Nearly-tight Bounds on Linear Regions of Piecewise Linear Neural Networks

Qiang Hu, Hao Zhang

Abstract

The developments of deep neural networks (DNN) in recent years have ushered a brand new era of artificial intelligence. DNNs are proved to be excellent in solving very complex problems, e.g., visual recognition and text understanding, to the extent of competing with or even surpassing people. Despite inspiring and encouraging success of DNNs, thorough theoretical analyses still lack to unravel the mystery of their magics. The design of DNN structure is dominated by empirical results in terms of network depth, number of neurons and activations. A few of remarkable works published recently in an attempt to interpret DNNs have established the first glimpses of their internal mechanisms. Nevertheless, research on exploring how DNNs operate is still at the initial stage with plenty of room for refinement. In this paper, we extend precedent research on neural networks with piecewise linear activations (PLNN) concerning linear regions bounds. We present (i) the exact maximal number of linear regions for single layer PLNNs; (ii) a upper bound for multi-layer PLNNs; and (iii) a tighter upper bound for the maximal number of linear regions on rectifier networks. The derived bounds also indirectly explain why deep models are more powerful than shallow counterparts, and how non-linearity of activation functions impacts on expressiveness of networks.

Deep neural network, input space partition, piecewise linear function, learning theory.

I. INTRODUCTION

The emergence of deep neural networks (DNN) has greatly promoted the development of artificial intelligence due to their state-of-the-art results in computer vision, speech recognition and a variety of other machine tasks [1–3]. Some popular networks proposed in recent years such as GoogleNet [4]...

Qiang Hu and Hao Zhang were with the Department of Electrical Engineering, Tsinghua University, Beijing, China, e-mail: huq16@mails.tsinghua.edu.cn.
and residual networks [5] have achieved record breaking performance on image classification. Despite unprecedented success, the design of DNNs mainly relies on empirical results without a solid theoretic basis. It’s a common view that such powerful capabilities of DNNs lie in greater depth and the use of piecewise linear activations, while the underlying reasons are still not fully investigated. Fortunately, a few of researchers endeavoring to bridge the gap between practice and theory have made great contributions to unveil the internal mechanism of DNNs in a theoretical perspective [6]–[13].

A chief concern about theoretical analysis is mathematically quantifying the expressive power of DNNs. It has been shown that deep models are exponentially efficient than shallow networks at modeling certain families of continuous functions [14]. The compositional property of DNNs enables higher layers reuse ingredients provided by lower layers to build gradually more complex function, while shallow models can only construct the target detectors based on the primitives learned by a single layer. As a result, the depth of modern neural network architectures on vision tasks always go beyond one hundred to extract complicated features from images.

A variety of activation functions also have a great influence on the modeling capabilities. Nowadays, piecewise linear functions, such as the rectifier activation \( f(x) = \max\{0, x\} \), have been mostly common choices in the design of deep models. Most of current marvelous and impressive achievements of DNNs involve piecewise linear activations. Glorot et al. (2011) have proved that rectifier activations can reduce the complexity of optimization problem compared with traditional bounded smooth activations, such as sigmoid and tanh [15]. The success of PLNNs has driven us to figure out the theoretical basis of their excellent information processing abilities.

The expressiveness of PLNNs has been intensively studied. A series of theoretical results have been proposed by showing that the input space of deep models can be partitioned into an exponential linear response regions than similar-sized shallow ones [8], [9], [12], [13]. Such analysis is based on the fact that it is itself still a piecewise linear function given a deep model that is a composition of piecewise linear function. The input space is divided into several linear regions by these piecewise linear functions and each region corresponds to a specific linear function. By counting the number of linear regions, we can quantify the expressiveness of PLNNs. The more linear regions are, the more complex functions PLNNs can model. Pacau et al. (2013) have shown that the number of linear regions partitioned by deep rectifier networks is exponentially more than that of shallow ones with the same number of hidden neurons in the asymptotic limit of layers. Such results are significantly improved by Montúfar et al. (2014) with upper and lower bounds on the maximal number of linear regions for rectifier networks and maxout networks [16] obtained. Raghu et al. (2017) further improved the upper bound for rectifier networks, and this upper bound is asymptotically close to lower bound of Montúfar el al. (2014) on...
certain conditions. Subsequently, Arora et al. (2018) improve the lower bound and provide a family of rectifier networks that achieve an exponential number of regions for fixed size and depth. Finally, Serra et al. (2018) further tighten both of upper and lower bounds on the number of linear regions for rectifier networks.

This paper extends and improves the results mentioned above by deriving the bounds on the number of linear regions for PLNNs. Our main contributions are summarized in the following lists:

- We extend the analysis of rectifier networks to PLNNs and provide the exact maximal number of linear regions as well as the corresponding asymptotic expansions. This bound grows asymptotically polynomially in the number of hidden neurons and the pieces of linear activation functions when input dimension is constant.
- We propose a tree recurrence to count the number of linear regions of deep models and derive the upper bounds for PLNNs based on the tree structure. The result indicates that the number of linear regions partitioned by deep models is exponentially efficient than shallow counterparts with the same number of hidden neurons as depth increased.
- We tighten the upper bound for rectifier networks by considering the constrains from zeroing-out properties of rectifier units. Additionally, this bound is equal to the exact maximal number of linear regions for rectifier networks when input dimension is one no matter what configuration is.

II. Preliminaries

In this paper, fully connected PLNNs $\mathcal{N}$ with $n_0$ input variables, $L$ hidden layers, and $m$ output variables are considered. Denote by $x = [x_1, x_2, \ldots, x_{n_0}]^T$ the input vector to $\mathcal{N}$, and $x \in \mathcal{X}$, where $\mathcal{X} \subseteq \mathbb{R}^{n_0}$ is an nonempty subset of $n_0$-dimension input space. Assume that each hidden layer $l \in [L]$ has $n_l$ neurons. The computation of $\mathcal{N}$ proceeds in a feed-forward way in the form of a piecewise linear (PWL) function $F_{\mathcal{N}} : \mathbb{R}^{n_0} \to \mathbb{R}^m$ given by

$$F_{\mathcal{N}}(x, \theta) = f_{L+1} \circ h_L \circ f_L \circ \cdots \circ h_1 \circ f_1(x),$$

where $f_l$ is a linear function and $h_l$ is a PWL activation function. Let $W^l \in \mathbb{R}^{n_l \times n_{l-1}}$ represents the weight matrix and $b^l \in \mathbb{R}^{n_l}$ be the bias vector assigned to hidden layer $l$. All the $W^l$ and $b^l$ compose the parameter $\theta$. Let $x^l = [x^l_1, \ldots, x^l_{n_l}]$ be the output of the $l$-th layer. Given the output from previous layer, the pre-activation of the $l$-th layer is given by

$$z^1 = f_1(x) = W_1 x + b^1,$$

$$z^l = f_l(x^{l-1}) = W^l x^{l-1} + b^l.$$
where \( \mathbf{z}^l = [z^l_1, \ldots, z^l_{n_l}]^T \) and \( z^l_i \) is weighted sum of real-valued activations \( x^l_1, \ldots, x^l_{n_l} \) of layer \( l-1 \) for \( i \in [n_l] \) and \( l > 1 \). Specifically, \( \mathbf{z}^1 \) is linear combination of input values. Applying PWL activation function \( h_i \), the activation of layer \( l \) is given by

\[
\mathbf{x}^l = h_l(\mathbf{z}^l) = [h_l(z^l_1), \ldots, h_l(z^l_{n_l})]^T.
\]

For the neuron \( i \in [n_l] \) of layer \( l \), the PWL activation function \( h_l(z^l_i) \) is written as

\[
h_l(z^l_i) = \begin{cases} 
  r_1 z^l_i + t_1, & \text{if } z^l_i \in A_1 \\
  r_2 z^l_i + t_2, & \text{if } z^l_i \in A_2 \\
  \vdots & \vdots \\
  r_p z^l_i + t_p, & \text{if } z^l_i \in A_{p+1}
\end{cases}
\]

where \( p \geq 1 \) is a constant integer representing the number of partitioned points, and \( A_1, \ldots, A_{p+1} \) are corresponding disjoint intervals satisfying \( \bigcup_{i=1}^{p+1} A_i = \mathbb{R} \). \( \{r_1, \ldots, r_{p+1}\} \) are constant slopes and \( \{t_1, \ldots, t_{p+1}\} \) are constant intercepts. Let \( \{e_1, \ldots, e_p\} \) be a set of disjoint breakpoints that partition \( \mathbb{R} \). It follows that \( A_1 = (-\infty, e_1], A_2 = (e_1, e_2], \ldots, A_{p+1} = (e_p, \infty) \). Generally, rectified linear unit (ReLU) is the most commonly used in PLNNs. Its activation function has only two pieces \( A_0 = (-\infty, 0], A_1 = (0, \infty) \) with \( h_l(z^l_i) = 0 \) and \( h_l(z^l_i) = z^l_i \), respectively. The simplified form of ReLU activation function is \( h_l(z^l_i) = \max\{0, z^l_i\} \).

Let vector \( \mathbf{n} = [n_0, n_1, \ldots, n_L] \) represent the neuron arrangement in \( \mathcal{N} \). Denote by \( \mathcal{F}_n \) the set of all the PWL functions \( \mathbb{R}^{n_0} \to \mathbb{R}^{n_L} \) computed by \( \mathcal{N} \). As considered in Montúfar et al. (2014), the number of PWL functions from \( \mathcal{F}_n \) is dependent on the structure of \( \mathcal{N} \), i.e., \( \mathbf{n} \) and the number of layers \( L \). Moreover, the functions computable from \( \mathcal{F}_n \) are determined by their number of linear regions. Given a PWL function \( f : \mathbb{R}^{n_0} \to \mathbb{R}^{n_L} \), a linear region is a maximal connected open subset of the input space \( \mathbb{R}^{n_0} \). In the next sections, we will compute bounds for the number of linear regions for PLNNs with one single hidden layer (shallow PLNNs) and PLNNs with multiple hidden layers (deep PLNNs).

In the remainder of this section, we introduce the definition of activation pattern of PLNNs. Given a fixed PLNN \( \mathcal{N} \), the pre-activation \( z^l_i \) of the \( i \)-th neuron of layer \( l \) is computed from the input vector \( \mathbf{x} \) for \( i \in [n_l] \). \( z^l_i \) further determines the form of \( h_l(z^l_i) \), namely which linear function in Eq. \((5)\) to apply. The status of each neurons can be encoded into \( p \) states based on the linear function applied. Denote by \( s^l_i \in \{1, \ldots, p+1\} \) the activation pattern of each neuron of layer \( l \) such that \( s^l_i = q(q \in \{1, \ldots, p+1\}) \) if and only if \( z^l_i \in A_q \). The activation pattern of all the neurons of layer \( l \) is then given by a vector \( s^l = [s^l_1, \ldots, s^l_{n_l}]^T \). The activation pattern of neurons up to layer \( l \leq L \) is an aggregate vector \( s_{l} = [s^1, \ldots, s^l] \). Let \( S^l \subseteq \{1, \ldots, p+1\}^{\sum_{i=1}^{n_l}} \) be the activation set that \( s_{l} \) belongs to, and \( S^L \) specifies all the possible
activation patterns of $\mathcal{N}$. The inputs located at the same linear region delimited by the functions from $\mathcal{F}_n$ correspond to the same activation pattern of $\mathcal{S}^L$.

III. Shallow PLNNs

Let us firstly discuss the number of linear regions of shallow PLNNs composing of $n_0$ input and $n_1$ hidden neurons. For every neuron $i \in [n_1]$ in hidden layer, $z^1_i$ decides which one of $p+1$ linear functions in Eq.(5) is activated. The boundaries between these $p+1$ patterns are given by the $p$ parallel hyperplanes $\{H_{i,j}\}_{j \in [p]}$ defined in $n_0$-dimension input space with $(w^1_i)^T x + b^1_i - e_j = 0$, where $w^1_i$ is the $i$-th row of $W^1$ and $b^1_i$ is the $i$-th entry of $b^1$, respectively. These parallel hyperplanes separate the input space into $p+1$ disjoint regions with each region corresponding to a distinct activation pattern. One of the linear functions in Eq.(5) is activated depending on which region $z^1_i$ located at. It follows that these hyperplanes form a hyperplane arrangement $\mathcal{A} = \{H_{i,j}\}, i \in [n_1], j \in [p]$ involving all the activation patterns of shallow PLNNs.

The number of linear regions of shallow PLNNs is equal to the number of regions delimited by the hyperplanes from $\mathcal{A}$. Formally, a region of $\mathcal{A}$ is a connected component formed by the complement $\mathbb{R}^{n_0} \setminus \left( \cup_{i \in [n_1], j \in [p]} H_{i,j} \right)$. According to Zaslavsky’s theorem [17], the maximal number of regions generated by an arrangement of $n_1$ hyperplanes in $\mathbb{R}^{n_0}$ is given by $\sum_{s=0}^{n_0} \binom{n_1}{s}$. Furthermore, this number of regions holds if and only if $\mathcal{A}$ is in general position. Unfortunately, Zaslavsky’s theorem can not be directly applied to shallow PLNNs considering of parallelisms in part of hyperplanes. It’s only valid in the special case that $p = 1$, e.g., rectifier networks with a single hidden layer [8].

As the number of output neurons has no influence on the maximal number of linear regions (See [8], Lemma2), the maximal number of linear regions of $\mathcal{A}$ is uniquely determined by $n_1$ and $p$. Denote by $\mathcal{A}_k = \mathbb{R}^{n_0} \setminus \left( \cup_{i \in [n_1]} H_{i,j} \right), k = 0, \ldots, n_1$ the subset of $\mathcal{A}$ that $j \in [p]$ when $i \leq k$ otherwise $j$ take any integer on the interval from 1 to $p$. Let $\mathcal{R}_{k}(n_0, n_1)$ be the maximal number of linear regions over $\mathcal{A}_k$. The following theorem derives the maximal number of linear regions of shallow PLNNs.

Theorem 1. Consider a single hidden layer neural network $\mathcal{N}$ with $p+1$ piecewise linear activations, $n_0$-dimension input and $n_1$ hidden neurons. The maximal number of linear regions of the functions computed by $\mathcal{N}$ is given by $\mathcal{R}_{n_1}(n_0, n_1)$ shown as follows

$$\mathcal{R}_{n_1}(n_0, n_1) = \sum_{i=0}^{n_1} \binom{n_1}{i} (p-1)^i \sum_{n=0}^{n_0-i} \binom{n_1-i}{n}. \quad (6)$$

When $n_1 \leq n_0$, $\mathcal{R}_{n_1}(n_0, n_1) = (p+1)^{n_0}$. Asymptotically, $\mathcal{R}_{n_1}(n_0, n_1)$ behaves as $\Theta \left( (p + n_1)^{n_0} \right)$ when $n_1 > n_0$ and $n_0 = O(1)$. 

November 2, 2018
Proof: See Appendix A.

Remark. See Appendix B.

The bound above suggests that non-linearity of activation functions has a great effect in the expressive power of neural network, which is not observed in the case of rectifier networks. The neural networks with more complex activation functions are considered to possess better representational abilities. In the next, the number of linear regions of deep PLNNs is discussed by making use of result in Theorem 1.

IV. DEEP PLNNs

This section mainly focus on showing the expressiveness of \( L(L \geq 2) \) layer PLNNs in terms of the number of linear regions. We propose a method of counting the number of linear regions of deep PLNNs. Upper bound on the maximal number of linear regions computable by deep PLNNs is also derived as well as its corresponding asymptotic expressions.

A. Problem Definitions

Denote by \( r^l_i \) and \( t^l_i \) the slope and the intercept of the activated linear function for every neuron of layer \( l \) for \( i \in [n_l] \) and \( l \in [L] \). It follows that \( r^l_i = r_q \) and \( t^l_i = t_q \) if and only if \( s^l_i = q \) \( (q \in \{1, \ldots, p + 1\}) \). In this way, the activation patterns are manifest in the chosen activated slopes and intercepts of hidden neurons. Aggregate all the slopes and intercepts of layer \( l \) into \( r^l = \left[ r^l_1, \ldots, r^l_{n_l} \right]^T \) and \( t^l = \left[ t_1, \ldots, t^l_{n_l} \right]^T \), respectively. The activation function of layer \( l \) can be rewritten as

\[
\text{h}_l(z^l) = \text{diag}(r^l)z^l + t^l.
\]  

(7)

Hence, the pre-activation \( z^{l+1} \) of the next hidden layer \( l + 1 \) is given by

\[
z^{l+1} = W^{l+1}x^l + b^{l+1} = W^{l+1}\text{diag}(r^l)z^l + W^{l+1}t^l + b^{l+1} = \tilde{W}^{l+1}z^l + \tilde{b}^{l+1}
\]  

(8)

where \( \tilde{W}^{l+1} = W^{l+1}\text{diag}(r^l) \) and \( \tilde{b}^l = W^{l+1}t^l + b^{l+1} \). By expanding \( x^l \), \( z^{l+1} \) is recursively rewritten as

\[
z^{l+1} = \prod_{i=1}^{l+1} \tilde{W}^i x + \sum_{i=1}^{l} \prod_{j=1}^{i} \tilde{W}^{l+1-j} \tilde{b}^{l+1-j} + \tilde{b}^{l+1}
\]  

(9)

where \( \tilde{W}^1 = W^1 \) and \( \tilde{b}^1 = b^1 \), and \( \tilde{W}^{l+1} = \prod_{i=1}^{l+1} \tilde{W}^i \) and \( \tilde{b}^{l+1} = \sum_{i=1}^{l} \prod_{j=1}^{i} \tilde{W}^{l+1-j} \tilde{b}^{l+1-j} + \tilde{b}^{l+1} \) are the equivalent coefficient matrix and the bias with respect to \( x \). The explicit form of \( f_N(x) \) is then given by

\[
f_N(x) = \tilde{W}^{L+1}x + \tilde{b}^{L+1}.
\]  

(10)
The result indicates that $f_{\mathcal{N}}(x)$ is a linear classifier dependent on $x$. As $x$ ranges over the input space, each distinct activation pattern corresponds to an equivalent linear classifier. More importantly, despite infinite number of instances $x$, the number of equivalent classifier $\mathcal{M}$ is subject to the number of activation patterns of $\mathcal{N}$. As mentioned in Appendix B, $p\sum_{l=1}^{L} n_l$ is a loosely upper bound on the maximal number of linear regions of $\mathcal{N}$. To gain a better understanding of classification ability of $\mathcal{N}$, a more precisely tight upper bound is derived in the next. In particular, rectifier networks need to be treated differently due to zeroing out operations of some hidden neurons during the feedforward transmission process.

B. Number of Linear Regions

The hyperplane arrangement $\mathcal{A}$ is slightly complicated in the case of deep PLNNs. The boundary of certain linear region of deep PLNNs up to layer $l$ is given by a series of hyperplanes $\{H_{i,j}^1, H_{i,j}^2, \ldots, H_{i,j}^l\}$ defined by $(\hat{w}_i^l)^T x + \hat{b}_i^l - e_j = 0$, where $\hat{w}_i^l$ is the $i$-th row of $\hat{W}^l$ and $\hat{b}_i^l$ is the $i$-th entry of $\hat{B}^l$ for $i \in [n_l]$ and $l \in [L]$. The explicit form of $\hat{W}_l^{l+1}$ is varied with $s_l$ for $l \in [L-1]$. The partition of input space is a recursive process. At each hidden layer, newly generated linear regions are obtained from partitioning the linear regions of previous layer. Let $\mathcal{R}^l$ be the set containing all the linear regions up to layer $l$. The linear regions of $\mathcal{R}^{l+1}$ are obtained by recursively partitioning the linear regions of $\mathcal{R}^l$. Given a linear region $R \subseteq \mathcal{R}^l$ that corresponds to a activation vector $s_l \in S^l$, it would be further partitioned by the hyperplanes $\{(\hat{w}_i^{l+1})^T x + \hat{b}_i^{l+1} - e_j = 0\}$ for $i \in [n_{l+1}]$ with $\hat{w}_i^{l+1}$ and $\hat{b}_i^{l+1}$ determined by $s_l$. Moreover, only a subset of these hyperplanes that intersect with $R$ can partition $R$. Denote by $\mathcal{N}^l_R$ the maximal number of linear regions that $R$ is delimited by the next layer. For $l \in [L-1]$, the number of linear regions up to layer $l+1$ is recursively given by

$$\mathcal{N}^{l+1} = \sum_{R \in \mathcal{R}^l} \mathcal{N}^l_R, \quad \mathcal{N}_R^0 = 1, \text{ for each region } R \subseteq \mathbb{R}^{n_0}. \quad (11)$$

The recursive formula Eq.(11) counts the number of linear region by moving along the branches of a tree rooted at $\mathcal{R}^0$, i.e., $n_0$-dimension input space. As the layer of PLNNs deepens, the height of tree increases and the number of linear regions grows exponentially with it. Based on the recurrence, the maximal number of linear regions of deep PLNNs is shown as follows.

Lemma 1. Consider an $L$ layer neural network $\mathcal{N}$ with piecewise linear activations. The maximal number of linear regions of the functions computed by $\mathcal{N}$ is $\mathcal{N}^L = \sum_{R \in \mathcal{R}^{L-1}} \mathcal{N}_R^{L-1}$, where $\mathcal{R}^{L-1}$ is the set of linear regions up to layer $L-1$, and $\mathcal{N}_R^{L-1}$ is the maximal number of linear regions that $R$ is partitioned by the hyperplanes of layer $L$. 

November 2, 2018 DRAFT
Remark. The number of linear regions is derived recursively by traversing the tree constructed layer by layer according to the PWL functions of $N$. The tree structure has an important influence on the number of linear regions generated. If subtracting a neuron from one of hidden layers, the one more close to the input layer would lead to a larger decline on the number of linear regions. It suggests that we should concentrate our neurons near the input layer to increase the expressiveness of neural networks.

In the next, we will give detailed analysis of upper bounds on the number of linear regions of rectifier networks and PLNNs based on the Lemma 1.

C. Upper Bound for Deep PLNNs

In this section, the upper bound on the number of linear regions of PLNNs is given by the following theorem. It is notable that the following result can not be applied to rectifier networks due to the potential zeroing out operations of hidden neurons.

**Theorem 2.** Consider an $L (L \geq 2)$-layer neural network $N$ with $p + 1$ piecewise linear activations, $n_l$ hidden neurons at each layer $l$, and $n_0$-dimension input. The maximal number of linear regions computed by the PWL functions of $N$ is upper bounded by

$$N^L \leq \prod_{l=1}^{L} R_{n_l} (d_l, n_l)$$

where $d_l = \min\{n_0, n_1, \ldots, n_l\}$ and $R_{n_l} (d_l, n_l)$ is given by Eq. (6).

**Proof:** See Appendix C

Remark. See Appendix D

Theorem 2 indicates that deep models are exponentially powerful in terms of expressiveness than that of shallow models. The growth of linear regions of deep models is like tree spanning as the number of leafs corresponds to the number of linear regions at the last layer. Such property can not be directly applied to rectifier networks. The outputs of nonactive neurons are zero in rectifier networks and their corresponding path in the tree is cut off without any newly linear regions generated. Moreover, the degree of freedom of the hyperplanes in the next layer would decline as well. In the next, we focus on the upper bound on the number of linear regions in the rectifier networks.

D. Upper Bound for Rectifier Networks

Rectifier networks is a special form of PLNNs. Rectifier networks with only a single hidden layer make no differences with shallow PLNNs in terms of the number of linear regions. In the case of
rectifier networks with multiple layers, counting the number of linear regions they generated should be treated differently from any other PLNNs. Serra et al. have proposed a upper bound for rectifier networks [13]. We tighten the upper bound by considering the properties of rectifier hidden units at a more detailed level.

Generally, the shapes of linear regions partitioned by the functions of deep PLNNs are classified into two types, cone and polyhedron. The space size of polyhedron is limited, while conic region stretches to infinity. It follows that conic regions always exist no matter how the parameters of hyperplanes configure as they involve the cases of infinity. In order to count the number of linear regions of rectifier networks, we need be aware that how conic regions and polyhedrons are distributed in the input space.

Lemma 2. Consider \( m \) hyperplanes in \( \mathbb{R}^{n_0} \) defined by \( \{ w_i^T x + b_i = 0 \} \), where \( w_i \in \mathbb{R}^{n_0} \) is the normal vector, \( x \) is \( n_0 \)-dimension real-valued input, and \( b_i \in \mathbb{R} \) is the bias for \( i \in [m] \). Let \( W = [w_1, \ldots, w_{n_0}] \) be the matrix containing all the normal vectors and \( r \) be the rank of \( W \). For \( m, r \geq 1 \), the maximal number of conic regions partitioned by these hyperplanes is at most \( 2 \sum_{n=0}^{r-1} (m-1)_n \).

Proof: See Appendix E.

If \( m \leq r \), the maximal number of conic regions is \( 2^m \), which is directly equal to the maximal number of linear regions. In this case, all the hyperplanes intersect with one point and all the linear regions are conic. If \( m > r \), some linear regions must be polyhedrons under the configuration that the number of linear regions is maximal as \( \sum_{n=0}^{r} (m)_n > 2 \sum_{n=0}^{r-1} (m-1)_n \), and the number of polyhedrons is simply given by \( \left( \begin{array}{c} m \\ r \end{array} \right) - \left( \begin{array}{c} m-1 \\ r-1 \end{array} \right) \).

When counting the number of linear regions of rectifier networks, the number of active hidden neurons of each layer is vital for the degree of freedom of hyperplanes of next layer. For convenience, we define an activation set \( S_l \subseteq \{0, 1, \ldots, n_l\} \) such that \( s \in S_l \) is the total number of active hidden neurons of layer \( l \). Aggregate all the activation sets into \( S = (S^1, \ldots, S^L) \). Each conic region and polyhedron correspond to specific activation patterns. These activation patterns may have the same number of active hidden neurons or not. Hence, conic regions and polyhedrons also correspond to specific number of active hidden neurons. Next lemma gives the relationship of the number of active hidden neurons between conic regions.

Lemma 3. Consider \( m \) hyperplanes partitioning \( n_0 \)-dimension input space. Each conic region has a counterpart satisfying their active hidden neurons added up to \( m \). Assume that the degree of freedom of these hyperplane is \( r \). The maximal number of active neurons a conic region corresponds to is not smaller than \( r \) when the number of conic regions is maximal.
Proof: See Appendix F

As we can see, the numbers of active hidden neurons of conic regions are complementary. Such property constrains the number of linear regions generated by rectifier networks. For example, if there is a conic regions that all the neurons are active, we must have another corresponding conic region that all the neurons are non-active.

When the number of neurons is smaller than the degree of freedom of hyperplanes, all the linear regions are conic regions. There must be a case when all the number of neurons are non-active. By taking such property into account, the upper bound on the number of linear regions for rectifier networks is given by the following theorem.

**Theorem 3.** Consider an $L$-layer rectifier networks with $n_0$-dimension input and $n_l$ hidden neurons of layer $l$. Its maximal number of linear regions is upper bounded by

$$
\sum_{(j_1,\ldots,j_L) \in J} \prod_{l=1}^{L} R(n_l, j_l)
$$

where $J = \{(j_1,\ldots,j_L) \in \mathbb{Z}^L : 0 \leq j_l \leq d_l \forall l = 1,\ldots,L\}$, $d_l = \min\{n_0, n_1 - j_1, \ldots, n_{l-1} - j_{l-1}, n_l\}$, and $R(n_l, j_l)$ is given by

$$
R(n_l, j_l) = \begin{cases} 
{n_l \choose j_l} & \text{if } n_l > d_l \\
{n_l \choose j_l} - 1_{d_l}(j_l) & \text{if } n_l \leq d_l
\end{cases}
$$

where $1_{d_l}(j_l)$ is an indicator function that $1_{d_l}(j_l) = 1$ if $j_l = d_l$ else $1_{d_l}(j_l) = 0$.

Proof: See Appendix G

This bound is tight no matter what structures of rectifier networks are when $n_0 = 1$. In this case, $d_l$ is fixed as 1 for all the layers. If $n_l \geq 2$, we can always partition $n_l + 1$ linear regions (See [13]; Theorem 7. Since we don’t need to constrain the domain of active values into $[0, 1]$, there are $n_l + 1$ linear regions when $n_l = 2$). When $n_l = 1$, there are only two conic regions and one corresponds to activation pattern that the hidden neuron outputs zero. In this case, only $n_l$ linear regions are effective. Therefore, maximal number of linear regions of rectifier networks when $n_0 = 1$ is directly given by Theorem 5

Moreover, this bound is equivalent to Serra’s result [13] if the numbers of hidden neurons for all the layers satisfying $n_l > d_l$. If $n_l \leq d_l$ for certain layers, this upper bound is more tight on account that we exclude the case that all the neurons are non-active. Though, we can still improve the bound by taking the complementary property of conic regions into consideration when $n_l > d_l$. 

November 2, 2018 DRAFT
V. DISCUSSION AND CONCLUSIONS

The complexity of functions computable by deep neural networks is studies in this paper by counting the number of linear regions of input space. We mainly focused on deep neural networks with piecewise linear activations that is widely used in deep learning with their number of linear regions discussed. We computed exact maximal number of linear regions for shallow PLNNs.

Furthermore, we showed that the growth of linear regions of deep PLNNs is like tree spanning as the linear regions are recursively partitioned layer by layer. According to such recurrence between adjacent layers, we derived the bounds on the number of linear regions for deep PLNNs. We analyzed the corresponding asymptotic expansions on the bounds as well. It indicated that the structure of neural networks has great influence on the complexity of functions computed by deep PLNNs. The neurons more close to the input layer are endowed with large weights to determine the number of linear regions. The composition of layers results in an exponential number of linear regions compared with shallow counterpart. As layers deeper, the functions computed by deep PLNNs are more expressive. This result provides another perspective on the reason of superior performance of DNNs.

Besides, we tightened the upper bound on the number of linear regions for rectifier networks. Such bound is derived based on the distribution of linear regions. We founded that conic linear regions are complementary on the number of active hidden neurons. We had to exclude the case when all the hidden neurons are non-active under certain circumstances. Hence, the bound were lowered down by taking inherent features of linear regions.

In the future works, three aspects are worth studying. Firstly, the bounds provided in this paper still have plenty of room for improvement, especially for rectifier networks due to their special properties. Secondly, how parameter space affects the number of linear regions is still unknown as parameters are assumed to be fixed in this paper. Finally, one interesting question is that how compute the expressive power of other popular neural network architecture, such as convolutional neural networks.

APPENDIX A
PROOF OF THEOREM 1

Proof: By definition, \( \mathcal{A}_k \) is equivalent to \( \mathcal{A} \) when \( k = n_1 \). Naturally, the maximal number of linear regions of \( \mathcal{N} \) is given by \( \mathcal{R}_{n_1} (n_0, n_1) \). When \( p = 1 \), \( \mathcal{R}_{n_1} (n_0, n_1) \) is directly equal to \( \sum_{n=0}^{n_0} \binom{n_1}{n} \) [8], which conforms to Theorem 1. When \( p > 1 \), parallelisms of the hyperplanes of \( \mathcal{A} \) needs to be taken into account. For proof convenience, the hyperplanes of \( \mathcal{A} \) are divided into \( n_1 \) groups based on the parallelisms, each group consisting of \( p \) parallel hyperplanes. Generally, we can only select at most \( n_1 \) mutually non-parallel hyperplanes from \( \mathcal{A} \). Assume that these \( n_1 \) non-parallel hyperplanes are in general.
position, which form an hyperplane arrangement $\mathcal{A}'$ with the maximal number of linear regions equal to
$$\sum_{n=0}^{n_1} \binom{n_1}{n}.$$ If adding a new hyperplane to $\mathcal{A}'$, it will intersect with at most $n_1 - 1$ hyperplanes as it must parallel to one of hyperplanes in $\mathcal{A}'$. Each intersection is a $(n_0 - 2)$-dimension hyperplane inside the intersected hyperplane. The maximal number of newly partitioned linear regions generated by introducing a new hyperplane is exactly the same with the maximal number of linear regions of the $n_1 - 1$ hyperplanes in $(n_0 - 1)$-dimensional space with the parallel hyperplane removed. If adding all the remaining $p - 1$ parallel hyperplanes to $\mathcal{A}'$, newly generated regions are at most $(p - 1)R_0(n_0 - 1, n_1 - 1)$.

Another $n_1 - 1$ groups of parallel hyperplanes in $\mathcal{A}$ can process in a similar way. Adding these groups one by one, we obtain a recurrence relation as follows
$$R_k(n_0, n_1) = \sum_{n=0}^{n_0} \binom{n_1}{n} + \sum_{i=0}^{k-1} (p-1)R_{i}(n_0 - 1, n_1 - 1)$$
for $k = 0, \ldots, n_1$. Then, $R_{n_1}(n_0, n_1)$ is recursively derived by substituting $k$ by $n_1$. Next, we will show that the explicit form of $R_k(n_0, n_1)$ is given by
$$R_k(n_0, n_1) = \sum_{i=0}^{k} \binom{k}{i} (p-1)^i \sum_{n=0}^{n_0} \binom{n_1-i}{n}$$
by induction.

**Base case** $k = 0$. The $n_0$-dimension input space is delimited by $n_1$ hyperplanes without parallelism constrain. The maximal number of linear regions in this case is directly given by $\sum_{n=0}^{n_0} \binom{n_1}{n}$, which is equal to $R_0(n_0, n_1)$. Hence, the base case holds.

**Induction step.** Assume that $R_{k-1}(n_0, n_1)$ satisfies the formula in Eq. (16). Based on the recurrence relation in Eq. (15), $R_k(n_0, n_1)$ is written as
$$R_k(n_0, n_1) = \sum_{n=0}^{n_0} \binom{n_1}{n} + \sum_{i=0}^{k-1} \sum_{j=0}^{i} \binom{i}{j} (p-1)^{j+1} \sum_{n=0}^{n_0-1-j} \binom{n_1-1-j}{n}$$
$$= \sum_{n=0}^{n_0} \binom{n_1}{n} + \sum_{i=0}^{k-1} \sum_{j=i}^{k-1} \binom{j}{i} (p-1)^{i+1} \sum_{n=0}^{n_0-1-i} \binom{n_1-1-i}{n}.$$ 

The coefficient $\sum_{j=i}^{k-1} \binom{j}{i}$ is given by
$$\sum_{j=i}^{k-1} \binom{j}{i} = \binom{i+1}{i+1} + \binom{i+1}{i} + \binom{i+2}{i} + \cdots + \binom{k-1}{i}$$
$$= \binom{i+2}{i+1} + \binom{i+2}{i} + \cdots + \binom{k-1}{i} = \binom{k}{i+1}. \quad (18)$$
Applying the result above, \( R_k(n_0, n_1) \) can be further written as
\[
R_k(n_0, n_1) = \sum_{n=0}^{n_0} \binom{n_1}{n} + \sum_{i=1}^{k} \binom{k}{i} (p-1)^i \sum_{n=0}^{n_0-i} \binom{n_1-i}{n}
\]
\[
= \sum_{i=0}^{k} \binom{k}{i} (p-1)^i \sum_{n=0}^{n_0-i} \binom{n_1-i}{n},
\]
which finishes the proof.

Next, we derive asymptotic expansions of \( R_{n_1}(n_0, n_1) \) on condition that \( n_0 = O(1) \). Substitute \( k \) by \( n_1 \), and \( R_{n_1}(n_0, n_1) \) is given by
\[
R_{n_1}(n_0, n_1) = \sum_{i=0}^{n_1} \binom{n_1}{i} (p-1)^i \sum_{n=0}^{n_0-i} \binom{n_1-i}{n},
\]
(19)

When \( n_1 \leq n_0 \), \( \sum_{n=0}^{n_0-i} \binom{n_1-i}{n} \) is bounded by \( n_1 - i \) and we have \( \sum_{n=0}^{n_1-i} \binom{n_1-i}{n} = 2^{n_1} \). Applying the result to Eq. (20), it follows that \( R_{n_1}(n_0, n_1) = (p+1)^{n_1} \).

When \( n_1 > n_0 \), we’ll show that \( R_{n_1}(n_0, n_1) \) behaves asymptotically as \( \Theta((p + n_1)^{n_0}) \). According to Pascanu’s result ( [8], Proposition 6), it follows that \( \sum_{n=0}^{n_0} \binom{n_1}{n} = \Theta(n_1^{n_0}) \). Asymptotically, \( R_{n_1}(n_0, n_1) \) behaves as
\[
R_{n_1}(n_0, n_1) = \sum_{i=0}^{n_0} \binom{n_1}{i} (p-1)^i \Theta((n_1-i)^{n_0-i})
\]
(21)

Furthermore, \( R_{n_1}(n_0, n_1) \) is bounded by
\[
\sum_{i=0}^{n_0} \binom{n_1}{i} (p-1)^i \Theta((n_1-i)^{n_0-i}) \leq R_{n_1}(n_0, n_1) \leq \sum_{i=0}^{n_0} \binom{n_1}{i} (p-1)^i \Theta((n_1)^{n_0-i})
\]
(22)
The upper and lower bound in Eq. (22) can be further written as
\[
\Theta((p-1+n_1-n_0)^{n_0}) \leq R_{n_1}(n_0, n_1) \leq \Theta((p-1+n_1)^{n_0})
\]
(23)

Since \( n_0 = O(1) \), it follows that \( R_{n_1}(n_0, n_1) = \Theta((p + n_1)^{n_0}) \).

**APPENDIX B**

**ANALYSIS OF THEOREM 1**

Intuitively, the maximal number of linear regions delimited by the PWL functions computed by any PLNN with a total of \( n \) hidden neurons and \( p+1 \) piece activation functions is upper bounded by \( (p+1)^n \). The derived bound above indicates that the number of linear regions partitioned by a finite set of PWL functions of shallow PLNNs actually grows polynomially in \( n \) and \( p \) if \( n_0 \) is constant, instead of growing exponentially in \( p \) and \( n \). The reason of polynomial constrain results from linear dependence of normal vectors of the hyperplanes from \( A \) when the number of hyperplanes is large than the dimension of input space.
**Proposition 1.** Consider a single hidden layer neural network $\mathcal{N}$ with $p+1$ piecewise linear activations, $n_0$-dimension input and $n$ hidden neurons. Its maximal number of linear regions is equal to $(p+1)^n$ if and only if normal vectors of hyperplanes in hyperplane arrangement are linearly independent.

**Proof:** Suppose that, if the normal vectors of the hyperplanes are linearly dependent, the number of linear regions is still upper bounded by $(p+1)^n$. Denote by $\{w_1, \ldots, w_n\} \subseteq \mathbb{R}^{n_0}$ and $\{\theta_1, \ldots, \theta_n\} \subseteq \mathbb{R}$ the corresponding weight vectors and biases. Let binary vector $v \in \{0, 1\}^n$ represent a specific activation pattern of $\mathcal{N}$. Since there are $(p+1)^n$ activation patterns, we have $(p+1)^n$ different configurations of $v$. Given a input vector $x \in \mathbb{R}^{n_0}$, the hyperplane arrangement of $\mathcal{N}$ is equivalent to

$$
\begin{pmatrix}
 w_1^T & \theta_1 - e_1 \\
 w_1^T & \theta_1 - e_2 \\
 \vdots & \vdots \\
 w_1^T & \theta_1 - e_p \\
 \vdots & \vdots \\
 w_n^T & \theta_n - e_p \\
\end{pmatrix}
\begin{pmatrix}
 x \\
 1 \\
\end{pmatrix}
= v,
$$

(24)

where $v \in \mathbb{R}^p$ determines the activation pattern with $v_i = 1$ if and only if $v_i \geq 0$ for $i \in [pm]$. Furthermore, there exits a set of $(p+1)^n$ input vectors $\{x_1, \ldots, x_{(p+1)^n}\}$ to configure $(p+1)^n$ different binary vectors, which is given by

$$
\begin{pmatrix}
 w_1^T & \theta_1 - e_1 \\
 w_1^T & \theta_1 - e_2 \\
 \vdots & \vdots \\
 w_1^T & \theta_1 - e_p \\
 \vdots & \vdots \\
 w_n^T & \theta_n - e_p \\
\end{pmatrix}
\begin{pmatrix}
 x_1 & x_2 & \ldots & x_{(p+1)^n} \\
 1 & 1 & \ldots & 1 \\
\end{pmatrix}
= (v_1 \ldots v_{(p+1)^n}).
$$

(25)

Since $\{(w_1^T, \theta_i - e_1), \ldots, (w_i^T, \theta_i - e_p)\}$ represent $p$ parallel non-overlapped hyperplanes, the corresponding $p+1$ binary vectors must be mutually different. Therefore, the configuration above is equivalent to select $n$ different normal vectors to configure $2^n$ different binary vectors as follows

$$
\begin{pmatrix}
 w_1^T & \theta_1 \\
 w_2^T & \theta_2 \\
 \vdots & \vdots \\
 w_n^T & \theta_n \\
\end{pmatrix}
\begin{pmatrix}
 x_1 & x_2 & \ldots & x_{2^n} \\
 1 & 1 & \ldots & 1 \\
\end{pmatrix}
= (v_1 \ldots v_{2^n}).
$$

(26)
As \{\mathbf{w}_1, \ldots, \mathbf{w}_n\} are linearly dependent, one of normal vectors would be linear combination of other normal vectors. Without loss of generality, we assume that

\[ \mathbf{w}_n = \sum_{i=1}^{n-1} \alpha_i \mathbf{w}_i \]  

(27)

for \{\alpha_1, \ldots, \alpha_{n-1}\} \subseteq \mathbb{R}. As a consequence, the \(n\)-th component of \(\mathbf{v}_i\) is written as

\[ v_{i,n} = \sum_{j=0}^{n-1} \alpha_j v_{i,j} + \tilde{\theta} \]  

(28)

where \(\tilde{\theta} = \theta_n - \sum_{j=0}^{n-1} \alpha_j \theta_j\) and \(i \in [2^n]\). Since the values of \(v\) capture all the possible combinations of the signs of all the components of \(\mathbf{v}_i\), we can choose the \(\mathbf{v}_i\) such that \(\alpha_j v_{i,j} \geq 0\) if \(\tilde{\theta} \geq 0\) or \(\alpha_j v_{i,j} < 0\) if \(\tilde{\theta} < 0\) for \(1 \leq j \leq m\). It means that \(\mathbf{v}_i\) would no longer take on \(2^m\) activation patterns no matter what the configuration of \{\(\mathbf{x}_1, \ldots, \mathbf{x}_{2^n}\}\) is, which contradicts to our assumption.

**Remark.** The maximal number of linearly independent \(n\)-dimension vectors is equal to \(n\). Some normal vectors in the hyperplane arrangement must be linearly dependent when the number of hidden neurons exceeds \(n\). In this case, exponential upper bound for the number of linear regions isn’t able to reach. Besides, the parallelism of the hyperplanes also lowers the number of possible linear regions. The underlying reason of polynomial upper bound is the linearly dependence and the parallelism of hyperplanes in the arrangement, which constrains the degree of freedom of parameter space.

**APPENDIX C**

**PROOF OF THEOREM 2**

**Proof:** According to Lemma 1, linear regions of deep PLNNs are partitioned recursively layer by layer. Each linear region of a specific layer is partitioned by a subset of the hyperplanes of next layer. Bearing this principle in mind, we can construct a recurrence to upper bound on the number of linear regions of deep PLNNs.

For a single layer, the maximal number of linear regions is exactly given by \(R_{n_l}(n_0, n_1)\). Consider the case of multiple layers with \(l \in [L]\). Suppose that \(R\) is a linear region of layer \(l\) that a specific activation vector \(\mathbf{s}_l \in \mathcal{S}^l\) corresponds to. \(R\) would be partitioned by a subset of \(p \times n_l\) hyperplanes of layer \(l+1\) that defined by \(\{ (\hat{\mathbf{w}}_{i}^{l+1})^T \mathbf{x} + \hat{b}_{i}^{l+1} - e_j = 0 \} \) for \(i \in [n_l]\) and \(j \in [p]\). Some hyperplanes may not intersect with the interior of \(R\). The form of \((\hat{\mathbf{w}}_{i}^{l+1}, \hat{b}_{i}^{l+1})\) is determined by the activation pattern of previous layer. Each activation pattern corresponds to a distinct pair of \((\hat{\mathbf{w}}_{i}^{l+1}, \hat{b}_{i}^{l+1})\). The upper bound on the number of linear regions partitioned by these hyperplanes is attained from Theorem 1. Moreover, the degree of freedom of these hyperplanes is constrained by the rank of \(\hat{\mathbf{W}}^{l+1}\). Let \(d_{l+1}\) be the rank of
\( \mathbf{W}^{l+1} \) and \( d_{l+1} = \min\{n_0, n_1, \ldots, n_{l+1}\} \). Hence, \( R \) has at most \( R_{n_{l+1}}(d_{l+1}, n_{l+1}) \) subregions, where \( R_{n_{l+1}}(d_{l+1}, n_{l+1}) \) is computed from Eq.\((6)\). The recurrence between different layers is written as

\[
\mathcal{N}^l \begin{cases} \leq R_{n_{l}}(d_{l}, n_{l}) \times \mathcal{N}^{l-1} \quad \text{if} \quad 2 \leq l \leq L, \\
= R_{n_{1}}(d_{l}, n_{1}) \quad \text{if} \quad l = 1.
\end{cases}
\] (29)

By unpacking the recurrence, the upper bound on the number of linear regions up to layer \( L \) is given by

\[
\mathcal{N}^L \leq \prod_{l=1}^{L} R_{n_{l}}(d_{l}, n_{l}),
\] (30)

which gives the result in Theorem 2.

\[ \blacklozenge \]

**APPENDIX D**

**ANALYSIS OF THEOREM 2**

Based on the upper bound derived in Theorem 2, we will derive its asymptotic expansions to illustrate key factors that impact the number of linear regions computable by deep models. The comparison between deep models and shallow models is also given to show powerful expressiveness of deep models.

**Lemma 4.** For \( n_l \geq d_l \geq 1 \), \( R_{n_l}(d_l, n_l) \) given by Eq.\((6)\) is upper bounded by

\[
R_{n_{l}}(d_{l}, n_{l}) \leq [p - 1 + e (n_{l} - d_{l} + 1)]^{d_{l}}.
\] (31)

**Proof:** According to Anthony et al. Theorem 3.7 [7], we have

\[
\sum_{i=0}^{d} \binom{m}{i} < \left( \frac{em}{d} \right)^d
\] (32)

for \( m \geq d \geq 1 \). Applying this theorem, \( R_{n_{l}}(d_{l}, n_{l}) \) can be rewritten as

\[
R_{n_{l}}(d_{l}, n_{l}) \leq \sum_{i=0}^{d_{l}-1} \binom{d_{l}}{i} (p - 1)^i \left[ e(n_{l} - i) \right]^{d_{l}-i} + (p - 1)^{d_{l}}
\]

\[
\leq \sum_{i=0}^{d_{l}-1} \binom{d_{l}}{i} (p - 1)^i [e(n_{l} - d_{l} + 1)]^{d_{l}-i} + (p - 1)^{d_{l}}
\]

\[
= [p - 1 + e (n_{l} - d_{l} + 1)]^{d_{l}}
\] (33)

for \( n_l \geq d_l \geq 1 \).

Substituting the bound into Eq.\((30)\), and \( \mathcal{N}^L \) is upper bounded by

\[
\mathcal{N}^L \leq \prod_{l=1}^{L} [p - 1 + e (n_{l} - d_{l} + 1)]^{d_{l}} \leq \left[ p - 1 + \sum_{l=1}^{L} e (n_{l} - d_{l} + 1) / L \right]^{\sum_{l=1}^{L} d_{l}}.
\] (34)
Define the effective length as $\bar{L} = \frac{1}{n_0} \sum_{i=1}^{L} d_i$, and let $N = \sum_{i=1}^{L} n_i$ be the total number of hidden neurons. It follows that the upper bound of $N^L$ is rewritten as

$$N^L \leq \left[ p - 1 + e \left( \frac{N}{L} - n_0 \bar{L}/L + 1 \right) \right]^{L n_0}.$$  \hfill (35)

Consider a shallow PLNN with $p$ piecewise linear activations, $N$ hidden neurons and $n_0$-dimension input. According to Lemma 4, its number of linear regions is upper bounded by

$$N^1 \leq \left[ p - 1 + e \left( N - n_0 + 1 \right) \right]^{n_0}.$$  \hfill (36)

Despite the same number of hidden neurons, deep models can generate much more linear regions than their shallow counterparts as shown above. The expressiveness of deep models grows exponentially over that of shallow models as the layer $L$ increases. The power of deep models lies in non-linearity introduced by hidden units layer by layer.

A key insight from Theorem 2 is that the degree of freedom of hyperplanes is non-increasing and even decreasing during recursive partition process. It occurs that $d_l$ is limited by the number of neurons of current and previous layers. The performances of deep PLNNs are sensitive to the positions of layers with small number of hidden neurons as the degrees of freedom of hyperplanes of all the next layers are constrained by previous ones. It’s in accordance with the conclusion in Lemma 1. Therefore, the structure of neural networks greatly affects their expressiveness. We should aggregate more neurons into the layers close to input in order to avoid a sharp decline in the number of linear regions when designing neural networks. In the next, we discuss an example illustrating the asymptotic expansions of the bound in Eq.(35). Details are given in the following proposition.

**Proposition 2.** Consider a deep neural network and a shallow neural network both with $n_0 = O(1)$ inputs, $m = O(1)$ outputs. Assume that deep model has $L(L \geq 2)$ hidden layers of $n(n \geq n_0)$ neurons and shallow model has $k n$ neurons. Asymptotically, the maximal ratio of the number of linear regions to the number of parameters of deep model behaves as

$$O \left( \left( \frac{p + n}{Ln} \right)^{L n_0} \right).$$  \hfill (37)

In the case of shallow model, the ratio is given by

$$\Theta \left( \frac{p + L n}{Ln} \right)^{n_0}.$$  \hfill (38)

**Proof:** According to Theorem 1 and Theorem 2, $N^L$ of deep model behaves asymptotically as $O \left( \left( p + n \right)^{L n_0} \right)$. For the shallow model, $N^1$ is given by $\Theta \left( \left( p + k n \right)^{n_0} \right)$ based on Theorem 1. The numbers of parameters of deep model and shallow model are $\Theta(k n^2)$ and $\Theta(k n)$, respectively (See Pascanu et al.)
Proposition 7). Combining these asymptotic expansions, the ratios of the number of linear regions to the number of parameters for shallow model and deep model are $O\left(\frac{(p+n)^{L_{n_0}}}{Ln^2}\right)$ and $\Theta\left(\frac{(p+Ln)^{n_0}}{L}\right)$.

**Remark.** Since $p$ and $n$ are independent, we can analyze the asymptotic expansions above by fixing $p$. The ratio of deep model is then rewritten as $O\left(n^{L_{n_0}} - 2\right)$. The ratio of shallow model is $\Theta\left(\frac{(n_{L_{n_0}} - 1)}{n}ight)$.

We see that the number of linear regions generated by the functions of deep model is exponential in $L$, while the ratio of shallow model is a polynomial of $L$ with its degree equal to $n_0$. When the number of parameters is fixed, deep models are far more powerful than shallow models in terms of expressiveness.

**APPENDIX E**

**PROOF OF LEMMA 2**

**Proof:** We prove the lemma by induction. Denote by $C(m, r)$ be the maximal number of conic regions that $m$ hyperplanes partition with $r$ degree of freedom.

**Base case.** When $r = 1$ or $m = 1$, it is clear that $C(m, 1) = 2$ for $m \geq 1$ and $C(1, r) = 2$ for $r \geq 1$.

**Induction step.** Assume that such claim is true when the number of hyperplanes is smaller than or equal to $m$ with any degree of freedom lower than or equal to $r$. Suppose that we have $m$ hyperplanes with the degree of freedom equal to $r$ partitioning input space and the number of conic regions is equal to $C(m, r)$. Introduce a new hyperplane, and it will intersect at most $m$ hyperplanes. Each intersection is a hyperplane within the intersected hyperplane. The degree of freedom of $m$ intersections are equal to $r - 1$. The number of newly generated conic regions is exactly the number of conic regions defined by $m$ intersection. The total number of conic regions is given by

$$C(m + 1, r) = C(m, r) + C(m, r - 1)$$

$$= 2 \sum_{n=0}^{r-1} \binom{m-1}{n} + \sum_{n=0}^{r-2} \binom{m-1}{n}$$

$$= 2 \left[ \binom{m}{0} + \sum_{n=1}^{r-1} \left( \binom{m-1}{n} + \binom{m-1}{n-1} \right) \right] = 2 \sum_{n=0}^{r-1} \binom{m+1}{n}. \quad (39)$$

It indicates that the inductive hypothesis is true for $m, r \geq 1$.

**APPENDIX F**

**PROOF OF LEMMA 3**

**Proof:** Denote by $w_i \in \mathbb{R}^{n_0}$ and $b_i \in \mathbb{R}$ the normal vector and the bias for $i \in [m]$. Given an input $x$ in general position, the activation pattern is determined by a set of linear inequalities that certain hidden neuron is active if $w_i^T x + b_i > 0$ otherwise outputs zero. Suppose that $x$ belongs to one of conic regions and its corresponding number of active neurons is equal to $m_1$. For $\alpha \in \mathbb{R}^+$, $\alpha x$ also belongs to the
conic region, and we have $\alpha w_j^T x + b_i > 0$ for $j \in [m_1]$. Therefore, $m_1$ linear inequalities must satisfy $w_j^T x > 0$. If we flip the sign of every element of $x$, $m_1$ linear inequalities is converted to $w_j^T x < 0$. The remaining $m - m_1$ linear inequalities are larger than zero. The conic region these linear inequalities correspond to has $m - m_1$ active hidden neurons. As a result, every conic region has a counterpart with their numbers of active hidden neurons added up to $m$.

Additionally, the maximal number of active neurons a conic region corresponds to must not smaller than $r$. According to Lemma 2, the maximal number of conic regions partitioned by these hyperplane is given by $2 \sum_{n=0}^{r-1} \binom{m-1}{n}$. It can be rewritten as

$$2 \sum_{n=0}^{r-1} \binom{m-1}{n} = \sum_{n=0}^{r-1} \binom{m}{r-1} + \binom{m-1}{r-1}. \quad (40)$$

If maximal number of active neurons is smaller than $r$, the number of conic regions is at most $\sum_{n=0}^{r-1} \binom{m}{r-1}$. Apparently, it is smaller than Eq. (40), which contradicts to Lemma 2. Hence, the maximal number of active neurons lower bounded by $r$. Conversely, the minimal number of active neurons is upper bounded by $m - r$.

**APPENDIX G**

**PROOF OF THEOREM 3**

According to Lemma 1, the upper bound on the number of linear regions of deep PLNNs is obtained by recursively bounding the number of subregions within a linear region. Each linear region corresponds to a specific activation pattern. The biggest difference between deep PLNNs and rectifier networks is that the number of active hidden neurons of rectifier networks would greatly affect the degree of freedom of the hyperplanes in the next layers. The information flow is cut off once hidden neurons are non-active and output zero. As a result, the parameters of next layers aren’t sufficient to satisfy the degree of freedom in the previous layers. In particular, if all the hidden neurons of certain layer is non-active, information flow is completely cut off. We shall exclude such case when counting the number of linear regions of rectifier networks. Hence, in order to upper bound the number of linear regions, we need to activate as many hidden neurons as possible. Meanwhile, Lemma 3 implies that the linear region corresponds to $|S^l| = n_l$ must have a counterpart that $|S^l| = 0$ when $n_l \leq d_l$. Bear these in mind, we recursively bound the number of linear regions of rectifier networks in the next.

Assume that the degree of freedom of hyperplanes at layer $l$ is $d_l$, and $d_l = \min\{n_0, d_1, \ldots, d_{l-1}, n_l\}$. The number of linear regions partitioned by these $n_l$ hyperplanes within a certain region is at most $\sum_{j=0}^{d_l} \binom{n_l}{j}$. Let $R(n_l, j), 0 \leq j \leq n_l$ be the number of linear regions with the same activation set that $|S^l| = n_l - j$. For each $|S^l| = n_l - j$, the number of linear regions is at most $\binom{n_l}{n_l - j}$. To activate as
many neurons as possible, each linear regions are assumed to have the highest allowable $|S^l|$. On account that the total number of linear regions is given by $\sum_{j=0}^{d_l} \binom{n_l}{j}$, the number of active hidden neurons is maximized by constraining the range over $j$ from 0 to $d_l$ and simply assigning $\binom{n_l}{n_l-j}$ linear regions with $|S^l| = n_l - j$. However, the linear region that $|S^l| = n_l$ must have a corresponding conic region that $|S^l| = 0$ when $n_l \leq d_l$. We must exclude the case that all the hidden neurons are non-active. As a result, $R(n_l, j)$ is given by

$$R(n_l, j) = \begin{cases} \binom{n_l}{j} & \text{if } n_l > d_l \\ \binom{n_l}{j} - 1_{d_l}(j) & \text{if } n_l \leq d_l \end{cases}$$

(41)

where $\binom{n_l}{n_l-j} = \binom{n_l}{j}$ and $1_{d_l}(j)$ is an indicator function that $1_{d_l}(j) = 1$ if $j = d_l$ else $1_{d_l} = 0$. For each $j$, it takes value from 0 to $d_l$. The degree of freedom of next layer $d_{l+1}$ is given by $\min\{d_l, n_l - j, n_{l+1}\}$.

Denote $j$ of layer $l$ by $j_l$. The number of active hidden neurons is $n_l - j_l$ and $(n_1 - j_1, \ldots, n_L - j_L) \in S$. Hence, $\prod_{l=1}^{L} R(n_l, j_l)$ is corresponding maximal number of linear regions under such activation. Adding up all the possible combinations of $(j_1, \ldots, j_L)$, we have

$$\sum_{(j_1, \ldots, j_L) \in J} \prod_{l=1}^{L} R(n_l, j_l)$$

(42)

where $J = \{(j_1, \ldots, j_L) \in \mathbb{Z}^L : 0 \leq j_l \leq d_l \forall l = 1, \ldots, L\}$ is a subset of $S$ with $d_l = \min\{n_0, n_1 - j_1, \ldots, n_{l-1} - j_{l-1}, n_l\}$.
