepsilon_t f(z_t) \right\|.$$  \hfill (2)

With this definition we are ready to provide a straightforward generalization of the standard real-valued symmetrization lemma.

**Proposition 2.** For any $\delta > 0$, with probability at least $1 - \delta$ over the data $\{(x_t, y_t)\}_{t=1}^n$,

$$\mathbb{E}\sup_{w \in \mathcal{W}} \| \nabla \bar{L}_n(w) - \nabla L_D(w) \| \leq \frac{4}{n} \cdot \mathcal{R}_{\| \cdot \|}(\nabla \ell \circ \mathcal{W}; x_{1:n}, y_{1:n}) + c \left( \frac{\log \left( \frac{1}{\delta} \right)}{n} \right),$$  \hfill (3)

where the constant $c$ depends only on the range of $\| \nabla \ell \|$.

To bound the complexity of the gradient class $\nabla \ell \circ \mathcal{W}$, we introduce a chain rule for the normed Rademacher complexity that allows to easily control gradients of composition of functions.
Theorem 1 (Chain Rule for Rademacher Complexity). Let sequences of functions $G_t : \mathbb{R}^K \to \mathbb{R}$ and $F_t : \mathbb{R}^d \to \mathbb{R}^K$ be given. Suppose there are constants $L_G$ and $L_F$ such that for all $1 \leq t \leq n$, $\|\nabla G_t\|_2 \leq L_G$ and $\sqrt{\sum_{k=1}^K \|\nabla F_{t,k}(w)\|^2} \leq L_F$. Then,

$$\frac{1}{2} \mathbb{E}_e \sup_{w \in \mathcal{W}} \left\| \sum_{t=1}^n \epsilon_t \nabla \ell(w; x_t, y_t) \right\| \leq L_F \mathbb{E}_e \sup_{w \in \mathcal{W}} \sum_{t=1}^n (\epsilon_t, \nabla G_t(F_t(w))) + L_G \mathbb{E}_e \sup_{w \in \mathcal{W}} \sum_{t=1}^n \nabla F_t(w) \epsilon_t,$$

where $\nabla F_t$ denotes the Jacobian of $F_t$, which lives in $\mathbb{R}^{d \times K}$, and $\epsilon \in \{\pm 1\}^{K \times n}$ is a matrix of Rademacher random variables with $\epsilon_t$ denoting the $t$th column.

The concrete learning settings we study—generalized linear models and robust regression—all involve composing non-convex losses and non-linearities or transfer functions with a linear predictor. That is, $\ell(w; x_t, y_t)$ can be written as $\ell(w; x_t, y_t) = G_t(F_t(w))$ where $G_t(a)$ is some $L$-Lipschitz function that possibly depends on $x_t$ and $y_t$ and $F_t(w) = (w, x_t)$. In this case, the chain rule for derivatives gives us that

$$\nabla \ell(w; x_t, y_t) = G_t'(F_t(w)) \cdot \nabla F_t(w) = G_t'((w, x_t)) x_t.$$  

Using the chain rule (with $K = 1$), we conclude that

$$\mathbb{E}_e \sup_{w \in \mathcal{W}} \left\| \sum_{t=1}^n \epsilon_t \nabla \ell(w; x_t, y_t) \right\| \leq \mathbb{E}_e \left[ \sup_{w \in \mathcal{W}} \sum_{t=1}^n \epsilon_t G_t'((w, x_t)) \right] + L \cdot \mathbb{E}_e \left\| \sum_{t=1}^n \epsilon_t x_t \right\|.$$  

Thus, we have reduced the problem to controlling the Rademacher average for a real valued function class of linear predictors and controlling the vector-valued random average $\mathbb{E}_e \left\| \sum_{t=1}^n \epsilon_t x_t \right\|$. The first term is handled using classical Rademacher complexity tools. As for the second term, it is a standard result (Pisier (1975); see Kakade et al. (2009a) for discussion in the context of learning theory) that for all smooth Banach spaces, and more generally Banach spaces of Rademacher type 2, one has $\mathbb{E}_e \left\| \sum_{t=1}^n \epsilon_t x_t \right\| = O(\sqrt{n})$; see Appendix A for details.

The key tool used to prove Theorem 1, which appears throughout the technical portions of this paper, is the vector-valued Rademacher complexity due to Maurer (2016).

Definition 3. For a function class $\mathcal{G} \subseteq (\mathbb{Z} \to \mathbb{R}^K)$, the vector-valued Rademacher complexity is

$$\mathcal{R}(g; z_{1:n}) \equiv \mathbb{E}_e \sup_{g \in \mathcal{G}} \sum_{t=1}^n (\epsilon_t, g(z_t)).$$

The vector-valued Rademacher complexity arises through an elegant contraction trick due to Maurer.

Theorem 2 (Vector-valued contraction (Maurer, 2016)). Let $\mathcal{G} \subseteq (\mathbb{Z} \to \mathbb{R}^K)$, and let $h_t : \mathbb{R}^K \to \mathbb{R}$ be a sequence of functions for $t \in [n]$, each of which is $L$-Lipschitz with respect to $\ell_2$. Then

$$\mathbb{E}_e \sup_{g \in \mathcal{G}} \sum_{t=1}^n \epsilon_t h_t(g(z_t)) \leq \sqrt{2L} \cdot \mathcal{R}(\mathcal{G}; z_{1:n}).$$

We remark that while our applications require only gradient uniform convergence, we anticipate that the tools of this section will find use in settings where convergence of higher-order derivatives is needed to ensure success of optimization routines. To this end, we have extended the chain rule (Theorem 1) to handle Hessian convergence; see Appendix E.

3 Application: Smooth Models

In this section we instantiate the general gradient uniform convergence tools and the GD condition to derive optimization consequences for two standard settings previously studied by Mei et al. (2016): generalized linear models and robust regression.
Generalized Linear Model. We first consider the problem of learning a generalized linear model with the square loss.\footnote{Mei et al. (2016) refer to the model as “binary classification”, since $\sigma$ can model conditional probabilities of two classes.} Fix a norm $\|\cdot\|$, take $\mathcal{X} = \{x \in \mathbb{R}^d \mid \|x\| \leq R\}$, $\mathcal{W} = \{w \in \mathbb{R}^d \mid \|w\|_\ast \leq B\}$, and $\mathcal{Y} = \{0, 1\}$. Choose a link function $\sigma : \mathbb{R} \to [0, 1]$, and define the loss to be $\ell(w; x, y) = (\sigma(w, x) - y)^2$. Standard choices for $\sigma$ include the logistic link function $\sigma(s) = (1 + e^{-s})^{-1}$ and the probit link function $\sigma(s) = \Phi(s)$, where $\Phi$ is the gaussian cumulative distribution function.

To establish the GD property and provide uniform convergence bounds, we make the following regularity assumptions on the loss.

\begin{assumption}[Generalized Linear Model Regularity] Let $\mathcal{S} = [-BR, BR]$. \begin{itemize}
\item[(a)] $\exists C_\sigma \geq 1$ s.t. $\max\{\sigma'(s), \sigma''(s)\} \leq C_\sigma$ for all $s \in \mathcal{S}$.
\item[(b)] $\exists c_\sigma > 0$ s.t. $\sigma'(s) \geq c_\sigma$ for all $s \in \mathcal{S}$.
\item[(c)] $\mathbb{E}[y \mid x] = \sigma(\langle w^*, x \rangle)$ for some $w^* \in \mathcal{W}$.
\end{itemize}
\end{assumption}

Assumption (a) suffices to bound the normalized Rademacher complexity $\mathcal{R}(\|\cdot\| (\nabla \ell \circ \mathcal{W}))$, and combined with (b) and (c) the assumption implies that $L_D$ satisfies three variants of GD condition, and this leads to three final rates: a dimension-independent “slow rate” that holds for any smooth norm, a dimension-dependent fast rate for the $\ell_2$ norm, and a sparsity-dependent fast rate that holds under an additional restricted eigenvalue assumption. This gives rise to a family of generic excess risk bounds.

To be precise, let us introduce some additional notation: $\Sigma = \mathbb{E}_x[xx^\top]$ is the data covariance matrix and $\lambda_{\min}(\Sigma)$ denotes the minimum non-zero eigenvalue. For sparsity dependent fast rates, define $C(S, \alpha) := \{\nu \in \mathbb{R}^d \mid \|\nu_{SC}\|_1 \leq \alpha \|\nu_S\|_1\}$ and let $\psi_{\min}(\Sigma) = \inf_{\nu \in C(S(w^*), 1)} \frac{\langle \nu, \Sigma \nu \rangle}{\langle \nu, \nu \rangle}$ be the restricted eigenvalue.\footnote{Recall that $S(w^*) \subseteq [d]$ is the set of non-zero entries of $w^*$, and for any vector $w$, $w_S \in \mathbb{R}^d$ refers to the vector $w$ with all entries in $S^C$ set to zero (as in (Raskutti et al., 2010)).} Lastly, recall that a norm $\|\cdot\|$ is said to be $\beta$-smooth if the function $\Psi(x) = \frac{1}{2} \|x\|^2$ has $\beta$-Lipschitz gradients with respect to $\|\cdot\|$.

\begin{theorem}
For the generalized linear model setting, the following excess risk inequalities each hold with probability at least $1 - \delta$ over the draw of the data $\{(x_i, y_i)\}_{i=1}^n$ for any algorithm $\hat{w}_{\text{alg}}$:
\begin{itemize}
\item **Norm-Based/High-Dimensional Setup.** When $\mathcal{X}$ is the ball for $\beta$-smooth norm $\|\cdot\|$ and $\mathcal{W}$ is the dual ball,
\[ L_D(\hat{w}_{\text{alg}}) - L^* \leq \mu_h \cdot \|\nabla L_n(\hat{w}_{\text{alg}})\| + \frac{C_h}{\sqrt{n}}. \]
\item **Low-Dimensional $\ell_2/\ell_2$ Setup.** When $\mathcal{X}$ and $\mathcal{W}$ are both $\ell_2$ balls:
\[ L_D(\hat{w}_{\text{alg}}) - L^* \leq \frac{1}{\lambda_{\min}(\Sigma)} \left( \mu_l \cdot \|\nabla L_n(\hat{w}_{\text{alg}})\|^2 + \frac{C_l}{n} \right). \]
\item **Sparse $\ell_\infty/\ell_1$ Setup.** When $\mathcal{X}$ is the $\ell_\infty$ ball, $\mathcal{W}$ is the $\ell_1$ ball, and $\|w^*\|_1 = B$:\footnote{The constraint $\|w^*\|_1 = B$ simplifies analysis of generic algorithms in the vein of the constrained LASSO (Tibshirani et al., 2015).}
\[ L_D(\hat{w}_{\text{alg}}) - L^* \leq \frac{\|w^*\|_0}{\psi_{\min}(\Sigma)} \left( \mu_s \cdot \|\nabla L_n(\hat{w}_{\text{alg}})\|^2 + \frac{C_s}{n} \right). \]
\end{itemize}
\end{theorem}

The quantities $C_h/C_l/C_s$ and $\mu_h/\mu_l/\mu_s$ are constants depending on $(B, R, C_\sigma, c_\sigma, \beta, \log(\delta^{-1}))$ but not explicitly on dimension (beyond logarithmic factors) or complexity of the class $\mathcal{W}$ (beyond $B$ and $R$).

Precise statements for the problem dependent constants in Theorem 3 including dependence on the norms $R$ and $B$ can be found in Appendix C.
We now formally introduce the robust regression setting and provide a similar guarantee.

**Robust Regression** Fix a norm \(\|\cdot\|\) and take \(\mathcal{X} = \{x \in \mathbb{R}^d \mid \|x\| \leq R\}, \mathcal{W} = \{w \in \mathbb{R}^d \mid \|w\|_* \leq B\},\) and \(\mathcal{Y} = [-Y, Y]\) for some constant \(Y\). We pick a potentially non-convex function \(\rho : \mathbb{R} \to \mathbb{R}_+\), and define the loss via \(\ell(w; x, y) = \rho(w, x − y)\). Non-convex choices for \(\rho\) arise in robust statistics, with a canonical example being Tukey’s biweight loss.\(^4\) While optimization is clearly not possible for arbitrary choices of \(\rho\), the following assumption is sufficient to guarantee that the population risk \(L_D\) satisfies the GD property.

**Assumption 2 (Robust Regression Regularity).** Let \(\mathcal{S} = [-BR + Y, (BR + Y)]\).

1. \(\exists C_\rho \geq 1\) s.t. \(\max\{\rho'(s), \rho''(s)\} \leq C_\rho\) for all \(s \in \mathcal{S}\).
2. \(\rho'\) is odd with \(\rho'(s) > 0\) for all \(s > 0\) and \(h(s) := \mathbb{E}_x[\rho'(s + \xi)]\) has \(h'(0) > c_\rho\).
3. There is \(w^* \in \mathcal{W}\) such that \(y = \langle w^*, x \rangle + \zeta\), and \(\zeta\) is symmetric zero-mean given \(x\).

Similar to the generalized linear model setup, the robust regression setup satisfies three variants of the GD depending on assumptions on the norm \(\|\cdot\|\) and the data distribution.

**Theorem 4.** For the robust regression setting, the following excess risk inequalities each hold with probability at least \(1 - \delta\) over the draw of the data \(\{(x_t, y_t)\}_{t=1}^n\) for any algorithm \(\hat{\omega}_{\text{alg}}\):

- **Norm-Based/High-Dimensional Setup.** When \(\mathcal{X}\) is the ball for \(\beta\)-smooth norm \(\|\cdot\|\) and \(\mathcal{W}\) is the dual ball,

\[
L_D(\hat{\omega}_{\text{alg}}) - L^* \leq \mu_h \cdot \|\nabla \tilde{L}_n(\hat{\omega}_{\text{alg}})\| + \frac{C_h}{\sqrt{n}}.
\]

- **Low-Dimensional \(\ell_2/\ell_2\) Setup.** When \(\mathcal{X}\) and \(\mathcal{W}\) are both \(\ell_2\) balls:

\[
L_D(\hat{\omega}_{\text{alg}}) - L^* \leq \frac{1}{\lambda_{\text{min}}(\Sigma)} \left( \mu_l \cdot \|\nabla \tilde{L}_n(\hat{\omega}_{\text{alg}})\|^2 + \frac{C_l}{n} \right).
\]

- **Sparse \(\ell_\infty/\ell_1\) Setup.** When \(\mathcal{X}\) is the \(\ell_\infty\) ball, \(\mathcal{W}\) is the \(\ell_1\) ball, and \(\|w^*\|_1 = B\):

\[
L_D(\hat{\omega}_{\text{alg}}) - L^* \leq \frac{\|w^*\|_0}{\psi_{\text{min}}(\Sigma)} \left( \mu_s \cdot \|\nabla \tilde{L}_n(\hat{\omega}_{\text{alg}})\|^2 + \frac{C_s}{n} \right).
\]

The constants \(C_h/C_l/C_s\) and \(\mu_h/\mu_l/\mu_s\) depend on \((B, R, C_\rho, c_\rho, \beta, \log(\delta^{-1}))\), but not explicitly on dimension (beyond log factors) or complexity of the class \(\mathcal{W}\) (beyond the range parameters \(B\) and \(R\)).

**Theorem 3** and **Theorem 4** immediately imply that standard non-convex optimization algorithms for finding stationary points can be converted to non-convex learning algorithms with optimal sample complexity; this

\[\text{for a fixed parameter } c > 0 \text{ the biweight loss is defined via } \rho(t) = \begin{cases} \frac{t^2}{\sigma^2} \cdot \left( 1 - \left( \frac{t}{c} \right)^2 \right)^3, & \text{for } |t| \leq c, \\ 1, & \text{for } |t| > c. \end{cases}\]
is summarized by the following theorem, focusing on the “high-dimensional” and “low-dimensional” setups above in the case of the $\ell_2$ norm for simplicity.

**Proposition 3.** Suppose that $\Sigma \geq \frac{1}{n} I$, $\| \cdot \| = \ell_2$. Consider the following meta-algorithm for the non-convex generalized linear model (under Assumption 1) and robust regression (under Assumption 2) setting.

1. Gather $n = \frac{1}{\epsilon^2} \wedge \frac{d}{\epsilon}$ samples $\{(x_t, y_t)\}_{t=1}^n$.
2. Find a point $\hat{w}^{\text{alg}} \in \mathcal{W}$ with $\| \nabla \mathcal{L}_n(\hat{w}^{\text{alg}}) \| \leq O\left(\frac{1}{\sqrt{n}}\right)$, which is guaranteed to exist.

This meta-algorithm guarantees $E L_D(\hat{w}^{\text{alg}}) - L^* \leq C \cdot \epsilon$, where $C$ is a problem-dependent but dimension-independent\(^5\) constant.

There are many non-convex optimization algorithms that provably find an approximate stationary point of the empirical risk, including gradient descent (Nesterov, 2013), SGD (Ghadimi and Lan, 2013), and Non-convex SVRG (Reddi et al., 2016; Allen-Zhu and Hazan, 2016). Note, however, that these algorithms are not generically guaranteed to satisfy the constraint $\hat{w}^{\text{alg}} \in \mathcal{W}$ a-priori. We can circumvent this difficulty and take advantage of these generic algorithms by instead finding stationary points of the regularized empirical risk. We show that any algorithm that finds a (unconstrained) stationary point of the regularized empirical risk indeed the obtains optimal $O\left(\frac{1}{\epsilon^2}\right)$ sample complexity in the norm-based regime.

**Theorem 9** (informal). Suppose we are in the generalized linear model setting or robust regression setting. Let $\mathcal{L}_n^\lambda(w) = \mathcal{L}_n(w) + \frac{\lambda}{2} \| w \|_2^2$. For any $\delta > 0$ there is a setting of the regularization parameter $\lambda$ such that any $\hat{w}^{\text{alg}}$ with $\nabla \mathcal{L}_n^\lambda(\hat{w}^{\text{alg}}) = 0$ guarantees $L_D(\hat{w}^{\text{alg}}) - L^* \leq O\left(\frac{\log(\delta^{-1})}{n}\right)$ with probability at least $1 - \delta$.

See Appendix C.3 for the full theorem statement and proof.

Now is a good time to discuss connections to existing work in more detail.

a) The sample complexity $O\left(\frac{1}{\epsilon^2} \wedge \frac{d}{\epsilon}\right)$ for Proposition 3 is optimal up to dependence on Lipschitz constants and the range parameters $B$ and $R$ (Tsybakov, 2008). The “high-dimensional” $O\left(\frac{1}{\epsilon^2}\right)$ regime is particularly interesting, and goes beyond recent analyses to non-convex statistical learning (Mei et al., 2016), which use arguments involving pointwise covers of the space $\mathcal{W}$ and thus have unavoidable dimension-dependence. This highlights the power of the norm-based complexity analysis.

b) In the low-dimensional $O\left(\frac{d}{\epsilon}\right)$ sample complexity regime, Theorem 3 and Theorem 4 recovers the rates of Mei et al. (2016) under the same assumptions—see Appendix C.3 for details. Notably, this is the case even when the radius $R$ is not constant. Note however that when $B$ and $R$ are large the constants in Theorem 3 and Theorem 4 can be quite poor. For the logistic link it is only possible to guarantee $c_\sigma \geq e^{-BR}$, and so it may be more realistic to assume $BR$ is constant.

c) The GLMtron algorithm of Kakade et al. (2011) also obtains $O\left(\frac{1}{\epsilon^2}\right)$ for the GLM setting. Our analysis shows that this sample complexity does not require specialized algorithms; any first-order stationary point finding algorithm will do. GLMtron has no guarantees in the $O\left(\frac{d}{\epsilon}\right)$ regime, whereas our meta-algorithm works in both high- and low-dimensional regimes. A significant benefit of GLMtron, however, is that it does not require a lower bound on the derivative of the link function $\sigma$. It is not clear if this assumption can be removed from our analysis.

d) As an alternative approach, stochastic optimization methods for finding first-order stationary points can be used to directly find an approximate stationary point of the population risk $\| L_D(w) \| \leq \epsilon$, so long as they draw a fresh sample at each step. In the high-dimensional regime it is possible to show that stochastic gradient descent (and for general smooth norms, mirror descent) obtains $O\left(\frac{1}{\epsilon^2}\right)$

\(^5\)Whenever $B$ and $R$ are constant.
sample complexity through this approach; this is sketched in Appendix C.3. This approach relies on returning a randomly selected iterate from the sequence and only gives an in-expectation sample complexity guarantee, whereas Theorem 9 gives a high-probability guarantee.

Also, note that many stochastic optimization methods can exploit the \((2, \mu)\)-GD condition. Suppose we are in the low-dimensional regime with \(\Sigma \geq \frac{1}{d}I\). The fastest GD-based stochastic optimization method that we are aware of is SNVRG (Zhou et al., 2018), which under the \((2, O(d))\)-GD condition will obtain \(\varepsilon\) excess risk with \(O\left(\frac{d}{\varepsilon} + \frac{d^{3/2}}{\varepsilon^{1/2}}\right)\) sample complexity.

This discussion is summarized in Table 3.

4 Non-Smooth Models

In the previous section we used gradient uniform convergence to derive immediate optimization and generalization consequences by finding approximate stationary points of smooth non-convex functions. In practice—notably in deep learning—it is common to optimize non-smooth non-convex functions; deep neural networks with rectified linear units (ReLUs) are the canonical example (Krizhevsky et al., 2012; He et al., 2016). In theory, it is trivial to construct non-smooth functions for which finding approximate stationary points is intractable (see discussion in Allen-Zhu (2018b)), but it appears that in practice stochastic gradient descent can indeed find approximate stationary points of the empirical loss in standard neural network architectures (Zhang et al., 2017). It is desirable to understand whether gradient generalization can occur in this setting.

The first result of this section is a lower bound showing that even for the simplest possible non-smooth model—a single ReLU—it is impossible to achieve dimension-independent uniform convergence results similar to those of the previous section. On the positive side, we show that it is possible to obtain dimension-independent rates under an additional margin assumption.

The full setting is as follows: \(X \subseteq \{x \in \mathbb{R}^d \mid \|x\|_2 \leq 1\}\), \(W \subseteq \{w \in \mathbb{R}^d \mid \|w\|_2 \leq 1\}\), \(Y = \{-1, +1\}\), and \(\ell(w ; x,y) = \sigma(-(w,x) \cdot y)\), where \(\sigma(s) = \max\{s, 0\}\); this essentially matches the classical Perceptron setup. Note that the loss is not smooth, and so the gradient is not well-defined everywhere. Thus, to make the problem well-defined, we consider convergence for the following representative from the subgradient:

\[ \nabla \ell(w ; x,y) := -y \mathbf{1}_{\{y(w,x) \leq 0\}} \cdot x. \]

Our first theorem shows that gradient uniform convergence for this setup must depend on dimension, even when the weight norm \(B\) and data norm \(R\) are held constant.

**Theorem 5.** Under the problem setting defined above, for all \(n \in \mathbb{N}\) there exist a sequence of instances \(\{(x_t, y_t)\}_{t=1}^n\) such that

\[ \mathbb{E}_e \sup_{w \in W} \left\| \frac{1}{n} \sum_{t=1}^n \epsilon_t \nabla \ell(w ; x_t, y_t) \right\|_2 = \Omega(\sqrt{dn \wedge n}). \]

This result contrasts the setting where \(\sigma\) is smooth, where the techniques from Section 2 easily yield a dimension-independent \(O(\sqrt{n})\) upper bound on the Rademacher complexity. This is perhaps not surprising since the gradients are discrete functions of \(w\), and indeed VC-style arguments suffice to establish the lower bound.

In the classical statistical learning setting, the main route to overcoming dimension dependence—e.g., for linear classifiers—is to assume a margin, which allows one to move from a discrete class to a real-valued class

---

\[ \text{For general non-convex and non-smooth functions one can extend this approach by considering convergence for a representative from the Clarke sub-differential (Borwein and Lewis, 2010; Clarke, 1990).} \]
upon which a dimension-independent Rademacher complexity bound can be applied (Shalev-Shwartz and Ben-David, 2014). Such arguments have recently been used to derive dimension-independent function value uniform convergence bounds for deep ReLU networks as well (Bartlett et al., 2017; Golowich et al., 2018). However, this analysis relies on one-sided control of the loss, so it is not clear whether it extends to the inherently directional problem of gradient convergence. Our main contribution in this section is to introduce additional machinery to prove dimension-free gradient convergence under a new type of margin assumption.

**Definition 4.** Given a distribution $P$ over the support $X$ and an increasing function $\phi : [0, 1] \rightarrow [0, 1]$, any $w \in W$ is said to satisfy the $\phi$-soft-margin condition with respect to $P$ if

$$\forall \gamma \in [0, 1], \quad \mathbb{E}_{x \sim P} \left[ 1 \left\{ \frac{|w \cdot x|}{|w||x||2|} \leq \gamma \right\} \right] \leq \phi(\gamma).$$

We call $\phi$ a margin function. We define the set of all weights that satisfy the $\phi$-soft-margin condition with respect to a distribution $P$ via:

$$\mathcal{W}(\phi, P) = \left\{ w \in W : \forall \gamma \in [0, 1], \quad \mathbb{E}_{x \sim P} \left[ 1 \left\{ \frac{|w \cdot x|}{|w||x||2|} \leq \gamma \right\} \right] \leq \phi(\gamma) \right\}. \quad (8)$$

Of particular interest is $\mathcal{W}(\phi, \mathcal{D}_n)$, the set of all the weights that satisfy the $\phi$-soft-margin condition with respect to the empirical data distribution. That is, any $w \in \mathcal{W}(\phi, \mathcal{D}_n)$ predicts with at least a $\gamma$ margin on all but a $\phi(\gamma)$ fraction of the data. The following theorem provides a dimension-independent uniform convergence bound for the gradients over the class $\mathcal{W}(\phi, \mathcal{D}_n)$ for any margin function $\phi$ fixed in advance.

**Theorem 6.** Let $\phi : [0, 1] \rightarrow [0, 1]$ be a fixed margin function. With probability at least $1 - \delta$ over the draw of the data $\{(x_t, y_t)\}_{t=1}^n$,

$$\sup_{w \in \mathcal{W}(\phi, \mathcal{D}_n)} \| \nabla_{\mathcal{D}}(w) - \nabla \mathcal{L}_n(w) \|_2 \leq \tilde{O} \left( \inf_{\gamma > 0} \left( \sqrt{\phi(4\gamma)} + \frac{1}{n} \sqrt{\frac{\log \left( \frac{1}{\gamma} \right)}{n}} + \frac{1}{\gamma^{\frac{1}{2}} n^{\frac{1}{4}}} \right) \right),$$

where $\tilde{O}(\cdot)$ hides $\log \log (\frac{1}{\gamma})$ and $\log n$ factors.

As a concrete example, when $\phi(\gamma) = \gamma^{\frac{1}{2}}$ Theorem 6 yields a dimension-independent uniform convergence bound of $O(n^{-\frac{1}{2}})$, thus circumventing the lower bound of Theorem 5 for large values of $d$.

## 5 Discussion

We showed that vector Rademacher complexities are a simple and effective tool for deriving dimension-independent uniform convergence bounds and used these bounds in conjunction with the (population) Gradient Domination property to derive optimal algorithms for non-convex statistical learning in high and infinite dimension. We hope that these tools will find broader use for norm-based capacity control in non-convex learning settings beyond those considered here. Of particular interest are models where convergence of higher-order derivatives is needed to ensure success of optimization routines. Appendix E contains an extension of Theorem 1 for Hessian uniform convergence, which we anticipate will find use in such settings.

In Section 3 we analyzed generalized linear models and robust regression using both the $(1, \mu)$-GD property and the $(2, \mu)$-GD property. In particular, the $(1, \mu)$-GD property was critical to obtain dimension-independent norm-based capacity control. While there are many examples of models for which the population risk satisfies $(2, \mu)$-GD property (phase retrieval (Sun et al., 2016; Zhang et al., 2016), ResNets with linear activations (Hardt and Ma, 2017), matrix factorization (Liu et al., 2016), blind deconvolution (Li et al.,
we do not know whether the \((1, \mu)\)-GD property holds for these models. Establishing this property and consequently deriving dimension-independent optimization guarantees is an exciting future direction.

Lastly, an important question is to analyze non-smooth problems beyond the simple ReLU example considered in Section 4. See Davis and Drusvyatskiy (2018) for subsequent work in this direction.

A Preliminaries

A.1 Contraction Lemmas

Lemma 1 (e.g., Ledoux and Talagrand (1991)). Let $\mathcal{F}$ be any scalar-valued function class and $\phi_1, \ldots, \phi_n$ be any sequence of functions where $\phi_t : \mathbb{R} \to \mathbb{R}$ is $L$-Lipschitz. Then

$$
\mathbb{E}_\epsilon \sup_{f \in \mathcal{F}} \sum_{t=1}^n \epsilon_t \phi_t(f(x_t)) \leq L \cdot \mathbb{E}_\epsilon \sup_{f \in \mathcal{F}} \sum_{t=1}^n \epsilon_t f(x_t). \quad (9)
$$

The following is a weighted generalization of the vector-valued Lipschitz contraction inequality.
Lemma 2. Let $\mathcal{F} \subseteq (\mathcal{X} \to \mathbb{R}^K)$, and let $h_t : \mathbb{R}^K \to \mathbb{R}$ be a sequence of functions for $t \in [n]$. Suppose each $h_t$ is 1-Lipschitz with respect to $\|z\|_{A_t} := \sqrt{\langle z, A_t z \rangle}$, where $A_t \in \mathbb{R}^{K \times K}$ is positive semidefinite. Then

$$
\mathbb{E}_t \sup_{f \in \mathcal{F}} \sum_{t=1}^n \epsilon_t h_t(f(x_t)) \leq \sqrt{2} \mathbb{E}_t \sup_{f \in \mathcal{F}} \sum_{t=1}^n \left( \epsilon_t, A_t^{1/2} f(x_t) \right),
$$

(10)

Proof sketch for Lemma 2. Same proof as Theorem 3 in Maurer (2016), with the additional observation that $\|z\|_{A_t} = \|A_t^{1/2} z\|_2$.

Lemma 3. Let $\mathcal{G}$ be a class of vector-valued functions whose output space forms $M$ blocks of vectors, i.e., each $g \in \mathcal{G}$ has the form $g : \mathcal{Z} \to \mathbb{R}^{d_1 + d_2 + \cdots + d_M}$, where $g(z)_i \in \mathbb{R}^{d_i}$ denotes the $i$th block. Let $h_t : \mathbb{R}^{d_1 + d_2 + \cdots + d_M} \to \mathbb{R}$, be a sequence of functions for $t \in [n]$ that satisfy the following block-wise Lipschitz property: For any assignment $a_1, \ldots, a_M$ with each $a_i \in \mathbb{R}^{d_i}$, $h_t(a_1, \ldots, a_M)$ is $L_i$-Lipschitz with respect to $a_i$ in the $\ell_2$ norm. Then

$$
\mathbb{E}_t \sup_{g \in \mathcal{G}} \sum_{t=1}^n h_t(g_1(z_t), \ldots, g_M(z_t)) \leq \sqrt{2M} \mathbb{E}_t \sup_{f \in \mathcal{F}} \sum_{t=1}^n \left( \epsilon_t, g_t(z_t) \right).
$$

Proof. Immediate consequence of Lemma 2, along with sub-additivity of the supremum.

A.2 Bound for Vector-Valued Random Variables

Definition 5. For any vector space $\mathcal{V}$, a convex function $\Psi : \mathcal{V} \to \mathbb{R}$ is $\beta$-smooth with respect to a norm $\|\cdot\|$ if

$$
\Psi(x) \leq \Psi(y) + \langle \nabla \Psi(y), x - y \rangle + \frac{\beta}{2} \|x - y\|^2 \quad \forall x, y \in \mathcal{V}.
$$

A norm $\|\cdot\|$ is said to be $\beta$-smooth if the function $\Psi(x) = \frac{1}{2} \|x\|^2$ is $\beta$-smooth with respect to $\|\cdot\|$.

Theorem 7. Let $\|\cdot\|$ be any norm for which there exists $\Psi$ such that $\Psi(x) \geq \frac{1}{2} \|x\|^2$, $\Psi(0) = 0$, and $\Psi$ is $\beta$-smooth with respect to $\|\cdot\|$. Then

$$
\mathbb{E}_t \left\| \sum_{t=1}^n \epsilon_t x_t \right\| \leq \sqrt{\beta} \sum_{t=1}^n \|x_t\|^2.
$$

The reader may consult Pinelis (1994) for a high-probability version of this theorem.

Fact 1. The following spaces and norms satisfy the preconditions of Theorem 7:

- $(\mathbb{R}^d, \ell_p)$ for $p \geq 2$, with $\beta = p - 1$ (Kakade et al., 2009a).
- $(\mathbb{R}^d, \ell_{\infty})$, with $\beta = O(\log d)$ (Kakade et al., 2009a).
- $(\mathbb{R}^{d_1 \times d_2}, \|\cdot\|_{op})$, with $\beta = O(\log(d_1 + d_2))$ (Kakade et al., 2012).

Proof of Theorem 7. Using Jensen’s inequality and the upper bound property of $\Psi$ we have

$$
\mathbb{E}_t \left\| \sum_{t=1}^n \epsilon_t x_t \right\| \leq \sqrt{\mathbb{E}_t \left\| \sum_{t=1}^n \epsilon_t x_t \right\|^2} \leq \sqrt{2} \cdot \mathbb{E}_t \left\| \sum_{t=1}^n \epsilon_t x_t \right\|.$$

14
Applying the smoothness property at time $n$, and using that $\epsilon_n$ is independent of $\epsilon_1, \ldots, \epsilon_{n-1}$:

$$
\sqrt{\mathbb{E}_e \left( \sum_{t=1}^{n} \epsilon_t x_t \right)^2} \leq \sqrt{\mathbb{E}_e \left[ \left( \sum_{t=1}^{n-1} \epsilon_t x_t \right)^2 + \left( \sum_{t=1}^{n-1} \epsilon_t x_t, \epsilon_n x_n \right)^2 + \frac{\beta}{2} \|x_n\|^2 \right]} = \sqrt{\mathbb{E}_e \left( \sum_{t=1}^{n-1} \epsilon_t x_t \right)^2 + \frac{\beta}{2} \|x_n\|^2}.
$$

The result follows by repeating this argument from time $t = n - 1$ to $t = 1$. \hfill \Box

### B Proofs from Section 2

**Theorem 8** (Bartlett et al. (2005), Theorem A.2/Lemma A.5). Let $\mathcal{F} \subseteq (\mathcal{Z} \to \mathbb{R})$ be a class of functions. Let $Z_1, \ldots, Z_n \sim \mathcal{D}$ i.i.d. for some distribution $\mathcal{D}$. Then with probability at least $1 - \delta$ over the draw of $Z_{1:n}$,

$$
\mathbb{E} \sup_{f \in \mathcal{F}} \left| \mathbb{E}_Z f(Z) - \frac{1}{n} \sum_{t=1}^{n} f(Z_t) \right| \leq 4 \mathbb{E} \sup_{f \in \mathcal{F}} \frac{1}{n} \sum_{t=1}^{n} \epsilon_t f(Z_t) + 4 \sup_{f \in \mathcal{F}} \sup_{x \in \mathcal{Z}} |f(x)| \frac{\log \left( \frac{2}{\delta} \right)}{n}. \tag{11}
$$

**Lemma 4** (Uniform convergence for vector-valued functions). Let $\mathcal{G} \subseteq \{ g : \mathcal{Z} \to \mathcal{B} \}$ for arbitrary set $\mathcal{Z}$ and vector space $\mathcal{B}$. Let $Z_1, \ldots, Z_n \sim \mathcal{D}$ i.i.d. for some distribution $\mathcal{D}$. Let a norm $\| \cdot \|$ over $\mathcal{B}$ be fixed. Then with probability at least $1 - \delta$ over the draw of $Z_{1:n}$,

$$
\mathbb{E} \sup_{g \in \mathcal{G}} \left\| \mathbb{E}_Z g(Z) - \frac{1}{n} \sum_{t=1}^{n} g(Z_t) \right\| \leq 4 \mathbb{E} \sup_{g \in \mathcal{G}} \left\| \frac{1}{n} \sum_{t=1}^{n} \epsilon_t g(Z_t) \right\| + 4 \sup_{g \in \mathcal{G}} \sup_{Z \in \mathcal{Z}} \|g(Z)\| \cdot \frac{\log \left( \frac{2}{\delta} \right)}{n} \tag{12}
$$

for some absolute constant $c > 0$.

**Proof of Lemma 4.** This follows immediately by applying Theorem 8 to the expanded function class $\mathcal{F} := \{ Z \mapsto (g(Z), v) \mid g \in \mathcal{G}, \| v \|_* \leq 1 \}$. \hfill \Box

**Proof of Proposition 1.** This is a direct consequence of McDiarmid’s inequality. Consider any vector-valued function class of functions $\mathcal{G}$. Let $Z_1, \ldots, Z_n \sim \mathcal{D}$ i.i.d. for some distribution $\mathcal{D}$. Then McDiarmid’s inequality implies that with probability at least $1 - \delta$ over the draw of $Z_{1:n}$,

$$
\sup_{g \in \mathcal{G}} \left\| \mathbb{E}_Z g(Z) - \frac{1}{n} \sum_{t=1}^{n} g(Z_t) \right\| \leq \mathbb{E} \sup_{g \in \mathcal{G}} \left\| \mathbb{E}_Z g(Z) - \frac{1}{n} \sum_{t=1}^{n} g(Z_t) \right\| + c \sup_{g \in \mathcal{G}} \sup_{Z \in \mathcal{Z}} \|g(Z)\| \cdot \sqrt{\frac{\log \left( \frac{2}{\delta} \right)}{n}}. \tag{13}
$$

\hfill \Box

**Proof of Proposition 2.** This follows by applying the uniform convergence lemma, Lemma 4, to the class $\mathcal{G} = \{ (x, y) \mapsto \nabla \ell(w ; x, y) \mid w \in \mathcal{W} \}$. \hfill \Box

**Proof of Theorem 1.** We write

$$
\mathbb{E}_e \sup_{w \in \mathcal{W}} \left\| \sum_{t=1}^{n} \epsilon_t \nabla \left( G_t(F_t(w)) \right) \right\| = \mathbb{E}_e \sup_{w \in \mathcal{W}} \sup_{v \in \mathcal{B}^* \|v\|_* \leq 1} \sum_{t=1}^{n} \epsilon_t \left\langle \nabla (G_t(F_t(w))), v \right\rangle,
$$

Using the chain rule for differentiation we have

$$
\left\langle \nabla (G_t(F_t(w))), v \right\rangle = \left\langle (\nabla G_t)(F_t(w)), \left( (\nabla F_t,k(w), v) \right)_{k \in [K]} \right\rangle.
$$

15
We now introduce new functions that relabel the quantities in this expression. Let \( h : \mathbb{R}^{2K} \to \mathbb{R} \) be given by \( h(a, b) = (a, b) \), let \( f_1 : \mathcal{W} \to \mathbb{R}^K \) be given by \( f_1(w) = (\nabla G_t)(F_t(w)) \) and \( f_2 \) be given by \( f_2(w, v) = (\{\nabla F_{t,k}(w), v\})_{k \in [K]} \). We apply the block-wise contraction lemma Lemma 3 with one block for \( f_1 \) and one block for \( f_2 \) to conclude

\[
\mathbb{E}_e \sup_{w \in \mathcal{W}} \sup_{v : \|v\| \leq 1} \sum_{t \in 1}^n \epsilon_t h(f_1(w), f_2(w, v))
\]

\[
\leq 2L_F \mathbb{E}_e \sup_{w \in \mathcal{W}} \sup_{v : \|v\| \leq 1} \sum_{t \in 1}^n \epsilon_t f_1(w) + 2L_G \mathbb{E}_e \sup_{w \in \mathcal{W}} \sup_{v : \|v\| \leq 1} \sum_{t \in 1}^n \epsilon_t f_2(w, v),
\]

which establishes the result after expanding terms. All that must be verified is that the assumptions on the norm bounds for \( \nabla G_t \) and \( \nabla F_t \) in the theorem statement ensure the the Lipschitz requirement in the statement of Lemma 3 is met.

\[ \square \]

C Proofs from Section 3

For all proofs in this section we adopt the notation \( s := \|w^*\|_0 \), and use \( c > 0 \) to denote an absolute constant whose precise value depends on context.

C.1 Generalized Linear Models

Proof of Theorem 3. To begin, we apply Proposition 1 and Proposition 2 to conclude that whenever \((\alpha, \mu)\)-PL holds, with probability at least \( 1 - \delta \) over the examples \( \{(x_t, y_t)\}_{t=1}^n \), any learning algorithm \( \bar{a}^{alg} \in \mathcal{W} \) satisfies

\[
L_D(\bar{a}^{alg}) - L^* \leq c \cdot \mu \left( \left\| \nabla \bar{L}_n(\bar{a}^{alg}) \right\|^\alpha + \left( \frac{9n \left( \nabla \ell \circ \mathcal{W} : x_{1:n}, y_{1:n} \right)}{n} + 2C_\sigma R \sqrt{\log(1/\delta)} \right) \right) \leq 2C_\sigma R.
\]

Here \( c > 0 \) is an absolute constant and we have used that \( \left\| \nabla \ell(w; x_t, y_t) \right\| \leq 2C_\sigma R. \)

Smooth high-dimensional setup For the general smooth norm pair setup in (14), Lemma 5 and Lemma 7 imply

\[
L_D(\bar{a}^{alg}) - L^* \leq c \cdot \frac{BC_\sigma}{c_\sigma} \left( \left\| \nabla \bar{L}_n(\bar{a}^{alg}) \right\|^\beta + \left( B R^2 C_\sigma^2 \sqrt{\frac{\beta}{n}} + 2C_\sigma R \sqrt{\log(1/\delta)} \right) \right) = \mu_h \cdot \left\| \nabla \bar{L}_n(\bar{a}^{alg}) \right\| + \frac{C_h}{\sqrt{n}},
\]

where we recall \( C_h = c \cdot \frac{B^2 R^2 C_\sigma^3 \sqrt{\beta} + 2C_\sigma^2 B R \sqrt{\log(1/\delta)}}{c_\sigma} \) and \( \mu_h = c \cdot \frac{BC_\sigma}{c_\sigma}. \)
Low-dimensional $\ell_2/\ell_2$ setup  For the low-dimension $\ell_2/\ell_2$ pair setup in (14), Lemma 5 and Lemma 7 imply

\[ L_D(\overline{w}^{alg}) - L^* \leq c \cdot \frac{C_\sigma}{4c_\sigma^3 \lambda_{\min}(\Sigma)} \left( \| \nabla L_n(\overline{w}^{alg}) \|^2 + \left( B R^2 C_\sigma^2 \sqrt{\frac{\log(1/\delta)}{n}} + 2 C_\sigma R \sqrt{\frac{\log(1/\delta)}{n}} \right)^2 \right) = \frac{\mu_1}{\lambda_{\min}(\Sigma)} \cdot \| \nabla L_n(\overline{w}^{alg}) \|^2 + \frac{C_1}{n \cdot \lambda_{\min}(\Sigma)}, \]

where we have used that the $\ell_2$ norm is 1-smooth in Lemma 7. Recall that $C_1 = c \cdot \frac{2C_\sigma^5 R^4 B^2 + 8C_\sigma^3 R^2 \log(1/\delta)}{4c_\sigma^3}$ and $\mu_1 = c \cdot \frac{C_\sigma}{4c_\sigma^3}$.

Sparse $\ell_\infty/\ell_1$ setup For the sparse $\ell_\infty/\ell_1$ pair setup in (14), Lemma 5 and Lemma 7 imply

\[ L_D(\overline{w}^{alg}) - L^* \leq c \cdot \frac{C_\sigma s}{c_\sigma^3 \psi_{\min}(\Sigma)} \left( \| \nabla L_n(\overline{w}^{alg}) \|^2 + \left( B R^2 C_\sigma^2 \sqrt{\frac{\log d}{n}} + 2 C_\sigma R \sqrt{\frac{\log(1/\delta)}{n}} \right)^2 \right) \]

\[ = \frac{\mu_2 \cdot s}{\psi_{\min}(\Sigma)} \cdot \| \nabla L_n(\overline{w}^{alg}) \|^2 + \frac{s \cdot C_s}{\psi_{\min}(\Sigma)}, \]

where we have used that the $\ell_\infty$ norm has the smoothness property with $\beta = O(\log(d))$ in Lemma 7. Recall that $C_s = c \cdot \frac{2C_\sigma^5 R^4 B^2 \log(d) + 8C_\sigma^3 R^2 \log(1/\delta)}{c_\sigma^3}$ and $\mu_2 = c \cdot \frac{C_\sigma}{c_\sigma^3}$.

\[ \square \]

**Lemma 5** (GD condition for the GLM). Consider the generalized linear model setup of Section 3.

- When $\| \cdot \|_\cdot$, are any dual norm pair, we have $\left( 1, \frac{BC_\sigma}{c_\sigma} \right)$-GD:

\[ L_D(w) - L_D(w^*) \leq \frac{BC_\sigma}{c_\sigma} \| \nabla L_D(w) \| \quad \forall w \in \mathcal{W}. \tag{15} \]

- In the $\ell_2/\ell_2$ setup, we have $\left( 2, \frac{C_\sigma}{4c_\sigma^3 \lambda_{\min}(\Sigma)} \right)$-GD:

\[ L_D(w) - L_D(w^*) \leq \frac{C_\sigma}{4c_\sigma^3 \lambda_{\min}(\Sigma)} \| \nabla L_D(w) \|_2 \quad \forall w \in \mathcal{W}. \tag{16} \]

- In the sparse $\ell_\infty/\ell_1$ setup, where $\| w^* \|_0 \leq s$, we have $\left( 2, \frac{C_\sigma s}{c_\sigma^3 \psi_{\min}(\Sigma)} \right)$-GD:

\[ L_D(w) - L_D(w^*) \leq \frac{C_\sigma s}{c_\sigma^3 \psi_{\min}(\Sigma)} \| \nabla L_D(w) \|_\infty \quad \forall w \in \mathcal{W}. \tag{17} \]

**Proof of Lemma 5.**

**Upper bound for excess risk.** We first prove the following intermediate upper bound:

\[ L_D(w) - L_D(w^*) \leq \frac{C_\sigma}{2c_\sigma} (\| \nabla L_D(w) \|, w - w^*). \tag{18} \]
Letting $w \in \mathcal{W}$ be fixed, we have
\[
\langle \nabla L_D(w), w - w^* \rangle = 2 \mathbb{E}_{(x,y)}[(\sigma(\langle w, x \rangle - y)\sigma'(\langle w, x \rangle)(w - w^*, x)].
\]
Using the well-specified assumption:
\[
= 2 \mathbb{E}_x[(\sigma(\langle w, x \rangle - \sigma(\langle w^*, x \rangle))\sigma'(\langle w, x \rangle)(w - w^*, x)].
\]
We now consider the term inside the expectation. Since $\sigma$ is increasing we have
\[
\sigma(\langle w, x \rangle - \sigma(\langle w^*, x \rangle)))\sigma'(\langle w, x \rangle)(w - w^*, x) = |\sigma(\langle w, x \rangle - \sigma(\langle w^*, x \rangle))| \cdot |(w - w^*, x)| \cdot \sigma'(\langle w, x \rangle)
\]
point-wise. We apply two lower bounds. First, $\sigma'(\langle w, x \rangle) > c_\sigma$ by assumption. Second, Lipschitzness of $\sigma$ implies
\[
|\sigma(\langle w, x \rangle) - \sigma(\langle w^*, x \rangle)| \leq C_\sigma |(w - w^*, x)|.
\]
Combining these inequalities, we also obtain the following inequality in expectation over $x$:
\[
\mathbb{E}_x(\sigma(\langle w, x \rangle) - \sigma(\langle w^*, x \rangle))^2 \leq \frac{C_\sigma}{2c_\sigma} \langle \nabla L_D(w), w - w^* \rangle.
\]
Lastly, since the model is well-specified we have
\[
L_D(w) - L_D(w^*) = \mathbb{E}_x(\sigma(\langle w, x \rangle) - \sigma(\langle w^*, x \rangle))^2,
\]
by a standard argument:
\[
L_D(w) - L_D(w^*) = \mathbb{E}_{x,y}[\sigma^2(\langle w, x \rangle) + y^2 - 2\sigma(\langle w, x \rangle)y - \sigma^2(\langle w^*, x \rangle) - y^2 + 2\sigma(\langle w^*, x \rangle)y]
\]
\[
= \mathbb{E}_x[\sigma^2(\langle w, x \rangle) - 2\sigma(\langle w, x \rangle)\sigma(\langle w^*, x \rangle) + \sigma^2(\langle w^*, x \rangle)]
\]
\[
= \mathbb{E}_x(\sigma(\langle w, x \rangle) - \sigma(\langle w^*, x \rangle))^2.
\]

**Proving the GD conditions.** With the inequality (18) established the various GD inequalities follow in quick succession.

- \((1, \frac{BC_\sigma}{c_\sigma})\)-GD:

  To prove this inequality, simply use Hölder’s inequality to obtain the upper bound,
  \[
  \langle \nabla L_D(w), w - w^* \rangle \leq 2B \| \nabla L_D(w) \|.
  \]

- \((2, \frac{C_\sigma}{4c_\sigma \lambda_{\min}(\mathbb{E}[xx^\top])})\)-GD:

  Resuming from (18) we have
  \[
  L_D(w) - L_D(w^*) \leq \frac{C_\sigma}{2c_\sigma} \langle \nabla L_D(w), w - w^* \rangle.
  \]
  
  Let $P_X$ denote the orthogonal projection onto span$(\mathbb{E}[xx^\top])$. Note that $\nabla \ell(w; x, y)$ is parallel to $x$, we can thus introduce the projection matrix $P_X$ while preserving the inner product
  \[
  = \frac{C_\sigma}{2c_\sigma} \langle P_X \nabla L_D(w), P_X (w - w^*) \rangle.
  \]
Applying Cauchy-Schwarz:

\[ \leq \frac{C_\sigma}{2c_\sigma} \left\| \nabla \mathcal{D}(w) \right\|_2 \cdot \left\| P_X(w - w^*) \right\|_2. \tag{19} \]

What remains is to relate the gradient norm to the term \( \left\| P_X(w - w^*) \right\|_2 \). We proceed with another lower bound argument similar to the one used to establish (18),

\[ \langle \nabla \mathcal{D}(w), w - w^* \rangle = 2 \mathbb{E}_{(x,y)} [\sigma(\langle w, x \rangle - y)\sigma'(\langle w, x \rangle)(w - w^*, x)]. \]

Using the well-specified assumption once more:

\[ = 2 \mathbb{E}_x \left[ (\sigma(\langle w, x \rangle - \sigma(\langle w^*, x \rangle))\sigma'(\langle w, x \rangle)(w - w^*, x) \right]. \]

Monotonicity of \( \sigma \), implies the argument to the expectation is non-negative pointwise, so we have the lower bound,

\[ \geq 2c_\sigma \mathbb{E}_x [(\sigma(\langle w, x \rangle - \sigma(\langle w^*, x \rangle)) (w - w^*, x)]. \]

Consider a particular draw of \( x \) and assume \( \langle w, x \rangle \geq \langle w^*, x \rangle \) without loss of generality. Using the mean value theorem, there is some \( s \in [\langle w^*, x \rangle, \langle w, x \rangle] \) such that

\[ \sigma(\langle w, x \rangle) - \sigma(\langle w^*, x \rangle) = (w - w^*, x) \sigma'(s) \geq (w - w^*, x)^2 c_\sigma. \]

Grouping terms, we have shown

\[ \langle P_X \nabla \mathcal{D}(w), P_X(w - w^*) \rangle = \langle \nabla \mathcal{D}(w), w - w^* \rangle \geq 2c_\sigma^2 \mathbb{E}(w - w^*, x)^2 \]

\[ = 2c_\sigma^2 \left[ (w - w^*, \mathbb{E}[xx^\top])(w - w^*) \right] \]

\[ \geq 2c_\sigma^2 \lambda_{\text{min}}(\mathbb{E}[xx^\top]) \left\| P_X(w - w^*) \right\|_2. \tag{20} \]

In other words, by rearranging and applying Cauchy-Schwarz we have

\[ \left\| P_X(w - w^*) \right\|_2 \leq \frac{1}{2c_\sigma^2 \lambda_{\text{min}}(\mathbb{E}[xx^\top])} \cdot \left\| \nabla \mathcal{D}(w) \right\|_2. \]

Combining this inequality with (19), we have

\[ \mathcal{D}(w) - \mathcal{D}(w^*) \leq \frac{C_\sigma}{4c_\sigma^2 \lambda_{\text{min}}(\mathbb{E}[xx^\top])} \cdot \left\| \nabla \mathcal{D}(w) \right\|_2^2. \]

• \( \left( 2, \frac{C_\sigma \psi_{\text{min}}(\mathbb{E}[xx^\top])}{c_\sigma^2 \psi_{\text{min}}(\mathbb{E}[xx^\top])} \right) \)-GD:

Using the inequality (20) from the preceding GD proof, we have

\[ \langle \nabla \mathcal{D}(w), w - w^* \rangle \geq 2c_\sigma^2 \left[ (w - w^*, \mathbb{E}[xx^\top])(w - w^*) \right]. \]

By the assumption that \( \left\| w \right\|_1 \leq \left\| w^* \right\|_1 \), we apply Lemma 6 to conclude that 1) \( w - w^* \in \mathcal{C}(S(w^*), 1) \) and 2) \( \left\| w - w^* \right\|_1 \leq 2\sqrt{s} \left\| w - w^* \right\|_2 \). The first fact implies that

\[ \langle w - w^*, \mathbb{E}[xx^\top](w - w^*) \rangle \geq \psi_{\text{min}}(\mathbb{E}[xx^\top]) \left\| w - w^* \right\|_2^2. \]
Rearranging, we have
\[
\|w - w^*\|_2 \leq \frac{1}{2c_\sigma^2 \psi_{\min}(E[x]^2)} \frac{\langle \nabla L_D(w), w - w^* \rangle}{\|w - w^*\|_2} \\
\leq \frac{1}{2c_\sigma^2 \psi_{\min}(E[x]^2)} \|\nabla L_D(w)\|_\infty \|w - w^*\|_2 \\
\leq \frac{\sqrt{s}}{c_\sigma \psi_{\min}(E[x]^2)} \|\nabla L_D(w)\|_\infty.
\]

On the other hand, from (18) we have
\[
L_D(w) - L_D(w^*) \leq \frac{C_\sigma}{2c_\sigma} \langle \nabla L_D(w), w - w^* \rangle \\
\leq \frac{C_\sigma}{2c_\sigma} \|\nabla L_D(w)\|_\infty \|w - w^*\|_1 \\
\leq \frac{C_\sigma \sqrt{s}}{c_\sigma} \|\nabla L_D(w)\|_\infty \|w - w^*\|_2.
\]

Combining this with the preceding inequality yields the result.

\[\square\]

The following utility lemma is a standard inequality in high-dimensional statistics (e.g. Tibshirani et al. (2015)).

**Lemma 6.** Let \( w, w^* \in \mathbb{R}^d \). If \( \|w\|_1 = \|w^*\|_1 \) then \( w - w^* =: \nu \in C(S(w^*), 1) \). Furthermore, \( \|\nu\|_1 \leq 2\sqrt{|S(w^*)|} \|\nu\|_2 \).

**Proof of Lemma 6.** Let \( S := S(w^*) \). Then the constraint that \( \|w\|_1 = \|w^*\|_1 \) implies
\[
\|w^*\|_1 \geq \|w\|_1 = \|w^* + \nu\|_1 = \|w^* + \nu_S\|_1 \geq \|w^*\|_1 - \|\nu_S\|_1.
\]
Rearranging, this implies \( \|\nu_S\|_1 \leq \|\nu\|_1 \), so the first result is established.

For the second result, \( \nu \in C(S, 1) \) implies \( \|\nu\|_1 = \|\nu_S\|_1 + \|\nu_{SC}\|_1 \leq 2\|\nu_S\|_1 \leq 2\sqrt{|S|} \|\nu_S\|_2 \leq 2\sqrt{|S|} \|\nu\|_2. \)

**Lemma 7.** Let the norm \( \|\cdot\| \) satisfy the smoothness property of Theorem 7 with constant \( \beta \). Then the empirical loss gradient for the generalized linear model setting enjoys the normed Rademacher complexity bound,
\[
\mathbb{E}_e \sup_{w \in \mathcal{W}} \left\| \sum_{t=1}^n \epsilon_t \nabla \ell(w; x_t, y_t) \right\| \leq O\left(BR^2C_\sigma^2 \sqrt{\beta n}\right).
\]

**Proof of Lemma 7.** Let \( G_t(s) = (\sigma(s) - y_t)^2 \) and \( F_t(w) = \langle w, x_t \rangle \), so that \( \ell(w; x_t, y_t) = G_t(F_t(w)) \).

Observe that \( G_t'(s) = 2(\sigma(s) - y_t)\sigma'(s) \) and \( \nabla F_t(w) = x_t \), so our assumptions imply that \( |G_t'(s)| \leq 2C_\sigma \) and \( \|\nabla F_t(w)\| \leq R \). We can thus apply Theorem 1 to conclude
\[
\mathbb{E}_e \sup_{w \in \mathcal{W}} \left\| \sum_{t=1}^n \epsilon_t \nabla \ell(w; x_t, y_t) \right\| \leq 2R \mathbb{E}_e \sup_{w \in \mathcal{W}} \left\| \sum_{t=1}^n \epsilon_t G_t'(\langle w, x_t \rangle) \right\| + 4C_\sigma \mathbb{E}_e \left\| \sum_{t=1}^n \epsilon_t x_t \right\|.
\]
For the first term on the left-hand side, observe that for any \( s, |G'_t(s)| \leq 2|\sigma''(s)| + 2|\sigma'(s)|^2 \leq 4C^2_\sigma \), so \( G_t \) is \( 4C^2_\sigma \)-Lipschitz. The classical scalar Lipschitz contraction inequality for Rademacher complexity (Lemma 1) therefore implies

\[
\mathbb{E}_x \sup_{w \in \mathcal{W}} \sum_{t=1}^n \epsilon_t G'_t((w, x_t)) \leq 4C^2_\sigma \mathbb{E}_x \sup_{w \in \mathcal{W}} \sum_{t=1}^n \epsilon_t \{ w, x_t \} = 4C^2_\sigma \beta \mathbb{E}_x \left\| \sum_{t=1}^n \epsilon_t x_t \right\|.
\]

Finally, by our smoothness assumption on the norm, Theorem 7 implies

\[
\mathbb{E}_x \left\| \sum_{t=1}^n \epsilon_t x_t \right\| \leq \sqrt{2\beta R^2 n}.
\]

\[\square\]

### C.2 Robust Regression

**Proof of Theorem 4.** This proof follows the same template as Theorem 3. We use Proposition 1 and Proposition 2 to conclude that whenever \((\alpha, \mu)\)-PL holds, with probability at least \(1 - \delta\) over the examples \(\{(x_t, y_t)\}_{t=1}^n\), any learning algorithm \(\hat{w}\) satisfies

\[
L_D(\hat{w}^{\text{alg}}) - L^* \leq c \cdot \mu \left( \| \nabla \mathcal{L}_n(\hat{w}^{\text{alg}}) \|_\alpha + \left( \frac{9R \| \nabla \ell \circ \mathcal{W}; x_{1:n}, y_{1:n} \|}{n} + C_\rho R \sqrt{\log(1/\delta)/n} \right) \right),
\]

where \( c > 0 \) is an absolute constant and we have used that \( \| \nabla \ell(w; x_t, y_t) \| \leq C_\rho R \) with probability 1.

**Smooth high-dimensional setup** For the general smooth norm pair setup in (22), Lemma 8 and Lemma 9 imply

\[
L_D(\hat{w}^{\text{alg}}) - L^* \leq c \cdot \frac{BC_\rho}{c_\rho} \left( \| \nabla \mathcal{L}_n(\hat{w}^{\text{alg}}) \| + \left( BR^2C_\rho \sqrt{\frac{\beta}{n}} + C_\rho R \sqrt{\frac{\log(1/\delta)}{n}} \right) \right) = \mu_h \cdot \left\| \nabla \mathcal{L}_n(\hat{w}^{\text{alg}}) \right\| + \frac{C_h}{\sqrt{n}}.
\]

Where we recall \( C_h = c \cdot \frac{BR^2C_\rho^2 \sqrt{\beta + C^2_\rho BR \sqrt{\log(1/\delta)}}}{c_\rho} \) and \( \mu_h = c \cdot \frac{BC_\rho}{c_\rho} \).

**Low-dimensional \( \ell_2 \)/\( \ell_2 \) setup** For the low-dimension \( \ell_2/\ell_2 \) pair setup in (22), Lemma 8 and Lemma 9 imply

\[
L_D(\hat{w}^{\text{alg}}) - L^* \leq c \cdot \frac{C_\rho}{2c_\rho \lambda_{\min}(\Sigma)} \left( \| \nabla \mathcal{L}_n(\hat{w}^{\text{alg}}) \|^2 + \left( BR^2C_\rho \sqrt{\frac{1}{n}} + C_\rho R \sqrt{\frac{\log(1/\delta)}{n}} \right)^2 \right) = \frac{\mu_1}{\lambda_{\min}(\Sigma)} \cdot \left\| \nabla \mathcal{L}_n(\hat{w}^{\text{alg}}) \right\|^2 + \frac{C_1}{n \cdot \lambda_{\min}(\Sigma)},
\]

where we have used that the \( \ell_2 \) norm is 1-smooth in Lemma 7. Recall that \( C_1 = c \cdot \frac{C_\rho R^4 B^2 + C^3_\rho R^2 \log(1/\delta)}{c_\rho^2} \) and \( \mu_1 = c \cdot \frac{C_\rho}{2c_\rho} \).
Lemma 7 implies and recall Lemma 8. Section 3. Lemma 9 where we have used that the \( \ell_\infty \) norm has the smoothness property with \( \beta = O(\log(d)) \) in Lemma 7. Recall that \( C_s = c \cdot \frac{4c_\rho^3 R^2 \log(d) + 4c_\rho^3 R^2 \log(1/\delta)}{c_\rho} \) and \( \mu_s = c \cdot \frac{2c_\rho s}{c_\rho} \).

\[ L_D(\tilde{w}^{\text{alg}}) - L^* \leq c \cdot \frac{2C_\rho s}{c_\rho^2 \psi_{\min}(\Sigma)} \left( \| \nabla L_n(\tilde{w}^{\text{alg}}) \|^2 + \left( BR^2 C_\rho \sqrt{\frac{\log d}{n}} + C_\rho R \sqrt{\frac{\log(1/\delta)}{n}} \right)^2 \right) \]

\[ = \frac{\mu_s \cdot s}{\psi_{\min}(\Sigma)} \cdot \| \nabla L_n(\tilde{w}^{\text{alg}}) \|^2 + \frac{s}{n} \cdot \frac{C_s}{\psi_{\min}(\Sigma)}, \]

where we have used that the \( \ell_\infty \) norm has the smoothness property with \( \beta = O(\log(d)) \) in Lemma 7. Recall that \( C_s = c \cdot \frac{4c_\rho^3 R^2 \log(d) + 4c_\rho^3 R^2 \log(1/\delta)}{c_\rho} \) and \( \mu_s = c \cdot \frac{2c_\rho s}{c_\rho} \).

Lemma 8 (GD condition for robust regression). Consider the robust regression setup of Section 3.

- When \( \|\cdot\|_2 \) are any dual norm pair, we have \( \left( 1, \frac{BC_\rho}{c_\rho} \right) \)-GD:
  \[ L_D(w) - L_D(w^*) \leq \frac{BC_\rho}{c_\rho} \| \nabla L_D(w) \| \quad \forall w \in \mathcal{W}. \]  (23)

- In the \( \ell_2/\ell_2 \) setup, we have \( \left( 2, \frac{C_\rho}{2c_\rho \psi_{\min}(\Sigma)} \right) \)-GD:
  \[ L_D(w) - L_D(w^*) \leq \frac{C_\rho}{2c_\rho \psi_{\min}(\Sigma)} \| \nabla L_D(w) \|_2^2 \quad \forall w \in \mathcal{W}. \]  (24)

- In the sparse \( \ell_\infty/\ell_1 \) setup, where \( \| w^* \|_0 \leq s \), we have \( \left( 2, \frac{2C_\rho s}{c_\rho \psi_{\min}(\Sigma)} \right) \)-GD:
  \[ L_D(w) - L_D(w^*) \leq \frac{2C_\rho s}{c_\rho \psi_{\min}(\Sigma)} \| \nabla L_D(w) \|_\infty^2 \quad \forall w \in \mathcal{W}. \]  (25)

Proof of Lemma 8.

Excess risk upper bound. To begin, smoothness of \( \rho \) implies that for any \( s, s^* \in \mathcal{S} \) we have

\[ \rho(s) - \rho(s^*) \leq \rho'(s^*) (s - s^*) + \frac{C_\rho}{2} (s - s^*)^2. \]

Since this holds point-wise, we use it to derive the following in-expectation bound

\[ L_D(w) - L_D(w^*) \leq \mathbb{E}_{x,y} [\rho((w^*, x) - y)(w - w^*, x)] + \frac{C_\rho}{2} \mathbb{E}(w - w^*, x)^2 \]

\[ = \langle \nabla L_D(w^*), w - w^* \rangle + \frac{C_\rho}{2} \mathbb{E}(w - w^*, x)^2. \]

Note however that

\[ \nabla L_D(w^*) = \mathbb{E}_{x, \zeta} [\rho'(-\zeta) x] = 0, \]

since \( \zeta \) is conditionally symmetric and \( \rho' \) is odd. We therefore have

\[ L_D(w) - L_D(w^*) \leq \frac{C_\rho}{2} \mathbb{E}(w - w^*, x)^2. \]
On the other hand, using the form of the gradient we have
\[ \langle L_D(w), w - w^* \rangle = \mathbb{E}_x \left[ \mathbb{E}_\zeta \rho'((w - w^*, x) - \zeta)(w - w^*, x) \right] \]
\[ = \mathbb{E}_x [h((w - w^*, x))(w - w^*, x)]. \]

To lower bound the term inside the expectation, consider a particular draw of \( x \) and assume \( (w - w^*, x) \geq 0 \); this is admissible because \( h \), like \( \rho' \), is odd. Then we have
\[ h((w - w^*, x))(w - w^*, x) = \frac{h((w - w^*, x))}{(w - w^*, x)} \leq c_\rho \frac{(w - w^*, x)^2}{c}, \]
where the last line follows because \( h(0) = 0 \) and \( h'(0) > c_\rho \). Since this holds pointwise, we simply take the expectation to show that
\[ \langle \nabla L_D(w), w - w^* \rangle \geq c_\rho \mathbb{E}_x (w - w^*, x)^2, \]
and consequently the excess risk is bounded by
\[ L_D(w) - L_D(w^*) \leq \frac{c_\rho}{2c_\rho} \langle \nabla L_D(w), w - w^* \rangle. \]

**Proving the GD conditions.** We now use (27) to establish the GD condition variants.

- \( \left(1, \frac{BC_\rho}{c_\rho}\right) \)-GD:

  Use Hölder’s inequality to obtain the upper bound,
  \[ \langle \nabla L_D(w), w - w^* \rangle \leq 2B \| \nabla L_D(w) \|. \]

- \( \left(2, \frac{C_\rho}{2c_\rho \lambda_{\min}(\Sigma)}\right) \)-GD:

  Begin with
  \[ L_D(w) - L_D(w^*) \leq \frac{C_\rho}{2c_\rho} \langle \nabla L_D(w), w - w^* \rangle. \]

  Using the same reasoning as in **Lemma 5**, this is upper bounded by
  \[ \leq \frac{C_\rho}{2c_\rho} \| \nabla L_D(w) \|_2 \cdot \| P_\mathcal{X}(w - w^*) \|_2, \]
  where \( P_\mathcal{X} \) denotes the orthogonal projection onto \( \text{span}(\Sigma) \).

  Recalling (26), it also holds that
  \[ \langle P_\mathcal{X} \nabla L_D(w), P_\mathcal{X}(w - w^*) \rangle = \langle \nabla L_D(w), w - w^* \rangle \geq c_\rho \mathbb{E}_x (w - w^*, x)^2 \]
  \[ = c_\rho \langle w - w^*, \mathbb{E}_x [xx^T](w - w^*) \rangle \]
  \[ = c_\rho \langle w - w^*, \Sigma(w - w^*) \rangle \]
  \[ \geq c_\rho \lambda_{\min}(\Sigma) \| P_\mathcal{X}(w - w^*) \|_2^2. \]

  Rearranging and applying Cauchy-Schwarz, we have
  \[ \| P_\mathcal{X}(w - w^*) \|_2 \leq \frac{1}{c_\rho \lambda_{\min}(\Sigma)} \cdot \| \nabla L_D(w) \|_2. \]
Combining this inequality with (28), we have

\[ L_D(w) - L_D(w^*) \leq \frac{C_\rho}{2c_\rho^2 \min(\Sigma)} \cdot \| \nabla L_D(w) \|_2^2. \]

• \( (2, \frac{2C_\rho s}{c_\rho^2 \min(\Sigma)}) \)-GD:

Using the inequality (29) from the \( \ell_2/\ell_2 \) GD condition proof above

\[ \langle \nabla L_D(w), w - w^* \rangle \geq c_\rho (w - w^*, \Sigma(w - w^*)). \]

By the assumption that \( \| w \|_1 \leq \| w^* \|_1 \), we apply Lemma 6 to conclude that 1) \( w - w^* \in C(S(w^*), 1) \) and 2) \( \| w - w^* \|_1 \leq 2\sqrt{s} \| w - w^* \|_2 \), and so

\[ \langle \nabla L_D(w), w - w^* \rangle \geq \psi_{min}(\Sigma) \| w - w^* \|_2^2. \]

Rearranging, and applying the \( \| w - w^* \|_1 \leq 2\sqrt{s} \| w - w^* \|_2 \) inequality:

\[
\begin{align*}
\| w - w^* \|_2 &\leq \frac{1}{c_\rho \psi_{min}(\Sigma)} \frac{\langle \nabla L_D(w), w - w^* \rangle}{\| w - w^* \|_2} \\
&\leq \frac{1}{c_\rho \psi_{min}(\Sigma)} \frac{\| \nabla L_D(w) \|_\infty \| w - w^* \|_1}{\| w - w^* \|_2} \\
&\leq \frac{2\sqrt{s}}{c_\rho \psi_{min}(\Sigma)} \| \nabla L_D(w) \|_\infty.
\end{align*}
\]

Finally, from (27) we have

\[
\begin{align*}
L_D(w) - L_D(w^*) &\leq \frac{C_\rho}{2c_\rho} \langle \nabla L_D(w), w - w^* \rangle \\
&\leq \frac{C_\rho}{2c_\rho} \| \nabla L_D(w) \|_\infty \| w - w^* \|_1 \\
&\leq \frac{C_\rho \sqrt{s}}{c_\rho} \| \nabla L_D(w) \|_\infty \| w - w^* \|_2.
\end{align*}
\]

Combining the two inequalities gives the final result.

\[ \square \]

Lemma 9. Let the norm \( \| \cdot \| \) satisfy the smoothness property (see Theorem 7) with constant \( \beta \). Then the gradient for robust regression satisfies the following normed Rademacher complexity bound:

\[ \mathbb{E}_\epsilon \sup_{w \in W} \left\| \sum_{t=1}^n \epsilon_t \nabla \ell(w; x_t, y_t) \right\| \leq O\left( BR^2 C_\rho \sqrt{\beta n} \right). \] (30)

Proof of Lemma 9. Let \( G_t(s) = \rho(s - y_t) \) and \( F_t(w) = \{ w, x_t \} \), so that \( \ell(w; x_t, y_t) = G_t(F_t(w)) \).

Then \( G'_t(s) = \rho'(s - y_t) \) and \( \nabla F_t(w) = x_t \), so our assumptions imply that that \( |G'_t(s)| \leq C_\rho \) and \( \| \nabla F_t(w) \| \leq R \). We apply Theorem 1 to conclude

\[ \mathbb{E}_\epsilon \sup_{w \in W} \left\| \sum_{t=1}^n \epsilon_t \nabla \ell(w; x_t, y_t) \right\| \leq 2RE_\epsilon \sup_{w \in W} \sum_{t=1}^n \epsilon_t G'_t(w, x_t) + 2C_\rho \mathbb{E}_\epsilon \left\| \sum_{t=1}^n \epsilon_t x_t \right\|. \]
For the first term on the left-hand side, we have that for any \( s \), \( |G_i''(s)| = 2|\rho''(s - y_t)| \leq 2C_\rho \), so \( G_i' \) is \( 2C_\rho \)-Lipschitz. Then the by scalar contraction for Rademacher complexity (Lemma 1),

\[
\mathbb{E}_e \sup_{w \in W} \sum_{t=1}^n \epsilon_t G_i'(\langle w, x_t \rangle) \leq 2C_\rho \mathbb{E}_e \sup_{w \in W} \sum_{t=1}^n \epsilon_t \langle w, x_t \rangle = 2C_\rho B \mathbb{E}_e \left\| \sum_{t=1}^n \epsilon_t x_t \right\|.
\]

Finally, the smoothness assumption on the norm (via Theorem 7) implies

\[
\mathbb{E}_n \left\| \sum_{t=1}^n \epsilon_t x_t \right\| \leq \sqrt{2\beta R^2 n}.
\]

\[\square\]

**Proof of Proposition 3.** Observe that Assumption 1 and Assumption 2 respectively imply that \( \| \nabla L_\ell(w^*) \| = 0 \) for the GLM and RR settings. Begin by invoking Theorem 3. It is immediate that any algorithm that guarantees \( \mathbb{E} \| \nabla \tilde{L}_n(\tilde{m}_{alg}) \| \leq 1/\sqrt{n} \) will obtain the claimed sample complexity bound (the high-probability statement Theorem 3 immediately yields an in-expectation statement due to boundedness), so all we must do is verify that such a point exists. Proposition 2 along with Lemma 7 and Lemma 9 respectively indeed imply that \( \| \nabla \tilde{L}_n(w^*) \| \leq C/\sqrt{n} \) for both settings.

For completeness, we show below that both models indeed have Lipschitz gradients, and so standard smooth optimizers can be applied to the empirical loss.

**Generalized Linear Model.** Observe that for any \((x, y)\) pair we have

\[
\| \nabla \ell(w; x, y) - \nabla \ell(w'; x, y) \|_2 = 2\| x \|_2 (\sigma(\langle w, x \rangle) - y)\sigma'(\langle w, x \rangle) - (\sigma(\langle w', x \rangle) - y)\sigma'(\langle w', x \rangle)).
\]

Letting \( f(s) = (\sigma(s) - y)\sigma'(s) \), we see that the assumption on the loss guarantees \( |f'(s)| \leq 3C_\sigma^2 \), so we have

\[
\| \nabla \ell(w; x, y) - \nabla \ell(w'; x, y) \|_2 \leq 6C_\sigma^2 R \| w - w' \|_2 \leq 6C_\sigma^2 R^2 \| w - w' \|_2,
\]

so smoothness is established.

**Robust Regression.** Following a similar calculation to the GLM case, we have

\[
\| \nabla \ell(w; x, y) - \nabla \ell(w'; x, y) \|_2 = \| x \|_2 |\rho'(\langle w, x \rangle - y) - \rho'(\langle w', x \rangle - y)|
\leq C_\rho \| x \|_2 \| w - w^* \|_2
\leq C_\rho R^2 \| w - w^* \|_2.
\]

Now let \( f(s) = (\sigma(s) - y)\sigma'(s) \), and observe that \( |f'(s)| \leq 3C_\sigma^2 \), so we have

\[
\| \nabla \ell(w; x, y) - \nabla \ell(w'; x, y) \|_2 \leq 6C_\sigma^2 R \| w - w' \|_2 \leq 6C_\sigma^2 R^2 \| w - w' \|_2.
\]

\[\square\]

**C.3 Further Discussion**

**Detailed comparison with Mei et al. (2016)** We now sketch in more detail the relation between the rates of Theorem 3 and Theorem 4 and those of Mei et al. (2016). We focus on the fast rate regime, and on the case \( R = \sqrt{d} \) (e.g., when \( x \sim N(0, I_{d \times d}) \)).
• **Uniform convergence.** Their uniform convergence bounds scale as \( O(\tau \sqrt{d/n}) \), where \( \tau \) is the sub-gaussian parameter for the data \( x \), whereas our uniform convergence bounds scale as \( O(R^2 \sqrt{1/n}) \). When \( R = \sqrt{d} \) both bounds scale as \( O(d \sqrt{1/n}) \), but our bounds do not depend on \( d \) when \( R \) is constant, whereas their bound always pays \( \sqrt{d} \).

• **Parameter convergence.** The final result of Mei et al. (2016) is a parameter convergence bound of the form \( \| \hat{w}^{\text{alg}} - w^* \|_2 \leq O\left( \frac{R^4}{\lambda_{\min}(\Sigma) n} \right) \) (see Theorem 4/6; Eqs. (106) and (96)). Our main result for the “low-dimensional” setup in Theorem 3 and Theorem 4 is an excess risk bound of the form \( L_D(\hat{w}^{\text{alg}}) - L_D(w^*) \leq O\left( \frac{R^4}{\lambda_{\min}(\Sigma) n} \right) \) which implies a parameter convergence bound of \( \| \hat{w}^{\text{alg}} - w^* \|_2 \leq \frac{R^2}{\lambda_{\min}(\Sigma) \sqrt{n}} \) (using similar reasoning as in the proof of Lemma 5 and Lemma 8). With \( \tau = R = \sqrt{d} \) and Assumptions 6 and 9 in Mei et al. (2016), we have \( \lambda_{\min}(\Sigma) = \gamma \tau^2 \), and so again both the bounds resolve to \( O\left( \frac{d}{\lambda_{\min}(\Sigma) \sqrt{n}} \right) \).

### Analysis of regularized stationary point finding for high-dimensional setting

Here we show that any algorithm that finds a stationary point of the regularized empirical loss generically succeeds obtains optimal sample complexity in the high-dimensional/norm-based setting. We focus on the generalized linear model in the Euclidean setting.

Let \( r(w) = \frac{1}{2} \| w \|_2^2 \). Define \( L_D^\lambda(w) = L_D(w) + r(w) \) and \( \tilde{L}_n^\lambda(w) = \tilde{L}_n(w) + r(w) \). We consider any algorithm that returns a point \( \tilde{w} \) with \( \nabla \tilde{L}_n^\lambda(\tilde{w}) = 0 \), i.e. any stationary point of the regularized empirical risk.

**Theorem 9.** Consider the generalized linear model setting. Let \( \tilde{w} \) be any point with \( \nabla \tilde{L}_n^\lambda(\tilde{w}) = 0 \). Suppose that \( \| w^* \|_2 = 1 \) and \( C_\sigma, R > 1 \). Then there is some absolute constant \( c > 0 \) such that for any fixed \( \delta > 0 \), if the regularization parameter \( \lambda \) satisfies

\[
\lambda > c \cdot \sqrt{\frac{R^4 C_\sigma^6}{c_\sigma^2} \cdot \frac{\log(\log(C_\sigma R n)/\delta)}{n}},
\]

then with probability at least \( 1 - \delta \),

\[
L_D(\tilde{w}) - L_D(w^*) \leq O\left( \frac{R^2 C_\sigma^4}{c_\sigma^2} \cdot \frac{\sqrt{\log(\log(C_\sigma R n)/\delta)}}{n} \right).
\]

Theorem 9 easily extends to the robust regression setting by replacing invocations of Lemma 7 with Lemma 9 and use of (18) with (27).

**Proof of Theorem 9.** Recall that \( w^* \) minimizes the unregularized population risk, and that \( \| w^* \|_2 = 1 \). The technical challenge is to apply Lemma 7 even though we lack a good a-priori upper bound on the norm of \( \tilde{w} \). We proceed by splitting the analysis into two cases. The idea is that if \( \| \tilde{w} \|_2 \leq \| w^* \|_2 \) we can apply Lemma 7 directly with no additional difficulty. On other hand, when \( \| \tilde{w} \|_2 \geq \| w^* \|_2 \) the regularized population risk satisfies the \( (2, O(1/\lambda)) \)-GD inequality, which is enough to show that excess risk is small even though \( \| \tilde{w} \|_2 \) could be larger than \( \| w^* \|_2 \).

**Case 1:** \( \| \tilde{w} \|_2 \geq \| w^* \|_2 \).
Let $\widehat{W} = \{ w \in \mathbb{R}^d \mid \| w \|_2 \geq \| w^* \|_2 \}$, so that $\widehat{w} \in \widehat{W}$. Observe that since $r(w)$ is $\lambda$-strongly convex it satisfies $r(w) - r(w^*) \leq \langle \nabla r(w), w - w^* \rangle - \frac{\lambda}{2} \| w - w^* \|^2_2$ for all $w$. Moreover, if $w \in \widehat{W}$, we have

$$\langle \nabla r(w), w - w^* \rangle \geq r(w) - r(w^*) + \frac{\lambda}{2} \| w - w^* \|^2_2 \geq 0.$$ 

Using (18) and the definition of $w^*$, along with the strong convexity of $r$, we get

$$L_D^\lambda(w) - L_D^\lambda(w^*) \leq \frac{C_\sigma}{c_\sigma} \langle \nabla L_D(w), w - w^* \rangle + \langle \nabla r(w), w - w^* \rangle - \frac{\lambda}{2} \| w - w^* \|^2_2.$$

Since $\langle \nabla L_D(w), w - w^* \rangle \geq 0$, this is upper bounded by

$$L_D^\lambda(w) - L_D^\lambda(w^*) \leq \frac{C_\sigma}{c_\sigma} \langle \nabla L_D(w), w - w^* \rangle + \langle \nabla r(w), w - w^* \rangle - \frac{\lambda}{2} \| w - w^* \|^2_2.$$

Using the non-negativity of $\langle \nabla r(w), w - w^* \rangle$ over $\widehat{W}$, and that $C_\sigma/c_\sigma > 1$, this implies

$$L_D^\lambda(w) - L_D^\lambda(w^*) \leq \frac{C_\sigma}{c_\sigma} \langle \nabla L_D(w), w - w^* \rangle - \frac{\lambda}{2} \| w - w^* \|^2_2 \quad \forall w \in \widehat{W}.$$

Applying Cauchy-Schwarz:

$$\leq \frac{C_\sigma}{c_\sigma} \| \nabla L_D^\lambda(w) \|_2 \| w - w^* \|_2 - \frac{\lambda}{2} \| w - w^* \|^2_2 \quad \forall w \in \widehat{W}.$$

Using the AM-GM inequality:

$$\leq \frac{C_\sigma^2}{c_\sigma^2 \lambda} \| \nabla L_D^\lambda(w) \|_2^2 \quad \forall w \in \widehat{W}.$$

Using that $\widehat{w} \in \widehat{W}$, and that $\nabla \tilde{L}_n^\lambda(\widehat{w}) = 0$, we have

$$L_D^\lambda(\widehat{w}) - L_D^\lambda(w^*) \leq \frac{C_\sigma^2}{c_\sigma^2 \lambda} \| \nabla L_D^\lambda(\widehat{w}) - \nabla \tilde{L}_n^\lambda(\widehat{w}) \|_2^2. \quad (31)$$

Observe that since $\widehat{w}$ is a stationary point of the empirical risk, $\nabla \tilde{L}_n(\widehat{w}) = -\lambda \widehat{w}$, and so $\| \widehat{w} \|_2 \leq \frac{1}{\lambda} \| \nabla \tilde{L}_n(\widehat{w}) \|_2 \leq \frac{2C_\sigma R}{\lambda}$ with probability 1. Thus, if we apply Lemma 10 with $B_{\text{max}} = \frac{2C_\sigma R}{\lambda}$, we get that with probability at least $1 - \delta$,

$$\| \nabla L_D^\lambda(\widehat{w}) - \nabla \tilde{L}_n^\lambda(\widehat{w}) \|_2 \leq O\left( \| \widehat{w} \|_2 R^2 C_\sigma^2 \sqrt{\frac{1}{n}} + C_\sigma R \sqrt{\frac{\log(\log(C_\sigma R/\lambda)/\delta)}{n}} \right),$$

where we have used additionally that the regularization term does not depend on data. Combining this bound with (31), and using that $\widehat{w} \in \widehat{W}$ and the elementary inequality $(a + b)^2 \leq 2(a^2 + b^2)$, we see that there exist constants $c, c' > 0$ such that

$$L_D^\lambda(\widehat{w}) - L_D^\lambda(w^*) \leq c \cdot \| \widehat{w} \|_2^2 \cdot R^2 C_\sigma \cdot \frac{1}{n} + c' \cdot \frac{R^2 C_\sigma^4}{\lambda c_\sigma^2} \cdot \frac{\log(\log(C_\sigma R/\lambda)/\delta)}{n}.$$

Expanding the definition of the regularized excess risk, this is equivalent to

$$L_D(\widehat{w}) - L_D(w^*) \leq \lambda + \| \widehat{w} \|_2^2 \left( c \cdot \frac{R^4 C_\sigma^6}{\lambda c_\sigma^2} \cdot \frac{1}{n} - \lambda \right) + c' \cdot \frac{R^2 C_\sigma^4}{\lambda c_\sigma^2} \cdot \frac{\log(\log(C_\sigma R/\lambda)/\delta)}{n}.$$
Observe that if \( \lambda > \sqrt{c \cdot \frac{R^4 C_0}{c_2^2}} \cdot \frac{1}{n} \) the middle term in this expression is at most zero. We choose

\[
\lambda > \sqrt{c \cdot \frac{R^4 C_0}{c_2^2}} \cdot \frac{\log (\log (C_\alpha R n) / \delta)}{n}.
\]

Substituting this into the expression above leads to a final bound of

\[
L_D(\bar{w}) - L_D(w^*) \leq O \left( \frac{R^2 C_\alpha^3}{c_\sigma} \cdot \sqrt{\frac{\log (\log (C_\alpha R n) / \delta)}{n}} \right).
\]

**Case 2:** \( \| \bar{w} \|_2 \leq \| w^* \|_2 \).

Recall that \( \nabla \tilde{L}_n(\bar{w}) = 0 \). This implies \( \nabla \tilde{L}_n(\bar{w}) = -\lambda \bar{w} \), and so \( \| \nabla \tilde{L}_n(\bar{w}) \|_2 \leq \lambda \| \bar{w} \|_2 \leq \lambda \). Using (18) we have

\[
L_D(\bar{w}) - L_D(w^*) \leq \frac{C_\sigma}{2c_\sigma} (\nabla L_D(\bar{w}), \bar{w} - w^*) \leq \frac{C_\sigma}{c_\sigma} \| \nabla L_D(\bar{w}) \|_2.
\]

Using the bound on the empirical gradient above, we get

\[
\| \nabla L_D(\bar{w}) \|_2 \leq \lambda + \| \nabla L_D(\bar{w}) - \nabla \tilde{L}_n(\bar{w}) \|_2.
\]

Using (12), (13), and Lemma 7, applied with \( B = 1 \), we have that with probability at least \( 1 - \delta \),

\[
\| \nabla L_D(\bar{w}) - \nabla \tilde{L}_n(\bar{w}) \|_2 \leq O \left( R^2 C_\sigma^2 \sqrt{n} \frac{\log (1/\delta)}{n} \right),
\]

and so

\[
L_D(\bar{w}) - L_D(w^*) \leq O \left( \lambda \frac{C_\sigma}{c_\sigma} + \frac{R^2 C_\sigma^3}{c_\sigma} \sqrt{n} \frac{\log (1/\delta)}{n} \right).
\]

Substituting in the choice for \( \lambda \):

\[
\leq O \left( \frac{R^2 C_\sigma^4}{c_\sigma^2} \cdot \sqrt{n} \frac{\log (\log (C_\alpha R n) / \delta)}{n} \right).
\]

**Lemma 10.** Let \( L_D \) and \( \tilde{L}_n \) be the population and empirical risk for the generalized linear model setting. Let a parameter \( B_{\max} \geq 1 \) be given. Then with probability at least \( 1 - \delta \), for all \( w \in \mathbb{R}^d \) with \( 1 \leq \| w \|_2 \leq B_{\max} \),

\[
\| \nabla L_D(w) - \nabla \tilde{L}_n(w) \|_2 \leq O \left( \| w \|_2 R^2 C_\sigma^2 \sqrt{n} + C_\sigma R \sqrt{n} \frac{\log (\log (B_{\max} / \delta))}{n} \right),
\]

where all constants are as in Assumption 1.

**Proof.** (12), (13), and Lemma 7 imply that for any fixed \( B \), with probability at least \( 1 - \delta \),

\[
\sup_{w : \| w \|_2 \leq B} \| \nabla L_D(w) - \nabla \tilde{L}_n(w) \| \leq O \left( BR^2 C_\sigma^2 \sqrt{n} + C_\sigma R \sqrt{n} \frac{\log (1/\delta)}{n} \right).
\]
Define $B_i = e^{i-1}$ for $1 \leq i \leq \lceil \log(B_{\max}) \rceil + 1$. The via a union bound, we have that for all $i$ simultaneously,

$$
\sup_{w: \|w\|_2 \leq B_i} \left\| \nabla L_D(w) - \nabla \hat{L}_n(w) \right\| \leq O \left( B_i R^2 C_\sigma^2 \sqrt{\frac{1}{n}} + C_\sigma R \sqrt{\frac{\log(\log(B_{\max})/\delta)}{n}} \right).
$$

In particular, for any fixed $w$ with $1 \leq \|w\|_2 \leq B_{\max}$, if we take $i$ to be the smallest index for which $\|w\|_2 \leq B_i$, the expression above implies

$$
\| \nabla L_D(w) - \nabla \hat{L}_n(w) \|_2 \leq O \left( \|w\|_2 R^2 C_\sigma^2 \sqrt{\frac{1}{n}} + C_\sigma R \sqrt{\frac{\log(\log(B_{\max})/\delta)}{n}} \right),
$$

since $B_i \leq e \|w\|_2$. \hfill \qed

**Analysis of mirror descent for high-dimensional setting.** Here we show that mirror descent obtains optimal excess risk for the norm-based/high-dimensional regime in Theorem 3 and Theorem 4.

Our approach is to run mirror descent with $\Psi^*$ as the regularizer. Observe that $\Psi^*$ is $\frac{1}{\beta^2}$-strongly convex with respect to the dual norm $\| \cdot \|_\ast$, and that we have $\| \nabla \ell(w; x, y) \| \leq 2C_\sigma R$ for the GLM setting and $\| \nabla \ell(w; x, y) \| \leq C_\rho R$ for the RR setting.

Focusing on the GLM, if we take a single pass over the entire dataset $\{(x_t, y_t)\}_{t=1}^n$ in order, the standard analysis for mirror descent starting at $w_1 = 0$ with optimal learning rate tuning (Hazan, 2016) guarantees that the following inequality holds deterministically:

$$
\frac{1}{n} \sum_{t=1}^n \langle \nabla \ell(w_t; x_t, y_t), w_t - w^* \rangle \leq O \left( RBC_\sigma \sqrt{\frac{\beta}{n}} \right).
$$

Since each point is visited a single time, this leads to the following guarantee on the population loss in expectation

$$
\mathbb{E} \left[ \frac{1}{n} \sum_{t=1}^n \langle \nabla L_D(w_t), w_t - w^* \rangle \right] \leq O \left( RBC_\sigma \sqrt{\frac{\beta}{n}} \right).
$$

Consequently, if we define $\bar{w}$ to be the result of choosing a single time $t \in [n]$ uniformly at random and returning $w_t$, this implies that

$$
\mathbb{E}[\langle \nabla L_D(\bar{w}), \bar{w} - w^* \rangle] \leq O \left( RBC_\sigma \sqrt{\frac{\beta}{n}} \right).
$$

Combining this inequality with (18), we have

$$
\mathbb{E}[L_D(\bar{w}) - L_D(w^*)] \leq O \left( RB \frac{C_\sigma^2}{c_\rho} \sqrt{\frac{\beta}{n}} \right).
$$

Likewise, combining the mirror descent upper bound with (27) leads to a rate of $O \left( RB \frac{C_\sigma^2}{c_\rho} \sqrt{\frac{\beta}{n}} \right)$ for robust regression. Thus, when all parameters involved are constant, it suffices to take $n = \frac{1}{\varepsilon}$ to obtain $O(\varepsilon)$ excess risk in both settings.

29
D Proofs from Section 4

Proof of Theorem 5. Let $B \in \mathbb{R}^{d \times d}$ be a matrix for which the $i$th row $B_i$ is given by $B_i = \frac{1}{\sqrt{d}}(1 - \varepsilon_i)$.

We first focus on the more technical case where $n \geq d$.

Let $n = N \cdot d$ for some odd $N \in \mathbb{N}$. We partition time into $d$ consecutive segments: $S_1 = \{1, \ldots, N\}$, $S_2 = \{N + 1, \ldots, 2N\}$ and on. The sequence of instances $x_{1:n}$ we will use will be to set $x_t = B_i$ for $t \in S_i$. Note that $\|B_i\|_2 \leq 1$, so this choice indeed satisfies the boundedness constraint.

For simplicity, assume that $y_t = -1$ for all $t \in [n]$. Then it holds that

$$
\mathbb{E}_\varepsilon \sup_{w \in W} \left\| \sum_{i=1}^n \varepsilon_i \nabla \ell(w; x_t, y_t) \right\|_2 = \mathbb{E}_\varepsilon \sup_{w \in W} \left\| \sum_{i=1}^n \varepsilon_i \mathbb{1}\{\langle w, x_t \rangle \geq 0\} x_t \right\|_2
$$

$$
= \mathbb{E}_\varepsilon \sup_{w \in W} \left\| \sum_{i=1}^d \mathbb{1}\{\langle w, B_i \rangle \geq 0\} \varphi_i B_i \right\|_2
$$

$$
= \mathbb{E}_\varepsilon \sup_{w \in W} \left\| \sum_{i=1}^d \mathbb{1}\{\langle w, B_i \rangle \geq 0\} \varphi_i \frac{1}{\sqrt{d}}(1 - \varepsilon_i) \right\|_2
$$

Using triangle inequality:

$$
\geq \mathbb{E}_\varepsilon \sup_{w \in W} \left\| \sum_{i=1}^d \mathbb{1}\{\langle w, B_i \rangle \geq 0\} \varphi_i \right\|_2 - \frac{1}{\sqrt{d}} \mathbb{E}_\varepsilon \sum_{i=1}^d |\varphi_i|
$$

$$
= \mathbb{E}_\varepsilon \sup_{w \in W} \left\| \sum_{i=1}^d \mathbb{1}\{\langle w, B_i \rangle \geq 0\} \varphi_i \right\|_2 - \frac{1}{\sqrt{d}} \mathbb{E}_\varepsilon \sum_{i=1}^d |\varphi_i|
$$

$$
\geq \mathbb{E}_\varepsilon \sum_{i=1}^d \mathbb{1}\{\text{sgn}(\varphi_i) \geq 0\} |\varphi_i|
$$

Now, for a given draw of $\varphi$, we choose $w \in W$ such that $\text{sgn}(\langle w, B_i \rangle) = \text{sgn}(\varphi_i)$. The key trick here is that $B$ is invertible, so for a given sign pattern, say $\sigma \in \{\pm1\}^d$, we can set $\tilde{w} = B^{-1}\sigma$ and then $w = \tilde{w}/\|\tilde{w}\|_2$ to achieve this pattern. To see that $B$ is invertible, observe that we can write it as $B = \frac{1}{\sqrt{d}}(11^T - I)$. The identity matrix can itself be written as $\frac{1}{d}11^T + A_1$, where $1 \notin \text{span}(A_1)$, so it can be seen that $B = \frac{1}{\sqrt{d}}((1 - \frac{1}{d})11^T - A_1)$, and that the $11^T$ component is preserved by this addition.

We have now arrived at a lower bound of $\mathbb{E}_\varphi \sum_{i=1}^d \mathbb{1}\{\text{sgn}(\varphi_i) \geq 0\} |\varphi_i|$. This value is lower bounded by

$$
\mathbb{E}_\varphi \sum_{i=1}^d \mathbb{1}\{\text{sgn}(\varphi_i) \geq 0\} |\varphi_i|
$$

$$
= \mathbb{E}_\varphi \sum_{i=1}^d \mathbb{1}\{\text{sgn}(\varphi_i) \geq 0\} |\varphi_i|
$$

30
Now, observe that since \( N \) is odd we have \( \text{sgn}(\varphi_i) \in \{ \pm 1 \} \), and so \( \mathbb{1}\{ \text{sgn}(\varphi_i) \geq 0 \} = (1 + \text{sgn}(\varphi_i))/2 \). Furthermore, since \( \varphi_i \) is symmetric, we may replace \( \text{sgn}(\varphi_i) \) with an independent Rademacher random variable \( \sigma_i \)

\[
= \mathbb{E}_\varphi \mathbb{E}_\sigma \frac{1}{2} \sum_{i=1}^d (1 + \sigma_i)|\varphi_i|
= \mathbb{E}_\varphi \frac{1}{2} \sum_{i=1}^d |\varphi_i|.
\]

Lastly, the Khintchine inequality implies that \( \mathbb{E}_\varphi |\varphi_i| \geq \sqrt{N}/2 \), so the final lower bound is \( \Omega(d\sqrt{N}) = \Omega(\sqrt{dN}) \).

In the case where \( d \geq n \), the argument above easily yields that \( \mathbb{E}_t \sup_{w \in W} \| \sum_{t=1}^n \epsilon_t \nabla \ell(w; x_t, y_t) \|_2 = \Omega(n) \).

**D.1 Proof of Theorem 6**

Before proceeding to the proof, let us introduce some auxiliary definitions and results. The following functions will be used throughout the proof. They are related by \( \text{Lemma 11} \).

\[
\xi_D(w, \gamma) = \mathbb{E}_{x \sim D} \mathbb{1}\left\{ \frac{\|w \cdot x\|}{\|w\|} \leq \gamma \right\},
\]

\[
\widehat{\xi}_n(w, \gamma) = \frac{1}{n} \sum_{t=1}^n \mathbb{1}\left\{ \frac{\|w \cdot x_t\|}{\|w\|} \leq \gamma \right\}.
\]

**Lemma 11.** With probability at least \( 1 - \delta \), simultaneously for all \( w \in W \) and all \( \gamma > 0 \),

\[
\xi_D(w, \gamma) \leq \widehat{\xi}_n(w, 2\gamma) + \frac{4}{\gamma \sqrt{n}} + \sqrt{\frac{2\log(\log(4/\gamma)/\delta)}{n}},
\]

\[
\widehat{\xi}_n(w, \gamma) \leq \xi_D(w, 2\gamma) + \frac{4}{\gamma \sqrt{n}} + \sqrt{\frac{2\log(\log(4/\gamma)/\delta)}{n}}.
\]

**Proof sketch for Lemma 11.** We only sketch the proof here as it follows standard analysis (see Theorem 5 of Kakade et al. (2009b)). The key technique is to introduce a Lipschitz function \( \zeta_\gamma(t) \):

\[
\zeta_\gamma(t) = \begin{cases} 
1 & |t| \leq \gamma \\
2 - |t|/\gamma & \gamma < |t| < 2\gamma \\
0 & |t| \geq 2\gamma
\end{cases}
\]

Observe that \( \zeta_\gamma \) satisfies \( \mathbb{1}\{|t| > \gamma\} \leq \zeta_\gamma(t) \leq \mathbb{1}\{|t| > 2\gamma\} \) for all \( t \). This sandwiching allows us to bound \( \sup_{w \in W} \{\xi_D(w, \gamma) - \widehat{\xi}_n(w, 2\gamma)\} \) (and \( \sup_{w \in W} \{\widehat{\xi}_n(w, \gamma) - \xi_D(w, 2\gamma)\} \) ) by instead bounding the difference between the empirical and population averages of the surrogate \( \zeta_\gamma \). This is achieved easily using the Lipschitz contraction lemma for Rademacher complexity, and by noting that the Rademacher complexity of the class \( \{ x \mapsto \langle w, x \rangle \mid \|w\|_2 \leq 1 \} \) is at most \( \sqrt{n} \) whenever data satisfies \( \|x_t\|_2 \leq 1 \) for all \( t \). Finally, a union bound over values of \( \gamma \) in the range \( [0, 1] \) yields the statement. \( \square \)
Proof of Theorem 6. Let the margin function \( \phi \) and \( \delta > 0 \) be fixed. Define functions \( \psi(\cdot) \), \( \phi_1(\cdot) \), and \( \phi_2(\cdot) \) as follows:

\[
\psi(\gamma) = \frac{4}{\gamma \sqrt{n}} + \sqrt{\frac{2\log(\log(4/\gamma)/\delta)}{n}}
\]

\[
\phi_1(\gamma) = \phi(2\gamma) + \psi(\gamma)
\]

\[
\phi_2(\gamma) = \phi(4\gamma) + 2\psi(2\gamma).
\]

Now, conditioning on the events of Lemma 11, we have that with probability at least \( 1 - \delta \),

\[
\mathcal{W}(\phi, \tilde{D}_n) \subseteq \mathcal{W}(\phi_1, D) \subseteq \mathcal{W}(\phi_2, \tilde{D}_n).
\]  

Consequently, we have the upper bound

\[
\sup_{w \in \mathcal{W}(\phi, \tilde{D}_n)} \| \nabla L_D(w) - \nabla \hat{L}_n(w) \|_2 \leq \sup_{w \in \mathcal{W}(\phi_1, D)} \| \nabla L_D(w) - \nabla \hat{L}_n(w) \|_2
\]

\[
\leq 4 \mathbb{E}_\epsilon \sup_{w \in \mathcal{W}(\phi_1, D)} \left\| \frac{1}{n} \sum_{t=1}^n \epsilon_t \nabla \ell(w; x_t, y_t) \right\| + 4 \sqrt{\frac{\log(2/\delta)}{n}}
\]

\[
\leq 4 \mathbb{E}_\epsilon \sup_{w \in \mathcal{W}(\phi_2, \tilde{D}_n)} \left\| \frac{1}{n} \sum_{t=1}^n \epsilon_t \nabla \ell(w; x_t, y_t) \right\| + 4 \sqrt{\frac{\log(2/\delta)}{n}},
\]  

where the second inequality holds with probability at least \( 1 - \delta \) using Lemma 4. They key here is that we are able to apply the standard symmetrization result because we have replaced \( \mathcal{W}(\phi, \tilde{D}_n) \) with a set that does not depend on data. Next, invoking the chain rule (Theorem 1), we split the Rademacher complexity term above as:

\[
\mathbb{E}_\epsilon \sup_{w \in \mathcal{W}(\phi_2, \tilde{D}_n)} \left\| \frac{1}{n} \sum_{t=1}^n \epsilon_t \nabla \ell(w; x_t, y_t) \right\| \leq 2 \mathbb{E}_\epsilon \sup_{w \in \mathcal{W}(\phi_2, \tilde{D}_n)} \left\| \frac{1}{n} \sum_{t=1}^n \epsilon_t \mathbb{I}\{ y_t \langle w, x_t \rangle \leq 0 \} \right\| + \frac{2}{n} \mathbb{E}_\epsilon \left\| \sum_{t=1}^n \epsilon_t x_t \right\|_2.
\]  

The second term is controlled by Theorem 7, which gives \( \frac{1}{n} \mathbb{E}_\epsilon \left\| \sum_{t=1}^n \epsilon_t x_t \right\|_2 \leq \frac{1}{\sqrt{n}} \). For the first term, we appeal to the fat-shattering dimension and the \( \phi_2 \)-soft-margin assumption.

Controlling \( \ast \). Observe that for any fixed \( \tilde{\gamma} > 0 \), we can split \( \ast \) as

\[
\mathbb{E}_\epsilon \sup_{w \in \mathcal{W}(\phi_2, \tilde{D}_n)} \frac{1}{n} \sum_{t=1}^n \epsilon_t \mathbb{I}\{ y_t \langle w, x_t \rangle \leq 0 \} \leq \mathbb{E}_\epsilon \sup_{w \in \mathcal{W}(\phi_2, \tilde{D}_n)} \frac{1}{n} \sum_{t=1}^n \epsilon_t \mathbb{I}\{ y_t \langle w, x_t \rangle \leq 0 \wedge \frac{|\langle w, x_t \rangle|}{\|w\|_2 \|x_t\|_2} \geq \tilde{\gamma} \}
\]

\[
\ast
\]

\[
+ \mathbb{E}_\epsilon \sup_{w \in \mathcal{W}(\phi_2, \tilde{D}_n)} \frac{1}{n} \sum_{t=1}^n \epsilon_t \mathbb{I}\{ y_t \langle w, x_t \rangle \leq 0 \wedge \frac{|\langle w, x_t \rangle|}{\|w\|_2 \|x_t\|_2} < \tilde{\gamma} \}.
\]  

For \( \ast \ast \), the definition of \( \mathcal{W}(\phi_2, \tilde{D}_n) \) implies

\[
\mathbb{E}_\epsilon \sup_{w \in \mathcal{W}(\phi_2, \tilde{D}_n)} \frac{1}{n} \sum_{t=1}^n \epsilon_t \mathbb{I}\{ y_t \langle w, x_t \rangle \leq 0 \wedge \frac{|\langle w, x_t \rangle|}{\|w\|_2 \|x_t\|_2} < \tilde{\gamma} \} \leq \sup_{w \in \mathcal{W}(\phi_2, \tilde{D}_n)} \frac{1}{n} \sum_{t=1}^n \mathbb{I}\{ \frac{|\langle w, x_t \rangle|}{\|w\|_2 \|x_t\|_2} < \tilde{\gamma} \} \leq \phi_2(\tilde{\gamma}).
\]  

(35)
The quantity \((\ast)\) can be bounded by writing it as
\[
\mathbb{E}_\xi \sup_{v \in V} \frac{1}{n} \sum_{t=1}^{n} e_t v_t,
\]
where \(V\) is a boolean concept class defined as \(V = \{(v_1(w), \ldots, v_n(w)) \in \{0,1\}^n \mid w \in \mathcal{W}(\phi_2, \bar{D}_n)\}\), where \(v_t(w) := 1\{y_t \frac{|w,x_t|}{\|w\|_2 \|x_t\|_2} \leq 0\} \cdot 1\{|w,x_t|_2 \geq \tilde{\gamma}\}\). The standard Massart finite class lemma (e.g. \cite{Mohri-2012}) implies
\[
\mathbb{E}_\xi \sup_{v \in V} \frac{1}{n} \sum_{t=1}^{n} e_t v_t \leq \sqrt{\frac{2 \log |V|}{n}}.
\]
All that remains is to bound the cardinality of \(V\). To this end, note that we can bound \(|V|\) by first counting the number of realizations of \(1\left\{\frac{|w,x_t|}{\|w\|_2 \|x_t\|_2} \geq \tilde{\gamma}\right\}, \ldots, 1\left\{\frac{|w,x_t|}{\|w\|_2 \|x_t\|_2} \geq \tilde{\gamma}\right\}\) as we vary \(w \in \mathcal{W}(\phi_2, \bar{D}_n)\). This is at most \(\binom{n}{n \phi_2(\tilde{\gamma})} \leq n^{n \phi_2(\tilde{\gamma})}\), since the number of points with margin smaller than \(\tilde{\gamma}\) is bounded by \(n \phi_2(\tilde{\gamma})\) via (32).

Next, we consider only the points \(x_t\) for which \(1\left\{\frac{|w,x_t|}{\|w\|_2 \|x_t\|_2} \geq \tilde{\gamma}\right\} = 1\). On these points, on which we are guaranteed to have a margin at least \(\tilde{\gamma}\), we count the number of realizations of \(1\left\{y_t \frac{|w,x_t|}{\|w\|_2 \|x_t\|_2} \leq 0\right\}\).

This is bounded by \(n^{O\left(\frac{1}{\tilde{\gamma}}\right)}\) due to the Sauer-Shelah lemma (e.g. \cite{Shalev-Shwartz-2014}). The fat-shattering dimension at margin \(\tilde{\gamma}\) coincides with the notion of shattering on these points, and \cite{Bartlett-1999} bound the fat-shattering dimension at scale \(\tilde{\gamma}\) by \(O\left(\frac{1}{\tilde{\gamma}^2}\right)\). Hence, the cardinality of \(V\) is bounded by
\[
|V| \leq n^{n \phi_2(\tilde{\gamma})} n^{O\left(\frac{1}{\tilde{\gamma}^2}\right)}.
\]

**Final bound.** Assembling equations (33), (34), (35), and (36) yields
\[
\sup_{w \in \mathcal{W}(\phi, \bar{D}_n)} \left\| \nabla L_{\mathcal{D}}(w) - \nabla \hat{L}_n(w) \right\|_2 \leq \hat{O}\left(1 + \sqrt{\frac{\log |V|}{n}} + \sqrt{\frac{\log(1/\delta)}{n}}\right).
\]
This is bounded by
\[
\hat{O}\left(1 + \sqrt{\frac{\log(1/\delta)}{n}}\right).
\]

The chain of inequalities above follows by observing that \(\phi_2(\tilde{\gamma}) = \phi(4\tilde{\gamma}) + 2\psi(2\tilde{\gamma})\) is bounded and thus \(\phi_2(\gamma) \leq c\sqrt{\phi_2(\gamma)}\) for some constant \(c\) independent of \(\tilde{\gamma}\). We get the desired result by optimizing over \(\tilde{\gamma}\). 

---

**E Additional Results**

**Theorem 10** (Second-order chain rule for Rademacher complexity). Let two sequences of twice-differentiable functions \(G_t : \mathbb{R}^K \to \mathbb{R}\) and \(F_t : \mathbb{R}^d \to \mathbb{R}^K\) be given, and let \(F_{t,i}(w)\) denote the \(i\)th of coordinate of
\(F_t(w)\). Suppose there are constants \(L_{F,1}, L_{F,2}, L_{G,1}, L_{G,2}\) such that for all \(1 \leq t \leq n\), \(\|\nabla G_t\|_2 \leq L_{G,1},\)
\[
\sqrt{\sum_{i,j} \|(\nabla F_{t,i})(\nabla F_{t,j})\|^2} \leq L_{F,1}, \quad \|\nabla^2 G_t\|_2 \leq L_{G,2} \text{ and } \sqrt{\sum_{k=1}^K \|\nabla^2 F_{t,k}\|_2^2} \leq L_{F,2}.
\]
Then,
\[
\frac{1}{2} \mathbb{E}_e \sup_{w \in \mathcal{W}} \left\| \sum_{t=1}^n \epsilon_t \nabla^2 (G_t(F_t(w))) \right\|_\sigma \leq L_{F,1} \mathbb{E}_e \sup_{w \in \mathcal{W}} \sum_{t=1}^n (\epsilon_t, \nabla G_t(F_t(w)))
\]
\[
+ L_{G,1} \mathbb{E}_e \sup_{w \in \mathcal{W}} \left\| \sum_{i=1}^n \epsilon_{t,i} \nabla^2 F_{t,i}(w) \right\|_\sigma
\]
\[
+ L_{F,2} \mathbb{E}_e \sup_{w \in \mathcal{W}} \sum_{t=1}^n (\tilde{\epsilon}_t, \nabla^2 G_t(F_t(w)))
\]
\[
+ L_{G,2} \mathbb{E}_e \sup_{w \in \mathcal{W}} \left\| \sum_{i=1,j=1}^n \tilde{\epsilon}_{t,i,j} \nabla F_{t,i}(w) \nabla F_{t,j}(w)^T \right\|_\sigma,
\]

where for all \(i \in [K]\), \(\nabla F_{t,i}(w)\) denotes the \(i\)th column of the Jacobian matrix \(\nabla F_t \in \mathbb{R}^{d \times K}\), \(\nabla^2 F_{t,i} \in \mathbb{R}^{d \times d}\) denotes the \(i\)th slice of the Hessian operator \(\nabla^2 F_t \in \mathbb{R}^{d \times d \times K}\), and \(\epsilon \in \{\pm 1\}^{n \times K}\) are matrices of Rademacher random variables.

As an application of Theorem 10, we give a simple proof of dimension-independent Rademacher bound for the generalized linear model setting.

**Lemma 12.** Assume in addition to Assumption 1 assume that \(|\sigma'''(s)| \leq C_\sigma\) for all \(s \in \mathcal{S}\), and suppose \(\|\cdot\|\) is any \(\beta\)-smooth norm. Then the empirical loss Hessian for the generalized linear model setting enjoys the normed Rademacher complexity bound,
\[
\mathbb{E}_e \sup_{w \in \mathcal{W}} \left\| \sum_{t=1}^n \epsilon_t \nabla^2 \ell(w; x_t, y_t) \right\|_\sigma \leq O\left( BR^3 C_\sigma^2 \sqrt{\beta} + C_\sigma^2 R^2 \sqrt{\log(d)} \sqrt{n} \right).
\] (37)

It is easy to see that the same approach leads to a normed Rademacher complexity bound for the Hessian in the robust regression setting as well. We leave the proof as an exercise.

**Lemma 13.** Assume in addition to Assumption 2 that \(|\sigma'''(s)| \leq C_\rho\) for all \(s \in \mathcal{S}\), and suppose \(\|\cdot\|\) is any \(\beta\)-smooth norm. Then the empirical loss Hessian for the robust regression setting enjoys the normed Rademacher complexity bound:
\[
\mathbb{E}_e \sup_{w \in \mathcal{W}} \left\| \sum_{t=1}^n \epsilon_t \nabla^2 \ell(w; x_t, y_t) \right\|_\sigma \leq O\left( BR^3 C_\rho \sqrt{\beta} + C_\rho R^2 \sqrt{\log(d)} \sqrt{n} \right).
\] (38)

**Proof of Theorem 10.** We start by writing
\[
\mathbb{E}_e \sup_{w \in \mathcal{W}} \left\| \sum_{t=1}^n \epsilon_t \nabla^2 (G_t(F_t(w))) \right\|_\sigma = \mathbb{E}_e \sup_{w \in \mathcal{W}} \sup_{\|u\|_2 \leq 1} \sum_{t=1}^n \epsilon_t u^T \nabla^2 (G_t(F_t(w))) u.
\] (39)

Using the chain rule for differentiation, we have for any \(u \in \mathbb{R}^n\)
\[
u^T \nabla^2 (G_t(F_t(w))) u = (\nabla F_t(w), u)^T \nabla^2 G_t(F_t(w)) (\nabla F_t(w), u) + \nabla G_t(F_t(w)), \nabla^2 F_t(w)[u, u],
\]
where \(\nabla G_t(F_t(w))\) and \(\nabla^2 G_t(F_t(w))\) denote the gradient and Hessian of \(G_t\) at \(F_t(w)\), and \(\nabla^2 F_t(w)[u, u] \in \mathbb{R}^K\) is a vector for which the \(i\)th coordinate is the evaluation of the Hessian operator for \(F_{t,i}\) at \((u, u)\). Using
this identity along with \((39)\), we get
\[
\mathbb{E}_\varepsilon \sup_{w \in \mathcal{W}} \left\| \sum_{t=1}^{n} \epsilon_t \nabla^2 (G_t(F_t(w))) \right\|_\sigma \leq \mathbb{E}_\varepsilon \sup_{w \in \mathcal{W}} \sup_{u \in \mathbb{R}^d} \left\| \sum_{t=1}^{n} \epsilon_t \langle \nabla G_t(F_t(w)), \nabla^2 F_t(w)[u, u] \rangle \right\|_\sigma + \mathbb{E}_\varepsilon \sup_{w \in \mathcal{W}} \left\| \sum_{t=1}^{n} \epsilon_t \langle \nabla F_t(w), u \rangle^T \nabla^2 G_t(F_t(w)) \langle \nabla F_t(w), u \rangle \right\|_\sigma.
\]

We bound the two terms separately.

1. **First Term:** We introduce a new function that relabels the quantities in the expression. Let \(h_1 : \mathbb{R}^{2K} \to \mathbb{R}\) be defined as \(h_1(a, b) = \langle a, b \rangle\), let \(f_1 : \mathcal{W} \times \mathbb{R}^d \to \mathbb{R}^K\) be given by \(f_1(w, u) = \nabla G_t(F_t(w))\) and \(f_2 : \mathcal{W} \times \mathbb{R}^d \to \mathbb{R}^K\) be given by \(f_2(w, u) = (\nabla^2 F_{t,k}(w))[u, u]_{k \in [K]}\). We apply the block-wise contraction lemma \textbf{Lemma 3} with one block for \(f_1\) and one block for \(f_2\) to conclude
\[
\frac{1}{2} \mathbb{E}_\varepsilon \sup_{w \in \mathcal{W}} \sup_{u \in \mathbb{R}^d} \left\| \sum_{t=1}^{n} \epsilon_t h_1(f_1(w, u), f_2(w, u)) \right\|_\sigma \leq L_{F,1} \mathbb{E}_\varepsilon \sup_{w \in \mathcal{W}} \sup_{u \in \mathbb{R}^d} \left\| \sum_{t=1}^{n} \epsilon_t f_1(w, u) \right\|_\sigma + L_{G,1} \mathbb{E}_\varepsilon \sup_{w \in \mathcal{W}} \sup_{u \in \mathbb{R}^d} \left\| \sum_{t=1}^{n} \epsilon_t f_2(w, u) \right\|_\sigma
\]
\[
\leq L_{F,1} \mathbb{E}_\varepsilon \sup_{w \in \mathcal{W}} \sup_{u \in \mathbb{R}^d} \left\| \sum_{t=1}^{n} \epsilon_t \nabla G_t(F_t(w)) \right\|_\sigma + L_{G,1} \mathbb{E}_\varepsilon \sup_{w \in \mathcal{W}} \sup_{u \in \mathbb{R}^d} \left\| \sum_{t=1}^{n} \epsilon_t \nabla^2 F_t(w)[u, u] \right\|_\sigma
\]
\[
\leq L_{F,1} \mathbb{E}_\varepsilon \sup_{w \in \mathcal{W}} \sum_{t=1}^{n} \epsilon_t \nabla G_t(F_t(w)) + L_{G,1} \mathbb{E}_\varepsilon \sup_{w \in \mathcal{W}} \left\| \sum_{t=1}^{n} \nabla^2 F_t(w)[u, u] \right\|_\sigma
\]
\[
= L_{F,1} \mathbb{E}_\varepsilon \sup_{w \in \mathcal{W}} \sum_{t=1}^{n} \epsilon_t \nabla G_t(F_t(w)) + L_{G,1} \mathbb{E}_\varepsilon \sup_{w \in \mathcal{W}} \left\| \sum_{t=1}^{n} \nabla^2 F_t(w)[u, u] \right\|_\sigma.
\]

2. **Second Term:** Let us first simplify as
\[
\langle \nabla F_t(w), u \rangle^T \nabla^2 G_t(F_t(w)) \langle \nabla F_t(w), u \rangle = \sum_{i,j=1}^{K} \langle \nabla F_t(w), u \rangle_i \nabla^2 G_t(F_t(w))_{i,j} \langle \nabla F_t(w), u \rangle_j
\]
\[
= \sum_{i,j=1}^{K} (u^T \nabla F_{t,i}(w)) \frac{\partial^2 G_t}{\partial z_i \partial z_j} (\nabla F_{t,j}(w))^T u
\]
\[
= \sum_{i,j=1}^{K} \frac{\partial^2 G_t}{\partial z_i \partial z_j} (u^T \nabla F_{t,i}(w) \nabla F_{t,j}(w))^T u,
\]
where \(\nabla F_{t,j}(w) := \nabla F_t(w)[i, j] \in \mathbb{R}^d\), and the last equality follows by observing that \(\frac{\partial^2 G_t}{\partial z_i \partial z_j}\) is scalar. We thus have
\[
\mathbb{E}_\varepsilon \sup_{w \in \mathcal{W}} \sup_{u \in \mathbb{R}^d} \sum_{t=1}^{n} \epsilon_t \langle \nabla F_t(w), u \rangle^T \nabla^2 G_t(F_t(w)) \langle \nabla F_t(w), u \rangle
\]
\[
= \mathbb{E}_\varepsilon \sup_{w \in \mathcal{W}} \sup_{u \in \mathbb{R}^d} \sum_{t=1}^{n} \epsilon_t \sum_{i,j=1}^{K} \frac{\partial^2 G_t}{\partial z_i \partial z_j} (u^T \nabla F_{t,i}(w) \nabla F_{t,j}(w))^T u.
\]
Similar to the first part, we introduce a new function that relabels the quantities in the expression. Let $h_2: \mathbb{R}^{2K^2} \to \mathbb{R}$ be defined as $h_2(a, b) = \sum_{i,j=1}^K a_{i,j} b_{i,j}$. Let $f_1: \mathcal{W} \times \mathbb{R}^d \to \mathbb{R}^{K^2}$ be given by $f_1(w, u) = (\nabla^2 G_t)(F_t(w))$ and $f_2: \mathcal{W} \times \mathbb{R}^d \to \mathbb{R}^{K^2}$ be given by $f_2(w, u) = (u^T \nabla F_t(w) \nabla F_t(w)^T)_{1, j}[K]$. We apply block-wise contraction (Lemma 3) with one block for $f_1$ and one block for $f_2$ to conclude

$$
\frac{1}{2} \mathbb{E}_{\epsilon} \sup_{u \in \mathcal{W}} \sup_{w \in \mathbb{R}^d} \frac{n}{\|u\|_2 \leq 1} \sum_{t=1}^n \epsilon_t h_2(f_1(w, u), f_2(w, u))
$$

$$
\leq L_{F, 2} \mathbb{E}_{\epsilon} \sup_{u \in \mathcal{W}} \sup_{w \in \mathbb{R}^d} \frac{n}{\|u\|_2 \leq 1} \sum_{t=1}^n \epsilon_t (f_1(w, u), f_2(w, u)) + L_{G, 2} \mathbb{E}_{\epsilon} \sup_{u \in \mathcal{W}} \sup_{w \in \mathbb{R}^d} \frac{n}{\|u\|_2 \leq 1} \sum_{t=1}^n \epsilon_t f_2(w, u)
$$

$$
\leq L_{F, 2} \mathbb{E}_{\epsilon} \sup_{u \in \mathcal{W}} \sup_{w \in \mathcal{W}} \frac{n}{\|u\|_2 \leq 1} \sum_{t=1}^n \epsilon_t \nabla^2 G_t(F_t(w)) + L_{G, 2} \mathbb{E}_{\epsilon} \sup_{u \in \mathcal{W}} \sup_{w \in \mathcal{W}} \frac{n}{\|u\|_2 \leq 1} \sum_{t=1}^n \epsilon_t t_{i,j} u^T \nabla F_t(w) \nabla F_t(w)^T u
$$

$$
= L_{F, 2} \mathbb{E}_{\epsilon} \sup_{u \in \mathcal{W}} \sup_{w \in \mathcal{W}} \frac{n}{\|u\|_2 \leq 1} \sum_{t=1}^n \epsilon_t \nabla^2 G_t(F_t(w)) + L_{G, 2} \mathbb{E}_{\epsilon} \sup_{u \in \mathcal{W}} \sum_{t=1}^n \sum_{i,j=1}^K \epsilon_t t_{i,j} \nabla F_t(w) \nabla F_t(w)^T u \|_{\sigma}.
$$

Combining the two terms gives the desired chain rule.

Proof of Lemma 12. As in Lemma 7, let $G_t(s) = (\sigma(s) - y_t)^2$ and $F_t(w) = \langle w, x_t \rangle$, so that $\ell(w; x_t, y_t) = G_t(F_t(w))$.

Observe that $G'_t(s) = 2(\sigma(s) - y_t)\sigma'(s)$, $\nabla F_t(w) = x_t$, $\nabla^2 F_t = 0$, $G''_t(s) = 2(\sigma'(s))^2 + 2y_t \sigma''(s)$, and $G'''_t(s) = 4 \sigma'(s) \sigma''(s) + 2 y_t \sigma'''(s)$, which implies that $|G'''_t(s)| \leq 6C_\sigma^2$. Using Theorem 10 with constants $L_{F, 1} = R^2$, $L_{F, 2} = 0$, $L_{G, 1} = 2C_\sigma^2$ and $L_{G, 2} = 4C_\sigma^2$, we get

$$
\mathbb{E}_{\epsilon} \sup_{u \in \mathcal{W}} \left\| \sum_{t=1}^n \epsilon_t \nabla^2 \ell(w; x_t, y_t) \right\|_{\sigma} \leq 2R^2 \mathbb{E}_{\epsilon} \sup_{u \in \mathcal{W}} \sum_{t=1}^n \epsilon_t G''_t(\langle w, x_t \rangle) + 8C_\sigma^2 \mathbb{E}_u \sup_{u \in \mathcal{W}} \left\| \sum_{t=1}^n \epsilon_t x_t \right\|_{\sigma},
$$

applying Lemma 3,

$$
\leq 12R^2 C_\sigma^2 \mathbb{E}_{\epsilon} \sup_{u \in \mathcal{W}} \sum_{t=1}^n \epsilon_t \langle w, x_t \rangle + 8C_\sigma^2 \mathbb{E}_u \sup_{u \in \mathcal{W}} \left\| \sum_{t=1}^n \epsilon_t x_t \right\|_{\sigma}
$$

$$
= 12R^2 C_\sigma^2 B \mathbb{E}_u \left\| \sum_{t=1}^n \epsilon_t x_t \right\|_{\sigma} + 8C_\sigma^2 \mathbb{E}_u \left\| \sum_{t=1}^n \epsilon_t x_t \right\|_{\sigma}.
$$

Invoking Theorem 7 and Fact 1, we have $\mathbb{E}_{\epsilon} \left\| \sum_{t=1}^n \epsilon_t x_t \right\| \leq \sqrt{2\beta R^2 n}$ and $\mathbb{E}_u \left\| \sum_{t=1}^n \epsilon_t x_t \right\|_{\sigma} \leq \sqrt{2 \log(d) R^4 n}.$

}\]
