Testing Halfspaces over Rotation-Invariant Distributions

Nathaniel Harms*

Abstract

We present an algorithm for testing halfspaces over arbitrary, unknown rotation-invariant distributions. Using $\tilde{O}(\sqrt{\pi} \varepsilon^{-7})$ random examples of an unknown function $f$, the algorithm determines with high probability whether $f$ is of the form $f(x) = \text{sign}(\sum_i w_i x_i - t)$ or is $\varepsilon$-far from all such functions. This sample size is significantly smaller than the well-known requirement of $\Omega(n)$ samples for learning halfspaces, and known lower bounds imply that our sample size is optimal (in its dependence on $n$) up to logarithmic factors. The algorithm is distribution-free in the sense that it requires no knowledge of the distribution aside from the promise of rotation invariance. To prove the correctness of this algorithm we present a theorem relating the distance between a function and a halfspace to the distance between their centers of mass, that applies to arbitrary distributions.

*This research was partially supported by the Natural Sciences and Engineering Research Council of Canada.
1 Introduction

Halfspaces (or linear threshold functions) cut $\mathbb{R}^n$ in half by drawing a hyperplane through the space. They are defined by a vector $w \in \mathbb{R}^n$ and a threshold $t$ and they label points $x \in \mathbb{R}^n$ by $\text{sign}(\sum_i w_i x_i - t)$. These functions are fundamental objects in many areas of study, like machine learning, geometry, and optimization. In machine learning, halfspaces are one of the most basic classes of functions that can be learned and algorithms for doing so have been studied extensively: it is well-known that, in the PAC learning model, a distribution-free algorithm (one with no knowledge of the distribution of examples) requires $\Theta(n/\epsilon)$ random samples to learn a halfspace with accuracy $\epsilon$ [SSBD14]; however, this requires that the function is guaranteed to be a halfspace, and in practice it may not be known what class the function belongs to. In this situation we can try to learn a halfspace and then check how well it works, but it would be better to find an algorithm that could quickly reject functions that are not halfspaces, which is the goal of the present paper. This is the problem of testing halfspaces: an $\epsilon$-testing algorithm for halfspaces is an algorithm which receives random samples of a function $f$, and determines whether the function is a halfspace or $\epsilon$-far from all halfspaces, where distance is measured by the probability that two functions differ on a random input.

Matulef et al. [MORS10] and Mossel and Neeman [MN15] give algorithms for testing halfspaces when the algorithm is allowed to make queries to the function and the underlying distribution of points is either Gaussian over $\mathbb{R}^n$ or uniform over $\{\pm 1\}^n$. Balcan et al. [BBBY12] present an algorithm in the model where the tester receives random samples from the Gaussian distribution. It is unknown whether there is a distribution-free testing algorithm, in the query or sample model, that improves upon the naive testing-by-learning strategy. Existing algorithms are tailored for the Gaussian or the hypercube, so for distributions significantly different from these, even for another rotation-invariant (RI) distribution, a testing algorithm is not known. RI distributions generalize both the Gaussian distribution and the uniform distribution over the sphere, two distributions that are commonly studied in the literature on halfspaces (e.g. [BBBY12, Kea98, Lon94, Lon03, MORS10, MN15]). In this paper we present an algorithm that will work for any unknown rotation-invariant distribution.

Theorem 1.1. There is an algorithm that is, for any unknown rotation-invariant distribution $\mu$ and any $\epsilon > 0$, an $\epsilon$-tester for halfspaces using at most $\tilde{O}(\sqrt{n\epsilon^{-7}})$ random samples.

This algorithm requires significantly fewer samples than the $\Omega(n/\epsilon)$ required for the naive testing algorithm that attempts to learn the function $\tilde{O}(\epsilon^{-7})$, and in fact it is optimal (up to logarithmic factors) due to the $\tilde{O}(\sqrt{n})$ lower bound for algorithms sampling from the Gaussian distribution [BBBY12].

Rotation invariance and halfspaces go hand-in-hand since, in an RI distribution, the normal vector $w$ of a halfspace is parallel to its center of mass, which, for example, allows one to learn a halfspace by learning its center (e.g. [Kea98]).

Definition 1.2 (Center of Mass). Let $\mu$ be a distribution over $\mathbb{R}^n$ and let $f : \mathbb{R}^n \to \{\pm 1\}$ be a measurable function. The center of mass of $f$ is the vector $\mathbb{E}_x[xf(x)]$ and the center-norm is $\|\mathbb{E}_x[xf(x)]\|_2$.

1The notation $f(n) = \tilde{O}(g(n))$ hides logarithmic factors; i.e. for sufficiently large $n$, $f(n) \leq g(n)\log^{c}n$ for some constant $c$, and $f(n) = \Omega(g(n))$ means $f(n) \geq g(n)\log^{-c}n$ for sufficiently large $n$. 

1
To prove the correctness of our algorithm, we show that for arbitrary distributions, the distance between a function and a halfspace is related to the distance between the two centers of mass, where this relationship is quantified by a parameter we call the width, $W_{\mu}(w, \epsilon)$, which is, informally, the size of the smallest interval $I$ with $\mathbb{P}_x[\langle w, x \rangle \in I] = \epsilon$ (see Definition 4.3).

**Theorem 1.3** (See Section 4 for the full statement). For any distribution $\mu$ over $\mathbb{R}^n$ and any function $f$, if $h$ is a halfspace with normal vector $w$ having distance $\epsilon$ to $f$ and the same mean as $f$, then

$$\|E[xh(x)] - E[xf(x)]\|_2 \geq \epsilon \cdot W_{\mu}(w, \epsilon/2).$$

Although the algorithm itself is for RI distributions, Theorem 1.3 actually holds much more generally. When applied to the Gaussian distribution, we recover a result of [MORS10] that was used to prove the correctness of their algorithm. That result used Fourier analysis in the Gaussian space, which we eliminate in our proof.

The testing algorithms of [MORS10, BBBY12] work by estimating the center-norm of the input function. In this paper we show that these algorithms do not generalize to the larger class of RI distributions.

**Theorem 1.4** (Informal). For any algorithm $A$ that has access to a function $f$ only through an estimate of its center-norm, there is an RI distribution and a function $f$, far from all halfspaces, that is indistinguishable to $A$ from a halfspace.

### 1.1 Related Work

Matulef et al. [MORS10] presented algorithms that use queries to test halfspaces over the Gaussian distribution and the uniform distribution over $\{\pm 1\}^n$ with query complexity $\text{poly}(1/\epsilon)$. Mossel and Neeman give another $\text{poly}(1/\epsilon)$-query algorithm for the Gaussian distribution that estimates the noise stability instead of the center-norm. Glasner and Servedio [GS07] show a $\tilde{\Omega}(n^{1/5})$ lower bound for distribution-free testing in the query model, which contrasts with the $\text{poly}(1/\epsilon)$ algorithms to show that testing with queries is much harder for general distributions than for the Gaussian.

Balcan et al. [BBBY12] adapt the center-norm algorithm of [MORS10] to get a sampling algorithm for the Gaussian distribution that requires $O(\sqrt{n \log n})$ random samples, and also show a lower bound of $\Omega(\sqrt{n/\log n})$ in the same setting.

There are a few related works that study similar problems: Matulef et al. [MORS09] and Ron and Servedio [RS15] gave algorithms for testing, under the uniform distribution over $\{\pm 1\}^n$, if a function is a halfspace with normal vector $w \in \{\pm 1\}^n$ (as opposed to $w \in \mathbb{R}^n$), which they show requires between $\Omega(\log n)$ and $\text{poly}(\log n)$ queries, rather than the constant number of queries required for testing halfspaces. Balcan et al. [BBBY12] also give a lower bound of $\Omega((n/\log n)^{1/3})$ labelled examples in their active testing model, where the algorithm receives unlabelled, randomly selected points, and may request labels for a subset of these. Finally, Raskhodnikova [Ras03] presents a query algorithm for testing halfspaces when the domain of the function is an image, i.e. an $n \times n$ matrix of binary values, that uses $O(1/\epsilon)$ queries.

Learning halfspaces is a related and well-studied problem; standard arguments about the VC dimension of halfspaces show that $\Theta(\frac{n}{\epsilon})$ random samples or queries are necessary and sufficient to learn halfspaces in the PAC learning model [SSBD14]; this holds when the algorithm is required
to be distribution-free (i.e., it is not given any knowledge of the distribution), but the lower bound of $\Omega(n/\epsilon)$ holds even when the distribution is uniform over the unit sphere in $\mathbb{R}^n$ [Lon94]. If we imagine that a testing algorithm has accepted a function $f$, then we know it is of distance at most $\epsilon$ to a halfspace; if we now wish to learn the function, the standard PAC model does not directly apply since the function still may not be exactly a halfspace. The learning model that applies in this situation is agnostic learning, in which the labels are not guaranteed to be consistent with a halfspace. In this model, the VC dimension arguments show that $\Theta(n/\epsilon^2)$ random examples are required to produce a nearly-optimal halfspace [SSBD14], but finding this halfspace is NP-Hard [BDEL03]; if we allow the learner to produce a function that is not necessarily a halfspace, learning can be done in polynomial time with $n^{O(1/\epsilon^2)}$ random examples when the distribution is uniform over the sphere [KKMS08].

Some recent work has been done on the Chow parameters problem [DDFS14, OS11], which asks how to construct a halfspace over $\{\pm 1\}^n$ given approximations of its center of mass and mean (known as Chow parameters). That work uses similar ideas to the work on testing and learning halfspaces, such as bounds on the center-norms.

2 Outline & Sketch of the Algorithm

In Section 3 we cover the notation and preliminaries required to present the algorithm, including some important facts about centers of mass, rotation-invariant distributions, and distances between functions.

The remainder of the paper is a construction of the testing algorithm, RI-Tester, found in §6, which we now sketch. Our first task is to show that the known algorithms (BBBY12, MORS10) for testing halfspaces fail on general RI distributions. This is done in §4.1 by defining the class of center-of-mass algorithms and constructing RI distributions to fool them (Theorem 1.4). This justifies our use of a new strategy and motivates the definition of the width and bounded RI distributions (Definitions 4.3 and 4.7) to isolate those distributions on which center-of-mass algorithms fail.

We then use the definition of width to prove a bound on the distance between two functions in terms of the distance between their centers of mass (Theorem 1.3). Using this theorem, we show that there is an algorithm, Simple-Tester, which will test halfspaces over bounded RI distributions, and has a small amount of tolerance, i.e., it will accept halfspaces and anything sufficiently close to a halfspace. The idea of this algorithm is the same as [BBBY12, MORS10]: estimate the center-norm and compare it with the center-norm we would expect if the function were a halfspace, but our algorithm eliminates the dependence on the Gaussian distribution. This method relies on the property that the center-norm of a halfspace is independent of its orientation in RI spaces.

Next we reduce the general RI distribution problem to the bounded case. Note that if $f$ is a halfspace with threshold $t$, then $f$ is constant on the ball of radius $|t|$ and it is nearly balanced on points $x$ with $|x| \gg t$. The subroutine Find-Pivot in §6.1 identifies these extreme regions by examining a set of examples and finding the smallest possible threshold. These extreme regions are treated separately from the rest of the space.

The ball of radius $|t|$ must be constant, which is guaranteed implicitly by the Find-Pivot algorithm. Balanced halfspaces are approximately preserved by rescaling the space (Lemma 6.2). Since a halfspace $f$ is nearly balanced in the extreme region of radius $\gg t$, we may rescale this region
so that it is bounded, while approximately preserving the halfspace property. We apply Simple-Tester to this region, which requires the tolerance guarantee.

Between the two extreme regions we partition the space into bounded sections. Now we apply Simple-Tester to each of these bounded sections along with the transformed outer region. Now each region on its own is a halfspace, so what remains is to ensure that these halfspaces are consistent with one another. This is accomplished with the Check-Consistency subroutine in §6.3 that checks if two (near-)halfspaces on two different RI distributions are consistent, i.e. that they have roughly the same thresholds and orientation. This check again depends on rotation invariance, since in RI spaces the orientation of the halfspaces does not change their center-norms, and the centers of mass are parallel to their normal vectors.

It may be the case that some sections did not contain enough random samples to run the Simple-Tester and Check-Consistency algorithms. This is handled by Lemma 6.6 which states that any section with insufficient samples also has small measure and may be ignored.

3 Preliminaries and Notation

See the appendix for the proofs of the propositions in this section.

For a vector $u \in \mathbb{R}^n$, $\|u\|$ is the 2-norm $\sqrt{\sum_i u_i^2}$. For two vectors $u, v \in \mathbb{R}^n$ we will write $\langle u, v \rangle$ for the inner product $\sum_i u_i v_i$. $P, E$ denote the probability of an event and the expected value respectively. We will write $e_1$ for the first standard basis vector $(1, 0, \ldots, 0)$.

Definition 3.1 (Halfspaces). A halfspace is a function $h : \mathbb{R}^n \to \{\pm 1\}$ such that for some unit vector $w \in \mathbb{R}^n$ (called the normal vector) and threshold $t \in \mathbb{R}$

$$h(x) = \text{sign}(\langle w, x \rangle - t).$$

We use the standard definition of distance between functions.

Definition 3.2 (Distance). Let $\mu$ be a distribution over $\mathbb{R}^n$ and let $f, g : \mathbb{R}^n \to \{\pm 1\}$ be measurable functions. Then the distance is defined as

$$\text{dist}_\mu(f, g) := P_{x \sim \mu} [f(x) \neq g(x)].$$

We say $f$ is $\epsilon$-far from $g$ if $\text{dist}_\mu(f, g) \geq \epsilon$ and $\epsilon$-close if $\text{dist}_\mu(f, g) \leq \epsilon$.

Functions that are close to being the same constant function are close to each other.

Proposition 3.3. Let $f, g$ be $\pm 1$-valued functions with $|E[f]| \geq 1 - \epsilon$ and $|E[f] - E[g]| \leq \delta$. Then $\text{dist}(f, g) \leq \epsilon + \delta/2$.

3.1 Spheres and Rotation Invariance

Definition 3.4 (Rotation-Invariant Distributions). Write $\sigma$ for the uniform distribution over the unit sphere. A distribution $\mu$ over $\mathbb{R}^n$ is rotation-invariant (RI) if for some distribution $\mu_\sigma$ over
\( \mathbb{R} \geq 0, \mu = \sigma \nu_0 \). That is, for a random vector \( x \sim \mu, x = au \) for independent random variables \( u \sim \sigma \) and \( a \sim \nu_0 \). We will refer to \( \nu_0 \) as the radial distribution of \( \mu \).

We will frequently use the projection of an RI distribution onto a one-dimensional line: for RI distributions this projection is the same for every line. We will define some notation for this projection operation:

**Definition 3.5** (1-Dimensional Projection). Let \( \mu \) be any RI distribution over \( \mathbb{R}^n \) with radial distribution \( \nu_0 \). We define \( \mu_\pi \) to be the distribution of \( \langle x, e_1 \rangle \) where \( x \sim \mu \) and \( e_1 \) is the first standard basis vector. Note that by rotation invariance, we could define \( \mu_\pi \) as the distribution of \( \langle x, u \rangle \) for any unit vector \( u \in \mathbb{R}^n \).

We will usually assume that our distributions have the same scale. For RI distributions it is convenient to assume that they are isotropic, which means that the 1-dimensional projection has unit variance.

**Definition 3.6** (Isotropic). A distribution \( \mu \) on \( \mathbb{R}^n \) is isotropic if for every unit vector \( u \in \mathbb{R}^n \), \( E[x \sim \mu][\langle u, x \rangle^2] = 1 \).

**Proposition 3.7.** Let \( \mu \) be any RI distribution over \( \mathbb{R}^n \). \( \mu \) is isotropic iff \( E[x \sim \mu][\|x\|^2] = n \).

RI distributions are essentially convex combinations of spheres, and the uniform distribution over the sphere behaves similarly to the Gaussian distribution. This is evident in the following propositions giving bounds on the tails and on the density of the 1-dimensional projection. The proofs of these propositions can be found in the appendix.

**Proposition 3.8.** Let \( \sigma \) be the uniform distribution over the sphere of radius \( r \), and let \( t \geq 0 \). Then for any unit vector \( u \),

\[
\mathbb{P}_{x \sim \sigma} \left[ \langle u, x \rangle \geq t \right] \leq \sqrt{2} e^{-t^2(n-2)/2r^2} \leq \sqrt{2} e^{-t^2 n/4r^2}
\]

(where the last inequality holds when \( n \geq 4 \)).

**Proposition 3.9.** Let \( \sigma \) be the uniform distribution of the sphere of radius \( r \) over \( \mathbb{R}^n \). Let \( \sigma_\pi \) be the density of the 1-dimensional projection. Then \( \sigma_\pi(x) \leq \frac{\sqrt{n-1}}{\sqrt{2\pi n}} e^{-\frac{x^2(n-2)}{2r^2}} \), and in particular, for \( r = \sqrt{n} \), \( \sigma_\pi(x) \leq \frac{1}{\sqrt{2\pi}} e^{-x^2/4} \) when \( n \geq 4 \).

### 3.2 Halfspaces and Rotation Invariance

Halfspaces have several useful properties in RI distributions, notably the fact that the normal vectors and centers of mass are parallel and that the distance between two halfspaces can be decomposed into angular and threshold components, which we present here.

**Proposition 3.10.** For any RI distribution \( \mu \) over \( \mathbb{R}^n \) and any halfspace \( h(x) = \text{sign}(\langle w, x \rangle - t) \), there exists a scalar \( s > 0 \), such that \( \mathbb{E}_{x \sim \mu}[xh(x)] = sw \).
We call two halfspaces *aligned* if their normal vectors (and therefore centers of mass) are parallel. For arbitrary functions, alignment refers to the centers of mass:

**Definition 3.11** (Aligned functions). Let \( \mu \) be any probability distribution over \( \mathbb{R}^n \) and let \( f, g : \mathbb{R}^n \rightarrow \{ \pm 1 \} \) be measurable functions. We will say \( f \) and \( g \) are aligned (with respect to \( \mu \)) if their centers of mass are parallel, i.e. for some scalar \( s > 0 \), \( \mathbb{E}_{x \sim \mu}[xf(x)] = s\mathbb{E}_{x \sim \mu}[xg(x)] \). In particular, if \( f, g \) are halfspaces with normal vectors \( u, v \), and \( \mu \) is RI, then \( f, g \) are aligned if and only if \( u = sv \).

Now we present the decomposition of distance into the angular component and the threshold component; following are the definitions of these components.

**Definition 3.12** (Threshold Distance). For any RI distribution \( \mu \) we will define \( \text{hdist}_\mu \) as a metric on \( \mathbb{R} \) as follows: for \( a, b \in \mathbb{R} \) define the halfspaces \( h_a(x) = \text{sign}(x_1 - a) \), \( h_b(x) = \text{sign}(x_1 - b) \). Then 
\[
\text{hdist}_\mu(a, b) = \text{dist}_\mu(h_a, h_b).
\]

We will drop the subscript when the distribution is clear from context. Next we will introduce notation for the angle between two halfspaces:

**Definition 3.13** (Halfspace Angle). For two halfspaces \( g, h \) with normal (unit) vectors \( u, v \) respectively, we will write \( \alpha(g, h) \) for the angle between \( u \) and \( v \):
\[
\alpha(g, h) := \cos^{-1}(\langle u, v \rangle).
\]

We can decompose the distance between two halfspaces into the sum of these two metrics:

**Proposition 3.14.** For any two halfspaces \( h(x) = \text{sign}(\langle v, x \rangle - q) \), \( g(x) = \text{sign}(\langle u, x \rangle - p) \) (where \( u, v \) are unit vectors) and RI distribution \( \mu \), 
\[
\text{dist}_\mu(h, g) \leq \frac{\alpha(h, g)}{\pi} + \text{hdist}_\mu(p, q).
\]

Finally, here is an identity for computing the mean of halfspaces:

**Proposition 3.15.** Let \( h \) be a halfspace with threshold \( t \) and normal vector \( w \). Then for any RI distribution, 
\[
|\mathbb{E}[h]| = \mathbb{P}[-|t| \leq \langle w, x \rangle \leq |t|].
\]

### 3.3 Concentration Inequalities and Empirical Estimation

We refer the reader to the appendix for a discussion of the standard empirical estimation techniques used in this paper. For now it suffices to mention that the algorithms in this paper will frequently refer to the algorithm \( \text{Estimate-Mean}(\mu, f, \epsilon, \delta) \) which produces an estimate of \( \mathbb{E}_{x \sim \mu}[f(x)] \) with additive error \( \epsilon \) and confidence \( \delta \).
4 Centers of Mass

Our algorithms will rely primarily on the properties of the centers of mass of Boolean functions, or more specifically the norms of these centers, which we will call the center-norms. Centers of mass are fundamental quantities in the study of halfspaces: in the language of Fourier analysis of Boolean functions (see for example [O’D14] for an introduction to this topic), what we call the center of mass $E[xf(x)]$ is the vector of degree-1 Fourier coefficients (one can see this by observing that the $i^{th}$ Fourier coefficient is $\hat{f}(i) = E[x_i f(x)]$). The relationship between the degree-1 Fourier coefficients and halfspaces has arisen in a number of works (e.g. [Cho61, MOR10, O’D14]). Another name for the set of $n+1$ quantities $E[f], E[x_i f(x)]$ is the Chow parameters, after a result of Chow which states that for any function $f : \{\pm 1\}^n \rightarrow \{\pm 1\}$ and any halfspace $h$, if $f$ and $h$ share the same Chow parameters then $f = h$ [Cho61]. Much of the work on halfspaces can be interpreted as variations on this theme, including our Theorem 1.3.

It has been known for some time that halfspaces maximize the quantity $\|E[xf(x)]\|$ when the distribution is uniform over $\{\pm 1\}^n$ or Gaussian (e.g. [Win71]). The main result of this section is a generalization of this relationship, Theorem 1.3: we will show that for any distribution $\mu$ over $\mathbb{R}^n$ with bounded width, halfspaces not only maximize the center-norm but the larger the center-norm of a function, the closer it must be to a halfspace. The other results in this section are bounds on the center-norms that we will require to prove guarantees on our algorithms.

4.1 Width

Recall the example from the introduction (Theorem 1.4) which stated that pure center-of-mass algorithms cannot work as testers. We now prove this theorem, which will illustrate that the main obstacle to generalizing the center-of-mass algorithms is that RI distributions can be densely concentrated on very small areas. This motivates the definition of width, which quantifies this dense concentration.

The algorithms of [MORS10, BBBY12] work by making an estimate of the center-norm: we will refer to such algorithms as center-of-mass algorithms and interpret them as making a single query to a center-norm estimator. Such algorithms should work regardless of which estimator is used, as long as it satisfies a sufficient accuracy guarantee. We formalize this in the next definition, which is inspired by the Statistical Query model of Kearns [Kea98]:

Definition 4.1. A center-norm oracle for an isotropic rotation-invariant distribution $\mu$ and function $f$ is an oracle $C_{f,\mu}(\epsilon)$ which on request $\epsilon \geq 0$ produces a random variable $C$ satisfying

$$P[|C - \|E_{x \sim \mu} [xf(x)]\|_2| > \epsilon] \leq 1/3.$$ 

A center-of-mass tester for balanced halfspaces is an algorithm $A$ which, when given access to any center-norm oracle $C_{f,\mu}$, must satisfy the following:

1. If $f$ is a balanced halfspace, then $A(C_{f,\mu})$ accepts with probability at least $2/3$, and
2. If $f$ is $1/4$-far (in $\mu$) from all halfspaces, then $A(C_{f,\mu})$ rejects with probability at least $2/3$.

Making more than one request to this oracle is superfluous: we could provide an oracle that always overestimates by exactly $\epsilon$, so making multiple requests would give no more information than just the request for highest accuracy.
Observe that $A$ does not have any knowledge of $\mu$, and note that we are weakening the standard requirements for a tester: we are only required to accept when $f$ is balanced, and we are concerned with only constant distance. For the Gaussian distribution, the algorithms of \cite{MORS10, BBBY12} would satisfy this definition, using a request $\epsilon = \Omega(1)$.

We can now show that such algorithms cannot exist for unknown isotropic RI distributions, since without knowledge of the distribution we must demand perfect estimations of the center-norm:

**Theorem 1.4.** Any center-of-mass tester $A$ for balanced halfspaces must request accuracy $\epsilon = 0$ from the center-norm oracle.

We will actually prove the following claim; from this claim, the theorem holds since the oracles give identical responses unless $\epsilon = 0$.

**Claim 4.2.** For any $\epsilon > 0$, there exist functions $f, h$ and a rotation-invariant distribution $\mu$ such that $h$ is a balanced halfspace, $f$ is $1/4$-far in $\mu$ from all halfspaces, and there exist center-norm oracles $C_{f,\mu}, C_{h,\mu}$ which on query $\epsilon$ produce random variables $C_f, C_h$ with the same distribution.

**Proof.** Let $\sigma_{\sqrt{n}}$ be the uniform distribution over the sphere of radius $\sqrt{n}$ and $\sigma_r$ be the uniform distribution over the sphere of radius $r$, to be chosen later. Let $\mu = \frac{1}{2}(\sigma_{\sqrt{n}} + \sigma_r)$. This distribution is clearly rotation-invariant, and we can transform it into an isotropic distribution by scaling it appropriately, by a factor of at most 2. Define $h(x) = \text{sign}(x_1)$, and define $f$ as follows:

$$f(x) = \begin{cases} h(x) & \text{if } \|x\| = \sqrt{n} \\ -h(x) & \text{if } \|x\| = r \end{cases}.$$ 

We will first show that $f$ is $1/4$-far from all halfspaces. Let $g(x) = \text{sign}((w, x) - t)$ for some arbitrary $w,t$; without loss of generality, assume $t \leq 0$. Now choose any unit vector $u$ satisfying $(w, u) \geq 0$ and any $a,b$ satisfying $0 \leq a \leq r < b$; we have $g(a \cdot u) = g(b \cdot u) = 1$ since $(w, u) \geq 0 \geq t$. But $f(r \cdot u) \neq f(\sqrt{n} \cdot u)$ so $f$ and $g$ disagree on at least one of those points; $\mathbb{P}[f(x) \neq g(x) \mid (x, u) = \|x\|] \geq 1/2$.

Since half of all unit vectors $u$ satisfy $(w, u) \geq 0$, we have $\mathbb{P}[f(x) \neq g(x)] \geq 1/4$, proving that $f$ is $1/4$-far from any halfspace.

We also have $\|\mathbb{E}[xh(x)]\|_2 - \|\mathbb{E}[xf(x)]\|_2 \leq \|\mathbb{E}[xf(x)] - \mathbb{E}[xh(x)]\|_2 \leq r$ since $f, h$ differ only on the points with $\|x\|_2 = r$. Thus, setting $r < \epsilon/2$ we can define the center-norm oracles by defining $C_{f,\mu}(\epsilon) = C_{h,\mu}(\epsilon)$ to be the random variable uniformly distributed over $\|\mathbb{E}[xh(x)]\|_2 \pm \epsilon$.

To get good bounds on the center-norms of functions on RI spaces, we will quantify the “maximum concentration” of distributions with a quantity we call the width; intuitively, the width at $\epsilon$ of a distribution over $\mathbb{R}$ is the size of the smallest interval with measure at least $\epsilon$.

**Definition 4.3 (Width).** We will use the Lévy anticoncentration function (see e.g. \cite{DS13}) which is defined as follows: let $\mu$ be an arbitrary distribution over $\mathbb{R}^n$, let $w \in \mathbb{R}^n$ and $r \in \mathbb{R}, r > 0$. Then

$$p_r(w) := \sup_{\theta \in \mathbb{R}} \mathbb{P}_{x \sim \mu} \left[ |\langle w, x \rangle - \theta| \leq r \right].$$
Using this function we define the width: for any \( \epsilon \in (0,1) \),
\[
W_\mu(w,\epsilon) := \inf\{ r > 0 : p_\epsilon(w) \geq \epsilon \}.
\]

**Example 4.4.** Consider the Gaussian distribution over \( \mathbb{R}^n \): we may ignore \( w \) since the distribution is rotation-invariant, and we can see that for any \( r > 0 \), the maximum in \( p_\epsilon(w) \) is achieved at \( \theta = 0 \). Then for any \( r \) such that \( p_\epsilon(w) \geq \epsilon \) we have \( \epsilon \leq \frac{\mathbb{P}}{\sqrt{2\pi}} \left( x \sim \mathcal{N}(0,1), \left| x \right| \leq r \right) \leq \frac{1}{\sqrt{2\pi}} r \) since \( 1/\sqrt{2\pi} \) is the maximum density of \( \mathcal{N}(0,1) \). Thus the Gaussian distribution has \( W(w,\epsilon) \geq C\epsilon \) for some constant \( C > 0 \).

### 4.2 Bounds on the Center-Norm

Equipped with our definition of width, we will now state the main theorem that allows the center-of-mass algorithm to work. This theorem relates the distance of a function from a halfspace to the difference between the two centers of mass. Similar theorems have been proven for the Gaussian space in earlier papers: see for example Theorem 29 in [MORS10] and the proof of Corollary 4 in [Eld15]. There have also been similar observations about the uniform distribution over the hypercube [DDFS14, Gol06, OS11]. Our theorem has the advantage of making no assumption on the distribution; applying the theorem with the bound \( W(w,\epsilon) \geq C\epsilon \) for the Gaussian distribution, as discussed above, will reproduce the theorems of [Eld15, MORS10] up to constant factors. The proof is also very simple.

**Theorem 1.3.** Let \( \mu \) be any distribution over \( \mathbb{R}^n \) and let \( f : \mathbb{R}^n \rightarrow \{\pm 1\} \) be any measurable function. Suppose \( h(x) = \text{sign}(\langle w,x \rangle - t) \) is a halfspace such that \( \mathbb{E}[h] = \mathbb{E}[f] \), and let \( \epsilon = \text{dist}_\mu(f,h) \). Write \( \alpha \) for the angle between \( \mathbb{E}[xh(x)] - \mathbb{E}[xf(x)] \) and \( w \). Then
\[
\|\mathbb{E}[xh(x)] - \mathbb{E}[xf(x)]\|_2 \geq \frac{\epsilon}{\cos \alpha} W_\mu(w,\epsilon/2).
\]

**Proof.** Let \( \mu_x \) be the distribution over \( \mathbb{R}^n \) obtained by projecting \( \mu \) onto the vector \( w \) (recall that, at the moment, \( \mu \) is not necessarily RI). We rewrite the left side of the theorem as an inner product:
\[
\|\mathbb{E}[x(h(x) - f(x))]\|_2 \cos \alpha = |\langle w, \mathbb{E}[x(h(x) - f(x))] \rangle|.
\]

We now give a lower bound on this inner product. Write
\[
A^+ := \{x : h(x) = 1, f(x) = -1\}, \quad A^- := \{x : h(x) = 1, f(x) = -1\}
\]
and note that \( \forall x \in A^+, \langle w,x \rangle \geq t \) and \( \forall x \in A^-, \langle w,x \rangle < t \). Note that \( \mu(A^+) = \mu(A^-) = \epsilon/2 \) since \( \mathbb{E}[h] = \mathbb{E}[f] \). Let \( X, Y \) be the following conditional random variables, where \( x,y \sim \mu \) are independent:
\[
X := \langle w,x \rangle \mid x \in A^+ , \quad Y := \langle w,x \rangle \mid x \in A^-.
\]
Then
\[
\langle w, \mathbb{E}_w[x(h(x) - f(x))] \rangle = \mathbb{E}_w[\langle h(x) - f(x),w\rangle] = 2 (\mu(A^+) \mathbb{E}[X] - \mu(A^-) \mathbb{E}[Y]) .
\]

Let \( m_X, m_Y \) be the medians of \( X, Y \) respectively. Since \( X \) is supported on values at least \( t \) and \( Y \) is supported on values at most \( t \), we have
\[
\mathbb{E}[X] \geq \frac{1}{2} m_X + \frac{1}{2} t, \quad \mathbb{E}[Y] \leq \frac{1}{2} m_Y + \frac{1}{2} t.
\]
Then since $\mu(A^+) = \mu(A^-) = \epsilon/2$ we get

$$2(\mu(A^+)E[X] - \mu(A^-)E[Y]) \geq (\mu(A^+)m_X - \mu(A^-)m_Y + (\mu(A^+) - \mu(A^-))t) = \frac{\epsilon}{2}(m_X - m_Y).$$

Now $\mu_\pi(A^+ \cap [t, m_X]), \mu_\pi(A^- \cap [m_Y, t]) \geq \epsilon/4$ since $m_X, m_Y$ are the medians of $X, Y$, so $\mu_\pi[t, m_X] \geq \epsilon/4, \mu_\pi[m_Y, t] \geq \epsilon/4$ and $\mu_\pi[m_Y, m_X] \geq \epsilon/2$. Selecting $r = (m_X - m_Y)/2$ we see that $p_r(w) \geq \mu_\pi[m_Y, m_X] \geq \epsilon/2$ so $m_X - m_Y = 2r \geq 2W_\mu(w, \epsilon/2)$, which gives us the lower bound of $\epsilon \cdot W_\mu(w, \epsilon/2)$.

**Remark 4.5.** Using the fact that the density of an isotropic log-concave distribution is bounded by 1 [LV03] we also get $W_\mu(w, \epsilon) \geq \epsilon$ for any unit vector $w$ and isotropic log-concave distribution $\mu$.

**Remark 4.6.** While the above theorem holds for discrete distributions, it may not be useful: e.g. for the uniform distribution over $\{\pm 1\}^n$ and $\epsilon = 2^{-n}$ we have $p_0(w) \geq \epsilon$ for every $w$, so $W(w, \epsilon) = 0$.

We define the class of bounded RI distributions for which the center-of-mass tester will work. The general algorithm will partition an arbitrary RI space into a number of these bounded distributions, allowing us to use the center-of-mass tester.

**Definition 4.7** (Bounded RI Distributions). An RI distribution $\mu$ over $\mathbb{R}^n$ is a **bounded RI distribution** if for some radius $R > 0$ and constant $0 < C \leq 1$, $\mathbb{P}_{x \sim \mu}[CR \leq \|x\| \leq R] = 1$.

We can easily show that bounded RI distributions have width at least linear in $\epsilon$; this will be important for the Simple-Tester in the next section.

**Proposition 4.8.** Let $\mu$ be an isotropic bounded RI distribution with parameters $R, C$. Then for all $\epsilon > 0$ and any $w$, $W_\mu(w, \epsilon) \geq C\epsilon$.

**Proof.** Since $\mathbb{E}[\|x\|^2] = n$ (Proposition 3.7) we must have $R \geq \sqrt{n}$. By rotation invariance we can drop the direction $w$ from the definition of width and consider the 1-dimensional projection $\mu_\pi$. Since $\mathbb{P}[\|x\| < CR] = 0$ we can bound the maximum density of $\mu_\pi$ by the maximum density of $(\sigma_{CR})_\pi$ where $\sigma_{CR}$ is the uniform distribution over the sphere of radius $CR$. By Proposition 3.9 this density is at most $\frac{\sqrt{n}}{\sqrt{2\pi}CR} \leq \frac{1}{C\sqrt{2\pi}}$. Then for any interval $[t - r, t + r]$ the total probability mass is at most $2r \frac{1}{C\sqrt{2\pi}}$; if $r < C\sqrt{\frac{\epsilon}{2\pi}}$ then this mass is less than $\epsilon$, so we must have $W_\mu(\epsilon) \geq \epsilon \cdot C\sqrt{\pi}/2$. 

Theorem 1.3 proves that a small gap in center-norms implies close to proximity to a halfspace. This is sufficient for a testing algorithm, but for the general algorithm we will also require a small amount of tolerance in our tester; that is, we will need to prove that the algorithm accepts not only halfspaces but functions that are very close to being halfspaces. For this purpose we will need an upper bound on the center-norm gap, which is provided by the next lemma.

**Lemma 4.9.** Let $\mu$ be any RI distribution with $\mathbb{P}[\|x\| \leq R] = 1$ and let $f : \mathbb{R}^n \to \{\pm 1\}$ be any measurable function. Suppose $h$ is a halfspace such that $\text{dist}_\mu(f, h) = \epsilon$. Then

$$\|\mathbb{E}[xh(x)]\| - \|\mathbb{E}[xf(x)]\| \leq O\left(\frac{R}{\sqrt{n}}\epsilon \sqrt{\ln(1/\epsilon)}\right).$$
Proof. First assume that $\mu$ is the uniform distribution over the sphere of radius $\sqrt{n}$. Let $w$ be the normal vector of the halfspace and let $p_w$ be the 1-dimensional projection of $\mu$ onto $w$. Let $A = \{x : h(x) = 1, f(x) = 1\}$ and $B = \{x : h(x) = -1, f(x) = 1\}$ so $\epsilon = \mu(A \cup B)$. Clearly we have $\|E[xh(x)]\| = \langle w, E[xh(x)] \rangle$, while $\|E[xf(x)]\| \geq \langle w, E[xf(x)] \rangle$, so we can get an upper bound on the difference as follows:

$$\|E[xh(x)]\| - \|E[xf(x)]\| \leq \langle w, E[xh(x)] - E[xf(x)] \rangle = \langle w, \mu(A)E[x \mid x \in A] - \mu(B)E[x \mid x \in B] - \mu(B)E[x \mid x \in B] + \mu(A)E[x \mid x \in A] \rangle = \epsilon \langle w, E[x \mid x \in A] - E[x \mid x \in B] \rangle \leq 2\epsilon \max_{S, \mu(S) = \epsilon} E[\langle w, x \rangle \mid x \in S].$$

This maximum is achieved when $S = \{x : \langle w, x \rangle > t_0\}$ for $t_0$ chosen such that $P[\{\langle w, x \rangle > t_0\}] = \epsilon$. Then we can get a bound on the expectation as follows. Let $t_k$ be the threshold such that $P[\{\langle w, x \rangle > t_k\}] = \epsilon/2^k$. Then, using Proposition 4.10 $\epsilon/2^k \leq \sqrt{2 e^{-t_k^2/4}}$ so $t_k \leq \sqrt{4 \ln(\sqrt{2} \cdot 2^k/\epsilon)}$. Thus

$$E[\langle w, x \rangle \mid \langle w, x \rangle > t] = \sum_{k=1}^{\infty} P[t_{k-1} < \langle w, x \rangle \leq t_k \mid t < \langle w, x \rangle] E[\langle w, x \rangle \mid t_{k-1} < \langle w, x \rangle \leq t_k] \leq \sum_{k=1}^{\infty} \frac{1}{2^k} t_k \leq \sum_{k=1}^{\infty} \frac{1}{2^k} \sqrt{2(k + \ln(\sqrt{2}/\epsilon))} \leq \left(2 \sum_{k=1}^{\infty} \frac{k + \ln(\sqrt{2}/\epsilon)}{2^k}\right)^{1/2} = \sqrt{2(2 + \ln(\sqrt{2}/\epsilon))}.$$  

The last inequality is Jensen’s inequality, and the final equality is due to the identity $\sum_{k=1}^{\infty} k2^{-k} = 2$. Thus we have an upper bound of $\epsilon \cdot O(\sqrt{\ln(1/\epsilon)}) = O\left(\epsilon \sqrt{\ln(1/\epsilon)}\right)$.

Now suppose $\mu$ is any bounded RI distribution. Then the largest sphere supported by the distribution is of radius $R$, so we can simply multiply the bound by $R/\sqrt{n}$, since the values on the left scale linearly with the radius. \hfill \Box

To conclude this section, we give two propositions that bound the center-norm.

**Proposition 4.10.** Let $\mu$ be any isotropic RI distribution over $\mathbb{R}^n$ and let $f : \mathbb{R}^n \to \{\pm 1\}$ be any measurable function. Then $\|E[xf(x)]\|_2 \leq 1$.

**Proof.** Let $\mu_0$ be the radial distribution for $\mu$. Suppose $u$ is the unit vector parallel to $E[xf(x)]$. Then using Jensen’s inequality we have

$$\|E[xf(x)]\| = \langle u, E[xf(x)] \rangle = E[(u, x) f(x)] \leq E[|\langle u, x \rangle|] \leq \sqrt{E[(u, x)^2]} = 1.$$  \hfill \Box

**Proposition 4.11.** Let $\mu$ be any RI distribution such that for some constant $C > 0$ and for all $\epsilon > 0$, $W_\mu(\epsilon) \geq C\epsilon$. Then for any halfspace $h$ with $|E[h]| \leq 1 - \epsilon$ we have $\|E[xh(x)]\|_2 \geq C\epsilon/4$.
Proof. By rotation invariance we may assume that the normal vector of \( h \) is \( e_1 \). Then
\[
\| \mathbb{E} [x h(x)] \| = \| \mathbb{P} [x_1 \geq t] \mathbb{E} [x \mid x_1 \geq t] - \mathbb{P} [x_1 < t] \mathbb{E} [x \mid x_1 < t] \|
\]
\[
= 2 \mathbb{P} [x_1 \geq t] \| \mathbb{E} [x \mid x_1 \geq t] \| \geq \varepsilon \mathbb{E} [\|x_1\|]
\]
since \( \mathbb{P} [x_1 \geq t] \geq \varepsilon /2 \). By taking the median, we have \( \mathbb{E} [\|x_1\|] \geq \sqrt{2} W_\mu (1/2) \geq C/4 \).

\[\Box\]

5 A Tester for Simple Distributions

We now implement Simple-Tester, a center-of-mass tester for bounded RI distributions. The main algorithmic ingredient is the subroutine \textsc{Estimate-IP} in the next subsection, that can be used for estimating the center-norm of a function and also, in the \textsc{Estimate-Halfspace-Norm} subroutine, to estimate the center-norm of the nearest halfspace.

5.1 Estimating Inner Products

\textsc{Estimate-IP} estimates the quantity \( \mathbb{E} [f(x)g(y) \langle x, y \rangle] \) for two independently random vectors \( x, y \) (whose distributions may be different). We could, of course, use standard empirical estimation to estimate this quantity by picking \( m \) pairs \((x, y)\) and computing \( f(x)g(y) \langle x, y \rangle \) for each of the \( m \) pairs, but with \( m \) samples points from each distribution we actually have \( m^2 \) pairings available; exploiting this fact lets us achieve \( \sqrt{n} \) sample complexity.

\begin{algorithm}[h]
\caption{\textsc{Estimate-IP}(\( \mu_1, \mu_2, f, g, m \))}
\begin{algorithmic}[1]
\STATE 1: Draw \( \{x_1, \ldots, x_m\} \sim \mu_1^m \)
\STATE 2: Draw \( \{y_1, \ldots, y_m\} \sim \mu_2^m \)
\STATE 3: \textbf{return} \( \bar{\rho} \leftarrow m^{-2} \sum_{i,j} f(x_i)g(y_j) \langle x_i, y_j \rangle \)
\end{algorithmic}
\end{algorithm}

Lemma 5.1. Let \( \mu_1, \mu_2 \) be any RI distributions over \( \mathbb{R}^n \) with \( \tau_1 = \mathbb{E}_{x \sim \mu_1} [x_1^2], \tau_2 = \mathbb{E}_{y \sim \mu_2} [y_1^2] \) satisfying \( \tau_1 \tau_2 \leq 1 \), let \( f, g : \mathbb{R}^n \to \{ \pm 1 \} \) be any measurable functions, and let \( \epsilon, \delta > 0 \). Write \( p = \langle \mathbb{E}_{x \sim \mu_1} [xf(x)], \mathbb{E}_{y \sim \mu_2} [yg(y)] \rangle \). Then for some universal constant \( L \), and arbitrary \( 0 < \epsilon, \delta < 1 \),

1. If \( p \geq \eta \) and \( m \geq \sqrt{\frac{p}{\varepsilon \eta^2}} \log(1/\delta) \) then with probability at least \( 1 - \delta \), \( (1 - \epsilon)p \leq \bar{\rho} \leq (1 + \epsilon)p \); and,

2. If \( m \geq \sqrt{\frac{p}{\varepsilon^2 \eta^2}} \log(1/\delta) \) then with probability at least \( 1 - \delta \), \( |p - \bar{\rho}| \leq \epsilon \).

Proof. By rotation invariance we have \( \mathbb{E}_{x \sim \mu_i} [(x, u)^2] = \tau_i \) for each \( i \in \{1, 2\} \) and any unit vector \( u \). We will use Chebyshev’s inequality. Let \( \{x_i\}_{i \in [m]}, \{y_j\}_{j \in [m]} \) be the sets of random points that the algorithm receives. We will write \( X_{i,j} := f(x_i)g(y_j) \langle x_i, y_j \rangle \). Then
\[
\mathbb{E} [X_{i,j}] = \mathbb{E} [(x_i f(x_i), y_j g(y_j))] = \langle \mathbb{E} [xf(x)], \mathbb{E} [yg(y)] \rangle = p
\]
so, since \( \bar{\rho} = m^{-2} \sum_{i,j} X_{i,j} \), we have \( \mathbb{E} [\bar{\rho}] = p \). By Chebyshev’s Inequality, we get a bound for each of the two desired conclusions; for the multiplicative error:
\[
\mathbb{P} [\bar{\rho} > (1 + \epsilon) \mathbb{E} [\bar{\rho}] \text{ or } \bar{\rho} < (1 - \epsilon) \mathbb{E} [\bar{\rho}]] = \mathbb{P} [|\bar{\rho} - \mathbb{E} [\bar{\rho}]| > \epsilon \mathbb{E} [\bar{\rho}]] \leq \frac{\text{Var} [\bar{\rho}]}{\epsilon^2 \mathbb{E} [\bar{\rho}]^2} \leq \frac{\text{Var} [\bar{\rho}]}{\epsilon^2 \eta^2} \quad (1)
\]
and for the additive error
\[ P[|\tilde{p} - \mathbb{E}[\tilde{p}]| > \epsilon] \leq \frac{\text{Var}[\tilde{p}]}{\epsilon^2}. \] (2)

We will compute the variance:
\[ \text{Var}[\tilde{p}] = m^{-4} \sum_{i,j,k,\ell} \text{Cov}(X_{i,j}, X_{k,\ell}). \]

If \( i \neq k \) and \( j \neq \ell \), the covariance is 0 since \( X_{i,j}, X_{k,\ell} \) are independent. When either \( i = k \) or \( j = \ell \) (say \( j = \ell \)), we have
\[
\text{Cov}(X_{i,j}, X_{k,\ell}) = \mathbb{E}[X_{i,j}X_{k,\ell}] - \mathbb{E}[X_{i,j}]^2 \leq \mathbb{E} [f(x_i)f(x_k)g(y_j)^2(x_i,y_j)\langle x_k,y_j \rangle]
= \mathbb{E} [(y_j, \mathbb{E}[xf(x)])^2]
= \|\mathbb{E}[xf(x)]\|^2\mathbb{E}[(y_j, \frac{\mathbb{E}[xf(x)]}{\|\mathbb{E}[xf(x)]\|})^2]
= \tau_2\|\mathbb{E}[xf(x)]\|^2 \leq \tau_2\tau_1 = 1
\]
where the bound is due to Proposition 4.10 in the case of \( i = k \) we get the same bound. This situation occurs \( m^3 \) times. Finally, for \( i = k, j = \ell \), we may use the identity \( \mathbb{E}[\|y_j\|^2] = n\tau_2 \) (Proposition 3.7) to get
\[
\text{Cov}(X_{i,j}, X_{k,\ell}) = \text{Var}[X_{i,j}] = \mathbb{E}[f(x_i)^2g(y_j)^2(x_i,y_j)^2] - p^4 = \mathbb{E}[\|y_j\|^2(x_i,y_j)^2] - p^4
= n\tau_1\tau_2 - p^4 \leq n,
\]
This situation occurs \( m^2 \) times, so in total the variance is at most
\[
\text{Var}[\tilde{p}] \leq m^{-4}(m^3 + m^2n) = \frac{1}{m} + \frac{n}{m^2} \leq 2\frac{n}{m^2} \quad \text{(for } m < n).\]

Thus setting \( m = O\left(\frac{\sqrt{\epsilon n}}{\epsilon^2}\right) \) for the multiplicative error and \( m = O\left(\frac{\sqrt{\epsilon n}}{\epsilon^2}\right) \) for the additive error suffices to a bound of \( 1/3 \) on inequalities (1) and (2).

Finally, we may apply a classic boosting technique and repeat this process \( M \) times, taking the median. The probability of failure is bounded by the probability that at least half of the trials fail; by the Chernoff bound this is at most \( O(\exp(-M)) \) so it succeeds with probability at least \( 1 - \delta \) when \( M = O(\log(1/\delta)) \).

To simplify the presentation of later algorithms, we define the following wrapper around \text{Estimate-IP} which estimates the center-norm of a function \( f \):

\begin{algorithm}
\caption{\text{Estimate-Norm}($\mu, f, m$)}
\begin{algorithmic}[1]
\State \text{return} \text{Estimate-IP}($\mu, \mu, f, f, m$)
\end{algorithmic}
\end{algorithm}

5.2 The Simple-Tester Algorithm

The previous section shows how to estimate the center-norm of an arbitrary function. We must compare that estimate to an estimate of the center-norm of a halfspace with the same mean; recall that due to rotation invariance we can ignore the orientation of the halfspaces since it does not
affect their center-norms. We will now show how to estimate the center-norm of a halfspace \( h \) with mean \( v \), being given only an estimate \( \tilde{v} \) of \( v \).

We first show that the center-norm of a halfspace with mean \( v \) is not very sensitive to changes in \( v \). We achieve this by taking the derivative of the center-norm with respect to the mean of the halfspace.

**Definition 5.2.** Let \( \mu \) any RI distribution over \( \mathbb{R}^n \), and write \( \Phi \) for the “two-sided CDF” of the 1-dimensional projection \( \mu_\pi \):

\[
\Phi(t) := \mathbb{P}_{z \sim \mu_\pi}[z \geq t] - \mathbb{P}_{z \sim \mu_\pi}[z < t] = 2 \mathbb{P}_{z \sim \mu_\pi}[z \geq t] - 1 = 2 \int_t^\infty \frac{d\mu_\pi(z)}{d\theta} - 1.
\]

Then for all \( v \in [-1, 1] \) we define \( \xi \) as the center-norm of the halfspace with mean \( v \) (recall that by rotation invariance, the orientation of the halfspace does not affect the center-norm):

\[
\xi(v) := \mathbb{E}_{z \sim \mu_\pi}[z \text{ sign}(z - \Phi^{-1}(v))] = 2 \int_{\Phi^{-1}(v)}^\infty zd\mu_\pi(z). 
\]

**Proposition 5.3.** Let \( \mu \) be an isotropic RI distribution. Then \( \frac{d}{dx} \xi(x)^2 \leq 1 \).

**Proof.** Write \( \theta = \Phi^{-1}(x) \). Observe that \( \frac{d\theta}{dx} = \left(\frac{d\mu_\pi}{d\theta}\right)^{-1} = (-2d\mu_\pi(\theta))^{-1} \). The derivative of \( \xi(x) \) is:

\[
\frac{d}{dx} \xi(x) = -2\theta d\mu_\pi(\theta) \frac{d\theta}{dx} = \theta .
\]

From here we have

\[
\frac{d}{dx}(\xi(x))^2 = 2\xi(x) \frac{d}{dx} \xi(x) = 2\theta \xi(x) 2\theta \int_{\theta}^\infty zd\mu_\pi(z) \leq 2 \int_{\theta}^\infty z^2d\mu_\pi(z) \leq \mathbb{E}_{z \sim \mu_\pi}[z^2] = 1 .
\]

where the last equality is by isotropy. \( \square \)

Using this fact, we show that we can estimate \( \|\mathbb{E}[xh(x)]\|_2^2 \) given an estimate of \( \mathbb{E}[h] \).

**Algorithm 3 Estimate-Halfspace-Norm(\( \mu, \tilde{v}, \epsilon, \delta \))**

1: Draw \( X \sim \mu^m \) for \( m = \frac{1}{2(\epsilon/2)^2} \ln(4/\delta) \);
2: \( q \leftarrow L \frac{m}{(\epsilon/2)^2} \ln(2/\delta) \) for \( L \) in Lemma 5.1
3: \( \tilde{t} \leftarrow \max\{t : \frac{1}{m} \#\{x \in X : x_1 \geq t\} \geq (1-\tilde{v})/2\} \)
4: \( \tilde{h}(x) := \text{sign}(x_1 - \tilde{t}) \)
5: \( \text{return } \tilde{p} \leftarrow \text{Estimate-Norm}(\mu_\pi, \tilde{h}, q) \)

**Lemma 5.4.** Let \( \epsilon, \delta > 0 \), let \( \mu \) be any isotropic RI distribution over \( \mathbb{R}^n \) and let \( h \) be a halfspace with \( \mathbb{E}[h] = v \). Suppose \( |\tilde{v} - v| < \epsilon \). Then with probability at least \( 1 - \delta \), Estimate-Halfspace-Norm produces an estimate \( \tilde{p}^2 \) satisfying \( \|\tilde{p}^2 - \mathbb{E}[xh(x)]\|_2^2 < \epsilon \), and uses at most \( O\left(\frac{1}{\epsilon^2} \ln(1/\delta)\right) \) random samples.

**Proof.** The bound on the number of samples is achieved by definition of \( m \) and \( q \). By Lemma 5.1, Estimate-Norm fails with probability at most \( \delta/2 \).
Let $t$ be the threshold of $h$, and let $t'$ be the threshold such that the halfspace $h'$ with threshold $t'$ satisfies $\mathbb{E}[h'] = \tilde{v}$. By the guarantee on $\tilde{v}$ we have $\text{hdist}(t, t') \leq \frac{1}{2}|v - \tilde{v}| \leq \epsilon/2$. From Proposition [A.5] we know that $\text{hdist}(t', t) < \epsilon/2$ so $\text{hdist}(\tilde{t}, t) \leq \text{hdist}(\tilde{t}, t'') + \text{hdist}(t', t) \leq \epsilon$.

From the bound on the derivative of $\xi$ (Proposition 5.3) we see that $\|\mathbb{E}[xh(x)]\|^2$ has error at most

$$|\mathbb{E}[\tilde{h}] - \mathbb{E}[h]| \leq \frac{1}{2}\text{hdist}(\tilde{t}, t) \leq \epsilon/2,$$

and from Estimate-IP (Lemma 5.1) we know that $\tilde{p}$ is close to $\pm \epsilon/2$ of $\|\mathbb{E}[xh(x)]\|^2$. Thus we conclude that $\tilde{p}$ is within $\epsilon$ of $\|\mathbb{E}[xh(x)]\|^2$.

Finally we compose these estimations to get a tester for bounded RI distributions. In the general algorithm, we will require a small amount of tolerance in our tester; i.e. the tester must accept halfspaces and also any function that is very close to being a halfspace.

**Algorithm 4 Simple-Tester($\mu, f, \epsilon, \delta$)**

1. $c_1^3 \leftarrow K_1 C^2 \epsilon^3$; $c_3^3 \leftarrow K_3 C^2 \epsilon^3$ (for some constants $K_1, K_3$)
2. $\tilde{v} \leftarrow$ Estimate-Mean($\mu, f, c_1^3, \delta/3$)
3. $\tilde{c}^2 \leftarrow$ Estimate-Norm($\mu, f, m := L \frac{\sqrt{n}}{c_1^3} \log(3/\delta))$ for $L$ in Lemma 5.1
4. $\tilde{p}^2 \leftarrow$ Estimate-Halfspace-Norm($\mu, \tilde{v}, c_1^3, \delta/3$)
5. if $\tilde{p}^2 - \tilde{c}^2 < \epsilon_3^3$ or $|\tilde{v}| \geq 1 - \epsilon$ then accept

**Theorem 5.5.** Let $C$ be a constant independent of $n$ and $R = \sqrt{n}$. For any $\eta > 0$ there exists a constant $K_2(\eta)$ depending only on $\eta$ so that Simple-Tester satisfies the following properties: Let $\mu$ be any bounded RI distribution over $\mathbb{R}^n$ with $R = \sqrt{n}$ and constant $C$, and let $f : \mathbb{R}^n \rightarrow \{\pm 1\}$ be a measurable function. Suppose $\epsilon, \delta \in (0, 1/2)$. Then for $\epsilon_2 = K_2(\eta) \epsilon^{3+\eta}$,

1. If $f$ is $\epsilon_2$-close to a halfspace, the the algorithm accepts with probability at least $1 - \delta$;
2. With probability at least $1 - \delta$, if the algorithm accepts $f$ then there exists a halfspace $h$ aligned with $f$ satisfying $\mathbb{E}[h] = \mathbb{E}[f]$ and $\text{dist}(f, h) \leq \epsilon$.

Furthermore, the algorithm requires at most $O\left(\frac{\sqrt{n}}{\epsilon_2^2} \log(1/\delta)\right)$ random samples.

**Proof.** Assume without loss of generality that $\mu$ is isotropic, since we may scale the distribution.

Estimate-Mean requires at most $O\left(\frac{1}{\epsilon_2^2} \log(1/\delta)\right)$ samples and fails with probability at most $\delta/3$ (Lemma A.4). Estimate-Halfspace-Norm requires at most $O\left(\frac{\sqrt{n}}{\epsilon_2^3} \log(1/\delta)\right)$ and fails with probability at most $\delta/3$ (Lemma 5.4), and Estimate-Norm uses $m = O\left(\frac{\sqrt{n}}{\epsilon_2^3} \log(1/\delta)\right)$ samples and fails with probability at most $\delta/3$ (Lemma 5.1); assume these estimations all succeed, which occurs with probability at least $1 - \delta$.

**Completeness:** Suppose $f$ is $\epsilon_2$-close to a halfspace $h$. First suppose $|\mathbb{E}[f]| \geq 1 - \epsilon/2$. Then by the guarantee on Estimate-Mean (Lemma A.4) we have $|\tilde{v}| \geq 1 - \epsilon$ so the algorithm accepts. Now suppose $|\mathbb{E}[f]| < 1 - \epsilon/2$.

For convenience, let $v = \mathbb{E}_\mu f$ and write $p = \|\mathbb{E}[xh(x)]\|, c = \|\mathbb{E}[xf(x)]\|$. 

15
From Proposition 4.10 we have \( p, c \leq 1 \). Letting \( K \) be the constant in Lemma 4.9 and using that lemma with the fact that \( \text{dist}(f, h) < \epsilon_2 \) and \( R = \sqrt{n} \), we have

\[
(p^2 - c^2) = (p + c)(p - c) \leq (p + c) \cdot K \epsilon_2 \sqrt{\ln(1/\epsilon_2)} \leq 2K \epsilon_2 \sqrt{\ln(1/\epsilon_2)}.
\]

Since \( n \mathbb{E}[x_1^2] = \mathbb{E}[\|x\|^2] \leq R^2 = n \) we have \( \mathbb{E}[x_1^2] \leq 1 \), so by the guarantee on \text{Estimate-Norm} (Lemma 5.1) we have \( \tilde{p}^2 \leq p^2 + \epsilon_3^3 \) and \( \tilde{c}^2 \leq c^2 + \epsilon_3^3 \), and we have \( \epsilon_2 = K_2 \epsilon_3^{3+n}, \epsilon_3^1 = K_1 C^2 \epsilon_3^3 \), for some constants \( K_1, K_2 \) to be chosen later, so

\[
\tilde{p}^2 - \tilde{c}^2 \leq p^2 - c^2 + 2 \epsilon_3^3 \leq 2K \epsilon_2 \sqrt{\ln(1/\epsilon_2)} + 2K_1 C^2 \epsilon_3^3 = 2K K_2 \epsilon_3^{3+n} \sqrt{\ln \left( \frac{1}{K_2 \epsilon_3^{3+n}} \right)} + 2K_1 C^2 \epsilon_3^3.
\]

We want to show that this is at most \( \epsilon_3^3 \). Recall \( \epsilon_3^3 = K_3 C^2 \epsilon_3^3 \); for the second term we have for \( K_1 \leq K_3/4 \) that this term is at most \( \epsilon_3^3/2 \), so it suffices to show that the first term is also at most \( \epsilon_3^3/2 \). Then we want to show, for \( A = K_3/4K \),

\[
K_2 \epsilon_3^{3+n} \sqrt{\ln \left( \frac{1}{K_2 \epsilon_3^{3+n}} \right)} \leq A \epsilon_3^3 \equiv \frac{1}{K_2} \leq \exp \left( A^2/K_2^2 \epsilon_3^{2n} - (3 + \eta) \ln(1/\epsilon) \right).
\]

For \( \eta > 0 \) the exponent is bounded so we can choose \( K_2 = K_2(\eta) \) (where \( K_2(\eta) \) is a constant depending on \( \eta \)) so that the above inequality holds; from this we conclude that \( \tilde{p}^2 - \tilde{c}^2 \leq K_4 \epsilon_3^3 = \epsilon_3^3 \), so the test passes.

**Soundness:** First suppose \( |\tilde{v}| \geq 1 - \epsilon \). Then \( |\mathbb{E}[f]| \geq 1 - \epsilon - \epsilon^3 \geq 1 - 2\epsilon \). Let \( h \) be any halfspace satisfying \( \mathbb{E}[h] = \mathbb{E}[f] \); then \( \text{dist}(f, h) \leq \epsilon \) (Proposition 3.3).

Now suppose \( |\tilde{v}| < 1 - \epsilon \) so \( |\mathbb{E}[f]| < 1 - \epsilon + \epsilon^3 \leq 1 - \epsilon/2 \), and let \( h \) be the halfspace aligned with \( f \) with \( \mathbb{E}[h] = \mathbb{E}[f] \). By Lemma 5.1 we have

\[
\tilde{c}^2 \in \||x|f(x)|\|^2 \pm \epsilon_3^3 = c^2 \pm \epsilon_3^3
\]

and from Lemma 5.1

\[
\tilde{p}^2 \in \||x|h(x)|\|^2 \pm \epsilon_3^3 = p^2 \pm \epsilon_3^3.
\]

Suppose for the sake of contradiction that \( \text{dist}(f, h) > \epsilon \). Then by Theorem 1.3, Proposition 4.8 and the identity \( (a + b)(a - b) = a^2 - b^2 \), we have

\[
\frac{C}{2} \epsilon^2 (p + c) \leq (p - c)(p + c) \leq \tilde{p}^2 - \tilde{c}^2 + 2 \epsilon_3^3 \leq \epsilon_3^3 + 2 \epsilon_3^3
\]

where the final inequality holds because the test has passed. From Proposition 4.11 and the fact that \( \mathbb{E}[h] < 1 - \epsilon/2 \), we have \( p \geq C\epsilon/8 \). We also have \( \epsilon_3^1 = K_1 C^2 \epsilon_3^3, \epsilon_3^3 = K_3 C^2 \epsilon_3^3 \), so

\[
\frac{C^2}{16} \epsilon^3 \leq \epsilon_3^3 + 2 \epsilon_3^1 = (K_3 + 2K_1) C^2 \epsilon_3^3 < \frac{C^2}{16} \epsilon^3
\]

for appropriate choices of constants \( K_1, K_3 \) (and recall from the completeness proof that we require only that \( K_1 \leq K_3/4 \)). This is a contradiction. Thus \( \text{dist}(f, h) \leq \epsilon \). \( \square \)

**Remark 5.6.** While we have proven the correctness of this tester for bounded RI distributions, we could also show that the tester, without the tolerance guarantee, works for any RI distribution satisfying \( W(w, \epsilon) = \Omega(\epsilon) \). An important example would be the isotropic log-concave RI distributions [LV03].
It is worth comparing this algorithm and analysis to those provided by Matulef et al. [MORS10] and Balcan et al. [BBBY12]. Those algorithms both used the same high-level strategy but were proven to work only for the Gaussian distribution. The [MORS10, BBBY12] algorithms had no need for the Estimate-Halfspace-Norm subroutine since for the Gaussian distribution the center-norm of a halfspace with mean \( v \) is given by the function \((2\phi(\Phi^{-1}(v)))^2\), where \( \phi, \Phi \) are the density and CDF of the standard normal distribution [MORS10]; by using a sampling algorithm instead, we eliminate the need for such exact relationships. Finally, our analysis provides a small tolerance guarantee, which was unnecessary for the earlier works.

6 A Tester for General RID Distributions

We will now show how to use the Simple-Tester as a subroutine to get a tester for general RID distributions. There are 3 ideas, covered in the next 3 subsections, that we will use to partition the RID space into simple sections:

1. (Subsection 6.1) A halfspace with threshold \( t \) will be constant on the ball of radius \( t \) and almost balanced outside a ball of radius \( T \gg t \). We can quickly identify the values of \( t \) and \( T \) using the Find-Pivot algorithm. The middle region can be partitioned into simple sections while the extreme outer regions will be treated specially.

2. (Subsection 6.2) The region outside radius \( T \gg t \), where the halfspace is nearly balanced, is essentially an arbitrary RID distribution. We can normalize all the sample points in this region so that they all lie in a large bounded space; we show that this preserves balanced halfspaces. Once they are in a bounded space we can apply Simple-Tester.

3. (Subsection 6.3) We can run the Simple-Tester on each of these bounded regions, but then we must ensure that the halfspaces in each region are consistent with each other. We do this with the Check-Consistency algorithm, which for any two functions that are close to halfspaces will check that the halfspaces are close to each other.

6.1 Finding the Important Radii

For a function \( f \), Find-Pivot identifies a threshold \( \tilde{t} \) (a "pivot") such that \( f \) is nearly constant on the ball of radius \( \tilde{t} \). It simply returns the smallest radius that can possibly satisfy this condition given a set of examples.

**Algorithm 5** Find-Pivot\((\mu, f, \epsilon, \delta)\)

1: Draw \( X \sim \mu^m \) for \( m = \frac{1}{\epsilon} \ln\left(\frac{2}{\delta}\right) \)
2: if \( f \) is monochromatic on \( X \) then return \( \infty \)
3: else
4: return \( \tilde{t} = \min\{\|x\| : x, y \in X, \|y\| \leq \|x\|, f(x) \neq f(y)\} \)

**Lemma 6.1.** Let \( \epsilon, \delta \in (0, 1) \). With probability at least \( 1 - \delta \), Find-Pivot returns \( \tilde{t} \) satisfying the following:

1. For some \( b \in \{\pm 1\} \), \( \mathbb{P}[f(x) \neq b, \|x\| < \tilde{t}] < \epsilon \) and \( \mathbb{P}[f(x) = b, \|x\| \leq \tilde{t}] > 0 \);
2. If \( f \) is a halfspace with threshold \( t \), then \( \tilde{t} \geq |t| \).
Proof. For all $t \geq 0$, define $b_t := \text{sign}\left(\E[f(x) \mid \|x\| < t]\right)$. If $\P[f(x) \neq b_t, \|x\| < t] < \epsilon$ for all $t$, the conclusion holds, so assume that $\P[f(x) \neq b_t, \|x\| < t] \geq \epsilon$ for some $t$. Then the following minimum exists:

$$T = \min_{t} \{\P[f(x) \neq b_t, \|x\| < t] \geq \epsilon\}.$$  

Clearly we have $\P[f(x) = b_t, \|x\| < t] \geq \P[f(x) \neq b_t, \|x\| < t]$ for all $t$ so in particular this holds for $T$.

If any two points $x, y \in X$ satisfy $f(x) \neq f(y)$ and $\|x\|, \|y\| < T$ then the algorithm returns $\hat{t}$ such that $\hat{t} < T$, implying $\P[f(x) \neq b_{\hat{t}}, \|x\| < \hat{t}] < \epsilon$, since otherwise there would be a contradiction. So we can bound the failure probability by the probability that this event fails. By the union bound, this probability is at most

$$\P[\forall x \in X : f(x) = b_T \text{ or } \|x\| \geq T] + \P[\forall x \in X : f(x) \neq b_T \text{ or } \|x\| \geq T]$$

$$\leq 2(1 - \epsilon)^m \leq 2e^{-\epsilon m}$$

which is bounded by $\delta$ when $m = \frac{1}{\epsilon} \ln(2/\delta)$. The second conclusion holds because, for a halfspace with a threshold $t$ and normal $w$, if two points $x, y$ satisfy $\|y\| \leq \|x\|, f(x) \neq f(y)$ then we must have $\|x\| \geq |\langle w, x \rangle| \geq |t|$ so in particular $t \geq |t|$.

### 6.2 Rescaling Arbitrary RI Distributions onto a Bounded Space

Given a set of examples of a balanced halfspace, we can normalize the example points so that they all lie on the same sphere and preserve the halfspace: a point $x$ satisfying $\langle w, x \rangle \geq 0$ also satisfies $\langle w, x/\|x\| \rangle \geq 0$; but this is not true for all halfspaces. Here we show that we can perform this transformation on any halfspace that is close to balanced, with a small cost to the distance.

Let $\pi_r : (0, \infty) \rightarrow (r, 2r)$ be the bijection $\pi_r(x) = r(2 - e^{-x})$ and define $\pi : \mathbb{R}^n \rightarrow \mathbb{R}^n$ as $\pi(x) = x \cdot \pi_r(\|x\|)/\|x\|$.

**Lemma 6.2.** Let $\mu$ be a RI distribution over $\mathbb{R}^n$, let $\epsilon \in (0, 1/2)$, and let $f : \mathbb{R}^n \rightarrow \{\pm 1\}$ be a measurable function. Then there exists some radius $r$ such that if $\sigma$ is the distribution of $\pi(x)$ for $x \sim \mu$, and $g(x) := f(\pi^{-1}(x))$, then:

1. If $f$ is a halfspace then $f, g$ are aligned;
2. If $\text{dist}_\mu(f, h) \leq \epsilon$, for some halfspace $h$ with $|\E[h]| < \eta$, then $\text{dist}_\sigma(g, h) < \epsilon + \eta$;
3. If $\text{dist}_\sigma(g, h) \leq \epsilon$ for a halfspace $h$ satisfying $\E[\sigma h] = \E[g]$ and $|\E[\sigma g]| < \eta$, and $h'$ is the balanced halfspace aligned with $h$, then $\text{dist}_\mu(f, h') < \epsilon + \eta/2$.

**Proof.** If $f$ is a halfspace with normal vector $w$ then $f, g$ are aligned since all points in a set $R_{a,b} = \{x : \|x\| = a, \langle w, x \rangle = b\}$ have the same function value and are centered on $wb$, which becomes $wb\epsilon(2 - e^{-a})$ after the transformation.

Suppose $f$ is a $\epsilon$-close to a halfspace $h$ with $|\E[h]| < \eta$, say $h(x) = \text{sign}(\langle e_1, x \rangle - t)$. Assume without
loss of generality that $t \geq 0$. Then

$$\text{dist}_\sigma(g, h) = \mathbb{P}_{x \sim \mu}[g(\pi(x)) \neq h(\pi(x))]$$

$$\leq \mathbb{P}_{x \sim \mu} [h(\pi(x)) = h(x) \land f(x) \neq h(x)] + \mathbb{P}_{x \sim \mu} [h(\pi(x)) \neq h(x)]$$

$$\leq \epsilon + \mathbb{P}_{x} [x_1 < t, (\pi(x))_1 \geq t] + \mathbb{P}_{x} [x_1 \geq t, (\pi(x))_1 < t].$$

$\mathbb{P}_{x} [x_1 < t] = |\mathbb{E}[h] |/2 \leq \eta/2$ so what remains is to bound the second probability. We have $(\pi(x))_1 \geq r x_1/\|x\|$ so for large enough $r$ this probability will be at most $\eta/2$. In particular if $\mathbb{E}[\|x\|^2] = n$ then $\mathbb{P}[x_1 > 2r] \leq \mathbb{P}[\|x\| > 2r] \leq n/4r^2$ by Chebyshev’s inequality, so for $r > n$ only an $o(1)$ fraction of points will get closer to the origin after applying $\pi$.

Now suppose that $h$ is a halfspace satisfying $\text{dist}_\sigma(g, h) \leq \epsilon$ and $\mathbb{E}_\sigma[h] = \mathbb{E}_\sigma[g]$, and $|\mathbb{E}_\sigma[g]| < \eta$. Let $h'$ be the balanced halfspace aligned with $h$. Then since $h'(x) = h'((\pi(x))_1)$ for all $x$ we have

$$\text{dist}_\mu(f, h') = \text{dist}_\sigma(g, h') \leq \text{dist}_\sigma(g, h) + \text{dist}_\sigma(h, h') \leq \epsilon + \eta/2. \quad \square$$

### 6.3 Checking the Consistency of Two Halfspaces

After dividing the space into many simple sections and applying the Simple-Tester, we need to combine the results to get the final decision. The main idea is that the distance between two halfspaces can be decomposed via the triangle inequality into a threshold component and an angle component (Proposition 3.13). Check-Threshold checks that there is a unifying threshold value for two halfspaces on different domains, and Check-Consistency further enforces that the angle between two halfspaces is small. Finally, Lemma 6.5 allows us to apply Check-Consistency pairwise and get a consistent result for all regions. The proofs of these lemmas are lengthy and are left until after the presentation of the complete testing algorithm (see Subsection 6.5).

**Algorithm 6 Check-Threshold($\mu_1, \mu_2, v_1, v_2, \epsilon, \delta$)**

1: Draw $X_1 \sim \mu_1^m, X_2 \sim \mu_2^m$ for $m = O \left( \frac{1}{\epsilon} \log(1/\delta) \right)$
2: for $i \in \{1, 2\}$ do
3: \hspace{1em} $\tilde{a}_i \leftarrow \max \{ z : \# \{ x \in X_i : x \geq z \} \geq m(v_i + 2\epsilon/3) \}$ (if no such $z$ exists, $\tilde{a}_i \leftarrow -\infty$)
4: \hspace{1em} $\tilde{b}_i \leftarrow \min \{ z : \# \{ x \in X_i : x \geq z \} \leq m(v_i - 2\epsilon/3) \}$ (if no such $z$ exists, $\tilde{b}_i \leftarrow -\infty$)
5: If $[a_1, b_1], [a_2, b_2]$ intersect, accept; else reject

**Lemma 6.3.** Let $\epsilon, \delta \in (0, 1/2)$, $v_1, v_2 \in [0, 1]$ and let $\mu_1, \mu_2$ be any distributions over $\mathbb{R}$, unknown to the algorithm. Let $t_1, t_2$ satisfy $\mathbb{P}_{x \sim \mu_1}[x_1 \geq t_1] = v_1, \mathbb{P}_{y \sim \mu_2}[y_1 \geq t_2] = v_2$. Then, using $O \left( \frac{1}{\epsilon} \log(1/\delta) \right)$ samples, with probability at least $1 - \delta$ Check-Threshold satisfies the following:

1. If there exists a threshold $t$ such that $h_{\text{dist}_\mu_1}(t_1, t), h_{\text{dist}_\mu_2}(t_2, t) < \epsilon/3$ then Check-Threshold accepts; and
2. If Check-Threshold accepts then there exists $t$ such that $h_{\text{dist}_\mu_1}(t_1, t), h_{\text{dist}_\mu_2}(t_2, t) \leq \epsilon$.

The idea behind Check-Consistency is simple: we will first ensure that the “angle between $f_1, f_2$” is small by estimating their center-norms and comparing it with the inner product of their centers of mass; this can be done with Estimate-IP. This will guarantee that if $f_1, f_2$ are close to
halves $h_1$ and $h_2$, then $h_1$ and $h_2$ have normal vectors pointing in roughly the same direction. We then make sure that $h_1, h_2$ have consistent thresholds using Check-Threshold.

**Algorithm 7** Check-Consistency($\mu_1, \mu_2, f_1, f_2, \epsilon, \delta$)

1. $\epsilon_1 \leftarrow \frac{C}{\sqrt{12}} \cdot \epsilon$
2. $\tilde{v}_1 \leftarrow$ Estimate-Mean($\mu_1, f_1, \epsilon/3, \delta/6$)
3. $\tilde{v}_2 \leftarrow$ Estimate-Mean($\mu_2, f_2, \epsilon/3, \delta/6$)
4. $m \leftarrow \Theta\left(\frac{\epsilon^2}{\epsilon^3} \log(1/\delta)\right)$
5. if $|v_1|, |v_2| < 1 - \epsilon$ then
6. $\tilde{c}_1^2 \leftarrow$ Estimate-Norm($\mu_1, f_1, m$)
7. $\tilde{c}_2^2 \leftarrow$ Estimate-Norm($\mu_2, f_2, m$)
8. $\tilde{p} \leftarrow$ Estimate-IP($\mu_1, \mu_2, f_1, f_2, m$)
9. if $\tilde{p} < \frac{\epsilon^2}{6} \epsilon^2$ then reject
10. if $\frac{\tilde{p}}{\sqrt{\tilde{c}_1^2 \tilde{c}_2^2}} < 1 - 2\epsilon_1^2$ then reject
11. if Check-Threshold($((\mu_1)_1, (\mu_2)_1), (\tilde{v}_1 + 1)/2, (\tilde{v}_2 + 1)/2, \epsilon, \delta/6$) accepts, accept; else reject

**Lemma 6.4.** Let $\mu_1, \mu_2$ be bounded RI distributions over $\mathbb{R}^n$, with shared constant $C$, unknown to the algorithm. Assume that for $\tau_1 = E_{\mu_1}[x_1^2], \tau_2 = E_{\mu_2}[x_2^2]$ that $\tau_1 \tau_2 = 1$. Let $\epsilon, \delta \in (0, 1/2)$ and let $f_1, f_2 : \mathbb{R}^n \rightarrow \{\pm 1\}$ be $\mu_1$- and $\mu_2$-measurable functions. Then Check-Consistency satisfies the following:

- If there exists a halfspace $h$ such that $\text{dist}_{\mu_1}(f_1, h), \text{dist}_{\mu_2}(f_2, h) < \epsilon/6$ and $h$ is aligned with $f_1, f_2$, the algorithm will accept with probability at least $1 - \delta$;

- If there exist halfspaces $h_1, h_2$ with thresholds $t_1, t_2$ such that $\text{dist}_{\mu_1}(f_1, h_1), \text{dist}_{\mu_2}(f_2, h_2) < \epsilon$ and $h_1, h_2$ are aligned with $f_1, f_2$ with $E_{\mu_1} h_1 = E_{\mu_1} f_1, E_{\mu_2} h_2 = E_{\mu_2} f_2$, then with probability at least $1 - \delta$: if the algorithm accepts then there exists a threshold $t$ such that $\text{hdist}_{\mu_1}(t_1, t), \text{hdist}_{\mu_2}(t_2, t) < 2\epsilon$, and one of the following holds:
  1. $\alpha(h_1, h_2) \leq \frac{\pi}{2} \epsilon$, or
  2. $|E_{\mu_1} f_1| \geq 1 - \frac{3}{2} \epsilon$ or $|E_{\mu_2} f_2| \geq 1 - \frac{3}{2} \epsilon$.

In particular, as a consequence, there exists a halfspace $h$ such that $\text{dist}_{\mu_1}(f_1, h), \text{dist}_{\mu_2}(f_2, h) < 5\epsilon$.

- The algorithm requires at most $O\left(\frac{\sqrt{n}}{\epsilon} \log(1/\delta)\right)$ random samples from each distribution.

Finally we show that we can extract a single consistent halfspace from a set of near-halfspaces by applying Check-Consistency to each pair of functions:

**Lemma 6.5.** Let $\epsilon, \delta > 0$, let $\mu_1, \ldots, \mu_k$ be a set of bounded RI distributions over $\mathbb{R}^n$ and let $f : \mathbb{R}^n \rightarrow \{\pm 1\}$ be a function measurable by all these distributions. Suppose that for all $i \in [k]$ there exists a halfspace $h_i$ satisfying $h_i$ is aligned with $f$ on $\mu_i, E_{\mu_i} h_i = E_{\mu_i} f$, and $\text{dist}_{\mu_i}(f, h_i) \leq \epsilon$. Assume that for all $i, j \in [k], i \neq j$, Check-Consistency($\mu_i, \mu_j, f, f, \epsilon/5, \delta$) has succeeded. Then there exists a halfspace $h$ such that for all $i \in [k], \text{dist}_{\mu_i}(f, h) < 3\epsilon$. 

20
6.4 The RI-Tester Algorithm

The RI-Tester algorithm will divide the whole RI space into several “rings”, each of which is simple. We will not take fresh samples for each run of a subroutine inside a ring: instead we will take a large set of samples at the start and ignore any rings which do not receive enough samples. We then simulate each subroutine, reusing these samples each time and using the union bound to ignore that the samples are not independent. The following lemma, whose proof is delayed until after the presentation of the algorithm, allows us to ignore the rings with few samples:

**Lemma 6.6.** Let \( \epsilon, \delta > 0 \) and let \( \mu \) be an arbitrary probability distribution over a space \( X \) and suppose \( X \) is partitioned into sets \( \{R_i\}_{i \in [k]} \) for some \( k \). Let \( \{m_i\}_{i \in [k]} \) be a set of arbitrary nonnegative numbers with maximum value \( m = \max_i m_i \geq \frac{k}{\epsilon} \ln(2k/\delta) \). Let \( X \) be a set of \( M = \frac{2k}{\epsilon} m \) random samples from \( \mu \). Write \( A = \{i \in [k] : \#(X \cap R_i) < m_i\} \). Then with probability at least \( 1 - \delta \) we have \( \sum_{i \in A} \mu(R_i) < \epsilon \).

In the application of this lemma, the number of samples \( m_i \) for each ring is determined by the number of samples required by the Simple-Tester and Check-Consistency algorithms:

**Definition 6.7.** For \( \epsilon, \delta \in (0, 1) \), the combined sample complexity of Simple-Tester and Check-Consistency with parameters \( \epsilon, \delta \) is

\[
m(\epsilon, \delta) = \Theta \left( \frac{\sqrt{n}}{\epsilon^6} \log \left( \frac{1}{\delta} \right) \right)
\]

by Theorem 5.5 and Lemma 6.4. (Check-Consistency requires samples from two distributions, but we only count the number of samples required from one of them).

**Theorem 1.1.** Let \( \mu \) be any RI distribution over \( \mathbb{R}^n \), \( f : \mathbb{R}^n \to \{\pm 1\} \) be any measurable function, and let \( \epsilon, \delta > 0 \). Then RI-Tester, using no knowledge of \( \mu \) and at most \( O \left( \frac{\sqrt{n} \log(n/\epsilon)}{\epsilon^7} \log \left( \frac{\log(n/\epsilon)}{\delta} \right) \right) \) random examples, satisfies the following:

1. If \( f \) is a halfspace, then RI-Tester accepts with probability at least \( 1 - \delta \); and
2. If \( \text{dist}_\mu(f, h) > \epsilon \) for all halfspaces \( h \) then RI-Tester rejects with probability at least \( 1 - \delta \).

**Proof.** We remark that the Simple-Tester subroutine is called on distributions not necessarily bounded by \( R = \sqrt{n} \); this is easily remedied by rescaling the samples, which we may do since the algorithm knows the bounds on each distribution \( \mu_i \).

We will prove the sample complexity and show that the algorithm succeeds with probability at least \( 1 - \delta \). First we note that the set \( X \) of samples has size

\[
M = \frac{2k}{\epsilon} m(\epsilon, \delta/K) = O \left( \frac{k \sqrt{n}}{\epsilon^7} \log(K/\delta) \right) = O \left( \frac{\sqrt{n} \log(n/\epsilon)}{\epsilon^6} \log \left( \frac{\log(n/\epsilon)}{\delta} \right) \right).
\]

The subroutines which do not use the samples in \( X \) are Find-Pivot, Estimate-Mean, and Check-Threshold, which together require \( O \left( \frac{1}{\epsilon^4} \log(K/\delta) \right) = O \left( \frac{1}{\epsilon^2} \log \left( \frac{\log(n/\epsilon)}{\delta} \right) \right) \) samples; thus the total number of samples is \( O \left( \frac{\sqrt{n} \log(n/\epsilon)}{\epsilon^7} \log \left( \frac{\log(n/\epsilon)}{\delta} \right) \right) \). We bound the probability that the algorithm fails by the probability that any of the subroutines fail, or if too few samples occur in
Algorithm 8 RI-Tester($\mu, \epsilon, \delta$)

Find the pivot and define the parameters:
1. $k \leftarrow \lceil \log \left( \frac{2n}{\sqrt{2\pi \epsilon}} \right) \rceil$; \hspace{1em} $K \leftarrow \left( \frac{k}{2} \right) + k + 5$
2. $\bar{t} \leftarrow \text{Find-Pivot}(\mu, f, \epsilon^2, \delta/K)$

Gather the samples and find the “significant” rings:
3. Draw $X \sim \mu^M$ for $M = \frac{2k}{\epsilon} m(\epsilon, \delta/K)$
4. $\forall i \in [k]: (f_i, R_i, S_i, \mu_i) \leftarrow (f, \{x : 2^{i-1} \leq \|x\|/\bar{t} \leq 2^i\}, X \cap R_i, \mu |_{R_i})$
5. Let $\mu_{k+1}, f_{k+1}$ be the projection for $f$ on $\mu |_{(T, \infty)}$, defined by Lemma 6.2
6. $A \leftarrow \{i \in [k+1] : \#S_i \geq m(\epsilon, \delta/K)\}$

Ensure the function is close to a halfspace on each ring:
7. for $i \in A$ do
8. \hspace{1em} Simulate $\text{Simple-Tester}(\mu_i, f_i, \epsilon, \delta/K)$ on $S_i$; reject if it rejects.

Check that the halfspaces for each ring are consistent with each other:
9. for $i, j \in A, i < j$ do
10. \hspace{1em} Simulate $\text{Check-Consistency}(\mu_i, \mu_j, f_i, f_j, \epsilon, \delta/K)$ on $S_i$; reject if it rejects.

Ensure all rings of large radius are close to balanced:
11. for $i \in A : i - 2 \geq \log \left( \frac{\sqrt{n}}{2 \sqrt{2 \pi \epsilon}} \right)$ do
12. \hspace{1em} if $|\text{Estimate-Mean}(\mu_i, f_i, \epsilon/2, \delta/K)| > \epsilon$ then reject

Ensure the central section is close to the correct constant:
13. if $\# \{x \in X : \|x\| < \bar{t} \} \geq m_0 := O \left( \frac{1}{\epsilon} \log(K/\delta) \right)$ and $A \neq \emptyset$ then
14. \hspace{1em} $\tilde{v}_1 \leftarrow \text{Estimate-Mean}(\mu_0, f, 2\epsilon/3, \delta/K)$
15. \hspace{1em} $\tilde{v}_2 \leftarrow \text{Estimate-Mean}((\mu_{\bar{t}}, \infty), f, \epsilon/2, \delta/K)$
16. \hspace{1em} if $\text{Check-Threshold}(\mu_0, \mu_{\bar{t}}, \infty), (\tilde{v}_1 + 1)/2, (\tilde{v}_2 + 1)/2, \epsilon, \delta/K)$ rejects then reject
17. accept

Each significant ring (i.e. $\sum_{i \in A} \mu(R_i) \geq \epsilon$). To bound the probability of this latter event, we use Lemma 6.4 on the set of $k + 1$ rings $R_i$, with the parameter $m(\epsilon, \delta/K)$ for each ring. For this we must have $m(\epsilon, \delta/K) \geq \frac{k}{\epsilon} \ln(2kK/\delta)$: since $k = \log \left( \frac{2n}{\sqrt{2\pi \epsilon}} \right)$ we have

$$m(\epsilon, \delta/K) \geq \frac{\sqrt{n}}{\epsilon^6} \ln(K/\delta) = \omega \left( \frac{k}{\epsilon} \ln(kK/\delta) \right),$$

Equation (3)

so with probability at least $1 - \delta/K, \sum_{i \in A} \mu(R_i) < \epsilon$. Assuming this is successful, we can bound the failure probability of the rest of the algorithm: There are at most $(\frac{k}{2}) + k + 4$ subroutines that succeed with probability at least $1 - \delta/K$ so by the union bound the probability of success is at least $1 - \delta$. For the rest of the proof, assume that all procedures have succeeded.

Completeness: Suppose $f$ is a halfspace with threshold $t$. The next claim bounds the mean for all large rings, which we will use to show that $\text{Simple-Tester}$ works on the projected function $f_{k+1}$ and that line 8 will pass.

Claim 6.8. Set $i^* = \log \left( \frac{\sqrt{n}}{\sqrt{2 \pi \epsilon}} \right)$. For all $i \in [k + 1], |E_{\mu_i} f| \leq \epsilon/2^{i - i^* - 1}$.
Proof. Let $r = 2^i \tilde{t} = 2^i r - 1 2^i \tilde{t} = 2^i r - 1 \sqrt{\pi n} \epsilon$. We have $|\mathbb{E}_\mu f| \leq |\mathbb{E}_\sigma f|$ since $f$ is a halfspace and $\mu_i$ is a convex combination of spheres of radius at least $\tilde{t} \cdot 2^i - 1$. Now by Proposition 3.15, the bound on the density Proposition 3.9 and the fact that $|t| \leq \tilde{t}$ by the guarantee of FIND-PIVOT (Lemma 6.1),

$$|\mathbb{E}_\sigma f| = \mathbb{P}_{x \sim \sigma_v} [-|t| < x_1 < |t|] \leq 2|t| \frac{\sqrt{n}}{2 \pi r} \leq 2 \tilde{t} \frac{\sqrt{n}}{2 \pi r} = \epsilon / 2^{i - r - 1}.$$ 

Lines 7, 8: The examples of functions $f_1, \ldots, f_k$ are not modified, so these lines pass for $i \in [k]$ by Theorem 5.5. It remains to show that $f_{k+1}$ passes, since these examples have been normalized. Let $c$ be the constant in the tolerance guarantee of Theorem 5.5 (for $\eta = 1$). We have $(k + 1) - i^* - 1 \geq \log(2n) - \log(2 \sqrt{n}) = \log(2 \sqrt{n})$ so the mean of the function on the $(k + 1)$th ring is at most $|\mathbb{E} f(x) | \| x \| \geq 2^k \tilde{t} | \leq \epsilon / 2 \sqrt{n} < ce^4$ when $\epsilon \geq \frac{1}{(4c^2 n)^{1/6}}$. Thus by Lemma 6.2 we know that $f_{k+1}$ is $ce^4$-close to a halfspace on the projected distribution $\mu_{k+1}$ so line 8 will pass.

Lines 9, 10: The functions $f_1, \ldots, f_k$ pass this test by Lemma 6.4. We have just proved that $f_{k+1}$ is $ce^4$-close to a halfspace, and again by Lemma 6.2 we know that $f_{k+1}$ is aligned with $f$, so it satisfies the requirement of CHECK-CONSISTENCY and will also pass these lines.

Lines 11, 12: Claim 6.8 proves that $|\mathbb{E}_\mu f| \leq \epsilon / 2$ for each $i$ on which line 12 is applied, so these lines pass.

Line 16: We have $|\tilde{v}_1 - \mathbb{E}_\mu f| < \epsilon, |\tilde{v}_2 - \mathbb{E}_{\mu_{[i, \infty)}} f| < \epsilon$. Let $t_1, t_2$ be thresholds such that the halfspaces $h_i(x) := \text{sign}(\langle u, x \rangle - t_i)$ satisfy $\mathbb{E}_\mu h_1 = \tilde{v}_1, \mathbb{E}_{\mu_{[i, \infty)}} h_2 = \tilde{v}_2$. For $i \in \{1, 2\}$ and distributions $\mu_0, \mu_{[i, \infty)}$ respectively, and assuming without loss of generality that $t \leq t_i$, we have

$$2\epsilon / 3 \geq |\tilde{v}_i - \mathbb{E} f| = |\mathbb{P} [z \geq t_i] - \mathbb{P} [z \geq t] - \mathbb{P} [z < t] - \mathbb{P} [z < t_i]| = 2 \mathbb{P} [t \leq z \leq t_i] = 2 \text{dist}(t, t_i),$$

so CHECK-THRESHOLD accepts by Lemma 6.3.

Soundness: Suppose $f$ is accepted by the algorithm. We want to find a halfspace $h$ such that $f$ is $\epsilon$-close to $h$.

Claim 6.9. Suppose the algorithm succeeds and accepts $f$, and let $\tilde{t}$ be the value of FIND-PIVOT. Then there exists a halfspace $h$ such that

$$\mu_{[\tilde{t}, \infty)} \cdot \text{dist}_{[\tilde{t}, \infty)}(f, h) < 5 \epsilon.$$ 

Proof. Since line 8 passes for each $i \in A$, we know from Theorem 5.5 that there exists a halfspace $h_i$ aligned with $f$ on $\mu_i$ satisfying $\mathbb{E}_\mu h_i = \mathbb{E}_\mu f$ and $\text{dist}_\mu(f, h_i) \leq \epsilon$. Thus from Lemma 6.5 there exists a halfspace $h$ such that $\text{dist}_\mu(f, h) < 3 \epsilon$ for each $i \in A$.

Special attention is required for $\mu_{k+1}$, which is the projection of the distribution over radii $[T, \infty)$ onto a sphere, as in Lemma 6.2. Write $\mu_{k+1}'$ for the distribution $\mu$ restricted to $R_{k+1}$ (i.e. the distribution $\mu_{k+1}$ before it was projected onto a sphere). If $k + 1 \in A$ then we know the projected function $f_{k+1}$ is $3\epsilon$-close to the halfspace $h$ on $\mu_{k+1}$. By line 12, we know that $|\mathbb{E}_{\mu_{k+1}} f_{k+1}| < \epsilon$, so by the lemma we know that $f$ is $2\epsilon$-close to the balanced halfspace $h'$ aligned with $h$; now we need to make sure $h'$ is close to $h$.

Since $\mu_{k+1}'$ is the distribution over radii greater than $T$, the distance between $h'$ and $h$ on $\mu_{k+1}'$ is at most the distance on the sphere of radius $T$. We want to show, for the sphere of radius $T$, that
the halfspace \( h \) should have threshold \( t \) satisfying

\[
\text{dist}_{\mu'_{k+1}}(h, h') = \mathbb{P}[0 \leq x_i < t] \leq 4\epsilon.
\]

Recall that \( r = 2\tilde{t} \sqrt{n}/\sqrt{2\pi\epsilon} \).

**Case 1:** Suppose there exists \( i \in A \) such that \( \tilde{t} \cdot 2^{i-1} \geq r \), so \( 12 \) is executed for some such \( i \).

Then we have \( |\mathbb{E}_{\mu_i} f| \leq \epsilon + \epsilon/2 \leq 2\epsilon \) and \( \text{dist}_{\mu_i}(f, h) \leq 3\epsilon \) so \( |\mathbb{E}_{\mu_i} h| < 8\epsilon \). Since \( \mu'_{k+1} \) is a distribution over spheres of larger radius than sphere \( i \), we know that \( |\mathbb{E}_{\mu_{k+1}} h| = 2\mathbb{P}[0 \leq x_1 < t] < 8\epsilon \), which proves equation (4).

**Case 2:** Suppose that for all \( i \leq k \) such that \( \tilde{t} \cdot 2^{i-1} \geq r, i \notin A \). Then lines 8 and 10 were not executed for any such rings \( i \), so we may ignore them. Suppose \( t > r \); then \( h \) is constant on all radii at most \( r \), and we can consider the halfspace with threshold \( r \) instead of \( t \) without changing the distance on those radii. Since \( f \) is close to balanced on \( \mu_{k+1} \), we can again consider threshold \( r \). Thus we can assume that \( t \leq r \). Since \( t \leq r \) we have, for the sphere of radius \( T \),

\[
|\mathbb{E}_{\mu_{k+1}} h| = 2\mathbb{P}[0 \leq x_1 < t] \leq 2r \frac{\sqrt{n}}{\sqrt{2\pi T}} \leq 2t \frac{\sqrt{n}}{\sqrt{2\pi T}} \leq 2\epsilon
\]

since \( r = 2\tilde{t} \frac{\sqrt{n}}{\sqrt{2\pi\epsilon}} \leq \epsilon T^{\frac{n}{2}} \) when \( T \geq 2\tilde{t} \frac{\sqrt{n}}{\sqrt{\epsilon}} \). Then equation (4) holds.

We have \( m(\epsilon, \delta/K) = \omega\left(\frac{1}{\epsilon} \ln(kK/\delta)\right) \) (equation (3)), so from Lemma 6.6 we know that \( \sum_{i \notin A} \mu(R_i) < \epsilon \). Since \( \bigcup_i R_i = \{x \in \mathbb{R}^n : \|x\| \geq \tilde{t}\} \), we conclude

\[
\mu_0[\tilde{t}, \infty) \cdot \text{dist}_{[\tilde{t}, \infty)}(f, h) = \sum_{i \in A} \mu(R_i) \text{dist}_{\mu_i}(f, h) + \sum_{i \notin A} \mu(R_i) \text{dist}_{\mu_i}(f, h) \leq 4\epsilon + \epsilon.
\]

Now if \( \mu_0[0, \tilde{t}) < \epsilon \) we may ignore this interval. If \( \mu_0[0, \tilde{t}) \geq \epsilon \) while \( \mu_0[\tilde{t}, \infty) < \epsilon \) then we may ignore the latter interval and by FIND-PIVOT we know that for some constant \( b \),

\[
\mathbb{P}[f(x) \neq b] \leq \mathbb{P}[f(x) \neq b \land \|x\| < \tilde{t}] + \epsilon \leq \epsilon^2 + \epsilon.
\]

Thus \( f \) is \( 2\epsilon \)-close to the constant function \( b \). So all that remains is the case where neither interval \( [0, \tilde{t}) \) or \( [\tilde{t}, \infty) \) can be safely ignored. In this case line 10 is executed. From FIND-PIVOT we have

\[
\epsilon \cdot \mathbb{P}_{f(x) \neq b}[\|x\| < \tilde{t}] \leq \mathbb{P}[f(x) \neq b \land \|x\| < \tilde{t}] < \epsilon^2
\]

so \( f \) is \( \epsilon \)-close to the constant \( b \) on \( \mu_0 \). Let \( h_1 \) be the halfspace aligned with \( h \) with \( \mathbb{E}_{\mu_0} h_1 = \tilde{v}_1 \) and let \( h_2 \) be the halfspace aligned with \( h \) with \( \mathbb{E}_{\mu_{[\tilde{t}, \infty)}} h_2 = \tilde{v}_2 \). Since \( f \) is \( \epsilon \)-close to the constant \( b \) on \( \mu_0 \) we have

\[
\text{dist}_{\mu_0}(f, h_1) \leq \text{dist}_{\mu_0}(f, b) + \text{dist}_{\mu_0}(b, h_1) \leq \epsilon + \frac{1}{2} \mathbb{E}[b - h_1(x) \mid \|x\| < \tilde{t}] \leq 2\epsilon,
\]

since \( \mathbb{E}[b - h_1(x) \mid \|x\| < \tilde{t}] \leq |1 - \tilde{v}_1| \leq 2\epsilon \). We can show a similar bound for \( h_2 \):

\[
\text{dist}_{[\tilde{t}, \infty)}(f, h_2) \leq \text{dist}_{[\tilde{t}, \infty)}(f, h) + \text{dist}_{[\tilde{t}, \infty)}(h, h_2)
\]

\[
\leq \epsilon + \frac{1}{2} \mathbb{E}_{[\tilde{t}, \infty)}[h - h_2]\|
\]

\[
\leq 2\epsilon + \frac{1}{2} \mathbb{E}_{[\tilde{t}, \infty)}[f - h_2]\|
\]

\[
\leq 3\epsilon.
\]
Now since \( h_1, h_2 \) are both aligned with \( h \), from CHECK-THRESHOLD (Lemma 6.3) we are guaranteed that there exists a halfspace \( h' \) such that \( \text{dist}_{[0, \tilde{t}]}(h_1, h'), \text{dist}_{[\tilde{t}, \infty)}(h_2, h') \leq \epsilon \). Therefore we have
\[
\text{dist}(f, h') \leq \mu_0[0, \tilde{t}) \cdot \text{dist}_{[0, \tilde{t}]}(f, h') + \mu_0[\tilde{t}, \infty) \cdot \text{dist}_{[\tilde{t}, \infty)}(f, h') \\
\leq \mu_0[0, \tilde{t}) (2\epsilon + \mu_0[\tilde{t}, \infty)(3\epsilon + \epsilon) \leq 4\epsilon. \]

\[\square\]

**Lemma 6.6 (repeated).** Let \( \epsilon, \delta > 0 \) and let \( \mu \) be an arbitrary probability distribution over a space \( \mathcal{X} \) and suppose \( \mathcal{X} \) is partitioned into sets \( \{R_i\}_{i \in [k]} \) for some \( k \). Let \( \{m_i\}_{i \in [k]} \) be a set of arbitrary nonnegative numbers with maximum value \( m = \max_i m_i \geq \frac{k}{\epsilon} \ln(2k/\delta) \). Let \( X \) be a set of \( M = \frac{2k}{\epsilon} m \) random samples from \( \mu \). Write \( A = \{i \in [k] : \#(X \cap R_i) < m_i\} \). Then with probability at least \( 1 - \delta \) we have \( \sum_{i \in A} \mu(R_i) < \epsilon \).

**Proof.** Write \( m = \max_i m_i \). Define a parameter \( L \), to be fixed later, and write \( M = (L + 1)\frac{k}{\epsilon} m \). Write \( S_i = \#(X \cap R_i) \). Let \( i \in [k] \) be any index such that \( \mu(R_i) \geq \epsilon/k \). Then we want to show that
\[
P[S_i < m_i] \leq \delta/k. \]

We have \( S_i = \sum_{x \in X} 1 [x \in R_i] \) so \( S_i \) is a sum of independent Bernoulli random variables with expectation \( \mathbb{E}[S_i] = M \mu(R_i) \). Then
\[
P[S_i < m_i] \leq P[|M \mu(R_i) - S_i| > M \mu(R_i) - m_i] \]
and
\[
M \mu(R_i) = \mu(R_i)(L + 1) \frac{km}{\epsilon} \geq (L + 1) \frac{\epsilon km}{k} = (L + 1)m. \]

Then \( M \mu(R_i) - m_i \geq (L + 1)m - m_i \geq Lm \) so
\[
P[S_i < m_i] \leq P[|M \mu(R_i) - S_i| > M \mu(R_i) - m_i] \leq P[|M \mu(R_i) - S_i| > Lm] \leq 2\exp \left(-\frac{2(Lm)^2}{M} \right) \]
by Hoeffding’s inequality. We want this probability to be at most \( \delta/k \) so we want
\[
\frac{2(Lm)^2}{M} \geq \ln(2k/\delta). \]
Substituting \( Lm = \frac{k}{\epsilon} m - 1 \) \( m = \frac{k}{\epsilon} M - m \), we have
\[
\frac{2(Lm)^2}{M} = \frac{2(\epsilon k - m)^2}{M} = 2M \frac{\epsilon^2}{k^2} - 4\frac{\epsilon}{k} m + 2\frac{m^2}{M} \]
Suppose \( m \geq \frac{k}{\epsilon} \ln(2k/\delta) \). Then for \( M = \frac{2m}{\epsilon} k \) the first two terms cancel out and the expression is
\[
\frac{2(Lm)^2}{M} = \frac{m \epsilon}{k} \geq \ln(2k/\delta), \]
which is what we want. Using the union bound, we get that the probability that any set \( R_i \) with \( \mu(R_i) \geq \epsilon/k \) has \( S_i < m_i \) is at most \( \delta \):
\[
P[\exists i : \mu(R_i) \geq \epsilon/k, S_i < m_i] \leq kP[S_i < m_i] \leq \delta. \]

Assuming this event does not occur, the only indices \( i \) satisfying \( S_i < m_i \) are those with \( \mu(R_i) < \epsilon/k \), so
\[
\sum_{i \in A} \mu(R_i) < \sum_{i \in A} \epsilon/k \leq \epsilon. \]

\[\square\]
6.5 Proofs for Checking Consistency

We now present the proofs of Lemmas 6.3 and 6.4. For convenience we will restate these lemmas:

Lemma 6.3 Let $\epsilon, \delta \in (0, 1/2)$, $v_1, v_2 \in [0, 1]$ and let $\mu_1, \mu_2$ be any distribution over $\mathbb{R}$, unknown to the algorithm. Let $t_1, t_2$ satisfy $P_{x \sim \mu_1} [x_1 \geq t_1] = v_1$, $P_{y \sim \mu_2} [y_1 \geq t_2] = v_2$. Then, using $O\left(\frac{1}{\epsilon^2} \log(1/\delta)\right)$ samples, with probability at least $1 - \delta$ CHECK-THRESHOLD satisfies the following:

1. If there exists a threshold $t$ such that $\text{dist}_{\mu_1}(t_1, t), \text{dist}_{\mu_2}(t_2, t) < \epsilon/3$ then CHECK-THRESHOLD accepts; and
2. If CHECK-THRESHOLD accepts then there exists $t$ such that $\text{dist}_{\mu_1}(t_1, t), \text{dist}_{\mu_2}(t_2, t) \leq \epsilon$.

Proof of Lemma 6.3. First we show that $\epsilon/3 \leq \mu_1(\tilde{a}_1, t_1), \mu_1(t_2, \tilde{b}_1), \mu_2(\tilde{a}_2, t_2), \mu_2(t_2, \tilde{b}_2) \leq \epsilon$ with high probability. This is accomplished by using Proposition A.5 4 times with parameters $\epsilon/3, \delta/4$ and each combination of $v = v_i \pm 2\epsilon/3$ for $i$ and $\pm$.

Suppose without loss of generality that $t_1 \leq t_2$, and assume the above estimations succeed. Note that if $\tilde{a}_i = -\infty$ then $v_1 + 2\epsilon/3 > 1$ so $v_1 > 1 - 2\epsilon/3 \geq 2/3$. Therefore $\tilde{b}_i$ is finite, and the opposite direction holds as well, so only one of $\tilde{a}_i, \tilde{b}_i$ is infinite. If $\tilde{a}_1$ is finite then $\mu_1[\tilde{a}_1, t_1) \geq \epsilon/3$ so $\tilde{a}_1 < t_1$; if $\tilde{a}_1 = -\infty$ this clearly holds as well. Similarly $t_2 < \tilde{b}_2$, so $\tilde{a}_1 \leq t_1 \leq t_2 \leq \tilde{b}_2$.

For the first guarantee, we have $\mu_1(t_1, t), \mu_2(t_2, t) < \epsilon/3$, and we want to show that the intervals $[\tilde{a}_1, \tilde{b}_1], [\tilde{a}_2, \tilde{b}_2]$ overlap. If $t > \tilde{b}_1$ then

$$\mu_1(t_1, t) \geq \mu_1(t_1, \tilde{b}_1) \geq \epsilon/3$$

which is a contradiction. Likewise if $t < \tilde{a}_2$ then $\mu_2(t_2, t) \geq \epsilon/3$; thus $\tilde{a}_2 \leq t \leq \tilde{b}_1$. Therefore the intervals overlap and the test passes.

Now suppose that the test passes, so the intervals $[\tilde{a}_1, \tilde{b}_1], [\tilde{a}_2, \tilde{b}_2]$ overlap. Let $t$ be some point inside the intersection. We need to show that $\mu_1(t_1, t), \mu_2(t_2, t) \leq \epsilon$, which is easily seen since $\mu_1(t_1, t) \leq \mu_1[\tilde{a}_1, \tilde{b}_1] \leq \epsilon$, and the analogous argument holds for $\mu_2$. \hfill \square

Lemma 6.4. Let $\mu_1, \mu_2$ be bounded RI distributions over $\mathbb{R}^n$, with shared constant $C$, unknown to the algorithm. Assume that for $\tau_1 = \mathbb{E}_{x \sim \mu_1} [x_1^2], \tau_2 = \mathbb{E}_{x \sim \mu_2} [x_1^2]$ that $\tau_1 \tau_2 = 1$. Let $\epsilon, \delta \in (0, 1/2)$ and let $f_1, f_2 : \mathbb{R}^n \to \{\pm 1\}$ be $\mu_1$- and $\mu_2$-measurable functions. Then CHECK-CONSISTENCY satisfies the following:

- If there exists a halfspace $h$ such that $\text{dist}_{\mu_1}(f_1, h), \text{dist}_{\mu_2}(f_2, h) < \epsilon/6$ and $h$ is aligned with $f_1, f_2$, the algorithm will accept with probability at least $1 - \delta$; and
- If there exist halfspaces $h_1, h_2$ with thresholds $t_1, t_2$ such that $\text{dist}_{\mu_1}(f_1, h_1), \text{dist}_{\mu_2}(f_2, h_2) < \epsilon$ and $h_1, h_2$ are aligned with $f_1, f_2$ with $E_{\mu_1} h_1 = E_{\mu_1} f_1, E_{\mu_2} h_2 = E_{\mu_2} f_2$, then with probability at least $1 - \delta$: if the algorithm accepts then there exists a threshold $t$ such that $\text{dist}_{\mu_1}(t_1, t), \text{dist}_{\mu_2}(t_2, t) < 2\epsilon$, and one of the following holds:
  1. $\alpha(h_1, h_2) \leq \frac{\epsilon}{2}$, or
  2. $|E_{\mu_1} f_1| \geq 1 - \frac{3}{2}\epsilon$ or $|E_{\mu_2} f_2| \geq 1 - \frac{3}{2}\epsilon$.

In particular, as a consequence, there exists a halfspace $h$ such that $\text{dist}_{\mu_1}(f_1, h), \text{dist}_{\mu_2}(f_2, h) < 5\epsilon$. 

26
The algorithm requires at most \( O\left(\frac{\sqrt[3]{\alpha}}{\epsilon^2} \log(1/\delta)\right) \) random samples from each distribution.

**Proof.** The calls to \textsc{Estimate-Mean} require at most \( O\left(\frac{1}{\epsilon^2} \log(1/\delta)\right) \) samples (Lemma \ref{lem:est-mean}), the call to \textsc{Check-Threshold} requires at most \( O\left(\frac{1}{\epsilon^2} \log(1/\delta)\right) \) samples (Lemma \ref{lem:check-threshold}), and the three calls to \textsc{Estimate-IP} and \textsc{Estimate-Norm} each require \( m = \Theta\left(\frac{\sqrt[3]{\alpha}}{\epsilon^2} \log(1/\delta)\right) \) samples. So the total sample complexity is \( \Theta\left(\frac{\sqrt[3]{\alpha}}{\epsilon^2} \log(1/\delta)\right) \). By the union bound, the probability of failure is at most \( \delta \). In the following, assume all estimations succeed, and let \( c_1 = \|\mathbb{E}_{\mu_1}[x f_1(x)]\|, c_2 = \|\mathbb{E}_{\mu_2}[x f_2(x)]\|, p = (\mathbb{E}_{\mu_1}[x f_1(x)], \mathbb{E}_{\mu_2}[x f_2(x)]) \).

**Completeness:** Suppose there exists a halfspace \( h \) of distance at most \( \epsilon/2 \) to both \( f_1 \) and \( f_2 \), and let \( t \) be the threshold of \( h \). Let \( t_1, t_2 \) be the thresholds of the halfspaces \( h_1, h_2 \) aligned with \( f_1, f_2, h \) such that \( \mathbb{E}_{\mu_1} f_1 = \mathbb{E}_{\mu_1} h_1 \) and \( \mathbb{E}_{\mu_2} f_2 = \mathbb{E}_{\mu_2} h_2 \). Then

\[
\text{hdist}_{\mu_1} (t_1, t) = \text{dist}_{\mu_1} (h_1, h) = \frac{1}{2} \left| \mathbb{E}_{x \sim \mu_1} [h_1(x) - h(x)] \right| = \frac{1}{2} \left| \mathbb{E}_{x \sim \mu_1} [f_1(x) - h(x)] \right| \leq \text{dist}_{\mu_1} (f_1, h) < \epsilon/6
\]

and same for \( \text{hdist}_{\mu_2} (t_2, t) \). Let \( \tilde{t}_1, \tilde{t}_2 \) be the thresholds for halfspaces with volumes \( \tilde{v}_1, \tilde{v}_2 \), respectively, on \( \mu_1 \) and \( \mu_2 \). Then \( \text{hdist}_{\mu_1} (\tilde{t}_1, t_1) = |\tilde{v}_1 - v_1|/2 \leq \epsilon/6 \) and the same for \( \tilde{t}_2 \). We have for each \( i \) that

\[
P_{z \sim (\mu_i)_x} \left[ z \geq \tilde{t}_i \right] = (\tilde{v}_i + 1)/2 \text{ are the parameters used for Check-Threshold. Since } \text{hdist}_{\mu_1} (\tilde{t}_1, t_1) \leq \text{hdist}_{\mu_1} (\tilde{t}_1, t_1) + \text{hdist}_{\mu_1} (t_1, t) \leq \epsilon/6 + \epsilon/6 \leq \epsilon/3,
\]

the condition for the first guarantee of \textsc{Check-Threshold} (Lemma \ref{lem:check-threshold}) is satisfied, so \textsc{Check-Threshold} passes.

Suppose \( |\tilde{v}_1|, |\tilde{v}_2| < 1 - \epsilon \), so that \( |\mathbb{E}[h_1]|, |\mathbb{E}[h_2]| < 1 - \epsilon/2 \). Keep in mind that \( \mu_1, \mu_2 \) may not be isotropic, so when we compare the estimates \( \tilde{c}_1, \tilde{c}_2 \), and \( \tilde{p} \) we will use the multiplicative guarantees of \textsc{Estimate-IP}. However, to prove that the multiplicative guarantees on each estimate hold, we scale the distributions appropriately to match the hypothesis of Lemma \ref{lem:ip-multiplicative}. The multiplicative guarantee holds for \( \tilde{c}_1 \) if it holds when \( \mu_1 \) is scaled to be isotropic, so assume this is the case. By Proposition \ref{prop:ip-multiplicative} we know that

\[
\| \mathbb{E}_{x \sim \mu_1} [x h_1(x)] \| \geq \frac{C}{2} \epsilon.
\]

Then from Lemma \ref{lem:ip-multiplicative} we have for some constant \( K > 0 \),

\[
c_1^2 \geq \left( \| \mathbb{E}_{\mu_1} [x h_1(x)] \| - K \epsilon \sqrt{\ln(1/\epsilon)} \right)^2 = \frac{C^2}{4} \epsilon^2 - \frac{C K}{2} \epsilon^2 \sqrt{\ln(1/\epsilon)} + K^2 \epsilon^2 \ln(1/\epsilon).
\]

We may assume \( K \geq 1 \) since \( K \) is an upper bound in Lemma \ref{lem:ip-multiplicative} and we also know \( C \leq 1 \). Thus the following inequalities hold when \( \epsilon \leq 1/2 \leq e^{-1/4} \):

\[
K \sqrt{\ln(1/\epsilon)} \geq C/2 \iff \sqrt{\ln(1/\epsilon)} \geq C/(2K) \iff \epsilon \leq \exp\left(-\frac{C^2}{4K^2}\right),
\]

and this implies that \( c_1^2 \geq \frac{C^2}{4} \epsilon^2 \); this holds also for \( c_2^2 \) by the same argument.

Now we must show that \( \tilde{p} \) satisfies the multiplicative guarantee. We may no longer assume that both \( \mu_1, \mu_2 \) are isotropic since we are comparing the two, but we know that for \( \tau_1 = \mathbb{E}_{\mu_1} [x_1^2], \tau_2 = \mathbb{E}_{\mu_2} [x_1^2], \tau_3 = \mathbb{E}_{\mu_3} [x_2^2], \tau_4 = \mathbb{E}_{\mu_4} [x_2^2] \),
\( \tau_1 \tau_2 = 1 \). Rescaling inequality (5) gives us \( c_1 \geq \sqrt{\tau_1} \cdot C\epsilon / 4 \) and similar for \( c_2 \). Since \( f_1, f_2 \) are aligned, \( p = c_1 c_2 \), so we also have \( p \geq \sqrt{\tau_1 \tau_2} \cdot C^2 \epsilon^2 / 4 = C^2 \epsilon^2 / 4 \). Thus
\[
\tilde{p} \geq \frac{C^2}{4} \epsilon^2 - \epsilon_1^2 \geq C^2 (3/12 - 1/12) \epsilon^2 \geq \frac{C^2}{6} \epsilon^2
\]
since \( \epsilon_1^2 = \frac{C^2}{12} \epsilon^2 \). Then line 9 passes and \( m = \Theta \left( \frac{\sqrt{\epsilon_1} \log(1/\delta)}{\epsilon_1^2} \right) \geq \Omega \left( \frac{\sqrt{\epsilon_1}}{\epsilon_1^2} \log(1/\delta) \right) \) so (for large enough constant in the definition of \( m \)) the multiplicative accuracy guarantee for Estimate-IP holds and we have \( c_1^2 = (1 \pm \epsilon_1^2) c_1^2, c_2^2 = (1 \pm \epsilon_1^2) c_2^2, \tilde{p} = (1 \pm \epsilon_1^2)p \). Then the test passes since, by Claim 6.10 below, we have
\[
\frac{\tilde{p}}{\sqrt{c_1^2 c_2^2}} \geq \frac{1 - \epsilon_1^2}{1 + \epsilon_1^2} \frac{p}{c_1 c_2} \geq 1 - 2\epsilon_1^2 \geq 1 - 2\epsilon^2.
\]

**Claim 6.10.** For any \( x \in [0, 1] \), \( \frac{1-x}{1+x} \geq 1 - 2x \).

**Proof.** \( \frac{d}{dx} \frac{1-x}{1+x} = -\frac{1}{1+x} + (1-x) \frac{d}{dx} (1+x)^{-1} = -\frac{1}{1+x} - (1-x) (1+x)^{-2} = -\frac{2}{(1+x)^2} \geq -2 \).

**Soundness:** Suppose that the algorithm accepts. By the guarantee on Check-Threshold (Lemma 6.3) there exists a threshold \( t \) such that \( h_{dist_{\mu_1}}(\tilde{t}_1, t), h_{dist_{\mu_2}}(\tilde{t}_2, t) \leq \epsilon \).

\[
h_{dist_{\mu_1}}(\tilde{t}_1, t) \leq h_{dist_{\mu_1}}(\tilde{t}_1, \tilde{t}_1) + h_{dist_{\mu_1}}(\tilde{t}_1, t) \leq \epsilon / 3 + \epsilon ,
\]
and the same for \( t_2 \), so the first conclusion holds. Now there are two cases for the remaining tests:

**Case 1:** Consider the case where either \( |\tilde{v}_1| \geq 1 - \epsilon \) or \( |\tilde{v}_2| \geq 1 - \epsilon \). Without loss of generality assume \( |\tilde{v}_1| \geq 1 - \epsilon \), so that \( |E_{\mu_1}| \geq 1 - \frac{3}{2} \epsilon \). We must show that there exists a halfspace \( h \) such that \( \text{dist}_{\mu_1}(f_1, h), \text{dist}_{\mu_2}(f_2, h) \leq 4\epsilon \). Let \( h \) be the halfspace with threshold \( t \) that is aligned with \( h_2 \). Then
\[
\text{dist}_{\mu_2}(f_2, h) \leq \text{dist}_{\mu_2}(f_2, h_2) + \text{dist}_{\mu_2}(h_2, h) \leq \epsilon + \text{dist}_{\mu_2}(t_2, t) \leq 3\epsilon .
\]

Next, let \( h_1' \) be the halfspace \( h_1 \) rotated to be aligned with \( h \). Then
\[
\text{dist}_{\mu_1}(f_1, h) \leq \text{dist}_{\mu_1}(f_1, h_1) + \text{dist}_{\mu_1}(h_1, h) \leq \epsilon + \text{dist}_{\mu_1}(h_1, h_1') + \text{dist}_{\mu_1}(h_1', h) \leq \epsilon + 2\epsilon + \text{dist}_{\mu_1}(t_1, t) \leq 5\epsilon
\]
where the second-last inequality holds because \( |E_{\mu_1}| = |E_{\mu_1}| f_1 \geq 1 - 2\epsilon \) (Proposition 3.3).

**Case 2:** Now consider the case where \( |\tilde{v}_1|, |\tilde{v}_2| \leq 1 - \epsilon \), so \( |E_{\mu_1}|, |E_{\mu_2}| \leq 1 - \epsilon / 2 \).

By line 9 we know \( \tilde{p} \geq \frac{C^2}{4} \epsilon^2 \) and using the additive error guarantee of Estimate-IP we know \( p \geq \frac{C^2}{12} \epsilon^2 \). Therefore \( p \) satisfies the guarantee for the multiplicative error as well, so we know \( \tilde{p} = (1 \pm \epsilon_1^2)p \). Now using the same argument from the completeness proof (equation (10)), we know that \( c_1^2, c_2^2 \geq \Omega(\epsilon^2) \) so the conditions for multiplicative error for \( \tilde{c}_1, \tilde{c}_2 \), from Lemma 5.4, are satisfied, and \( \tilde{c}_i = (1 \pm \epsilon_i^2)c_i \) for each \( i \).

Write \( \beta = p / \sqrt{c_1 c_2} \) and \( \tilde{\beta} = \tilde{p} / \sqrt{c_1^2 c_2^2} \), which by the multiplicative guarantees satisfies \( \tilde{\beta} = \frac{1}{(1 \pm \epsilon^2)(1 \pm \epsilon^2)} \beta \). Since the algorithm accepts, we must have \( \tilde{\beta} \geq 1 - 2\epsilon_1^2 \) so
\[
\beta = \frac{\sqrt{(1 \pm \epsilon_1^2)(1 \pm \epsilon_1^2)}}{1 \pm \epsilon_1^2} \tilde{\beta} \geq \frac{1 - \epsilon_1^2}{1 + \epsilon_1^2} \beta \geq (1 - 2\epsilon_1^2) \tilde{\beta} \quad \text{(Proposition 6.10)}
\]
\[
\geq (1 - 2\epsilon_1^2)^2 = 1 - 4\epsilon_1^2 + 4\epsilon_1^4 \geq 1 - 4\epsilon_1^2 .
\]
Then since \( \epsilon_1 \leq \epsilon / \sqrt{12} \), the angle is at most
\[
\alpha(h_1, h_2) = \sin^{-1}(\sqrt{1 - \beta^2}) \leq \frac{\pi}{2} \sqrt{1 - \beta^2} \leq \frac{\pi}{2} \sqrt{1 - (1 - 4\epsilon_1^2)^2} = \frac{\pi}{2} \sqrt{8\epsilon_1^2(1 - 2\epsilon_1^2)} \leq \frac{\pi}{2} \sqrt{8\epsilon_1} \leq \frac{\pi}{2} \epsilon.
\]

Finally, we will prove that there exists a halfspace \( h \) such that \( \text{dist}_{\mu_1}(f_1, h), \text{dist}_{\mu_2}(f_2, h) < 5\epsilon \). Let \( h \) be the halfspace aligned with \( h_1 \) with threshold \( t \). Then
\[
\text{dist}_{\mu_1}(f_1, h) \leq \text{dist}_{\mu_1}(f_1, h_1) + \text{dist}_{\mu_1}(h_1, h) = \text{dist}_{\mu_2}(f_1, h_1) + \text{hdist}_{\mu_1}(t_1, t) \leq 3\epsilon
\]
and
\[
\text{dist}_{\mu_2}(f_2, h) \leq \text{dist}_{\mu_2}(f_2, h_2) + \text{dist}_{\mu_2}(h_2, h) \leq \epsilon + \text{hdist}_{\mu_2}(t_2, t) + \frac{\alpha(h_2, h)}{\pi} \leq (4 + 1/2)\epsilon.
\]

**Lemma 6.5.** Let \( \epsilon, \delta > 0 \), let \( \mu_1, \ldots, \mu_k \) be a set of bounded RI distributions over \( \mathbb{R}^n \) and let \( f : \mathbb{R}^n \to \{\pm 1\} \) be a function measurable by all these distributions. Suppose that for all \( i \in [k] \) there exists a halfspace \( h_i \) such that \( h_i \) is aligned with \( f \) on \( \mu_i \), \( \mathbb{E}_{\mu_i} h_i = \mathbb{E}_{\mu_i} f \), and \( \text{dist}_i(f, h_i) \leq \epsilon \). Assume that for all \( i, j \in [k], i \neq j \), \textsc{Check-Consistency}(\( \mu_i, \mu_j, f, f, \epsilon/5, \delta \)) has succeeded. Then there exists a halfspace \( h \) such that for all \( i \in [k], \text{dist}_i(f, h) < 3\epsilon \).

**Proof.** By the guarantee on \textsc{Check-Consistency} (Lemma 6.3), we have for all \( i, j \) there exists a threshold \( t_{i,j} \) such that \( \text{hdist}_i(t_i, t_{i,j}), \text{hdist}_j(t_j, t_{i,j}) < \epsilon \) and one of the following holds:

1. \( \alpha(h_i, h_j) \leq \frac{\pi}{2} \epsilon \), or
2. \( |\mathbb{E}_{\mu_i} f| \geq 1 - \epsilon \) or \( |\mathbb{E}_{\mu_j} f| \geq 1 - \epsilon \).

We will first show that there exists some threshold \( t \) such that \( \text{hdist}_i(t_i, t) \leq \epsilon \) for all \( i \in [k] \). For each \( i \) define the interval \( I(i) := [a_i, b_i] \) where \( a_i, b_i \) are
\[
a_i := \min_j t_{i,j} \quad \text{and} \quad b_i := \max_j t_{i,j}.
\]

\( \text{hdist}_i(a, b) \) is a non-decreasing function with \( |a - b| \), so for any \( t' \in I(i) \) we have \( \text{hdist}_i(t_i, t') \leq \max\{ \text{hdist}_i(t_i, a_i), \text{hdist}_i(t_i, b_i) \} \leq \epsilon \). For any \( i, j, t_{i,j} \in I(i) \cap I(j) \) so \( I(i) \cap I(j) \neq \emptyset \); this implies that the set of intervals \( I(i) \) are pairwise nonempty, so \( \bigcap_i I(i) \neq \emptyset \). Then there is some \( t \) in this intersection, and \( t \) therefore satisfies \( \text{hdist}_i(t_i, t) \leq \epsilon \) for all \( i \).

If there exists some \( z \) such that \( |\mathbb{E}_{\mu_i} f| < 1 - \epsilon \), let \( h \) be the halfspace aligned with \( h_z \) with threshold \( t \). Otherwise let \( h \) be an arbitrary halfspace with threshold \( t \). Now let \( i \in [k] \). There are two cases.

**Case 1:** \( |\mathbb{E}_{\mu_i} f| \geq 1 - \epsilon \). In this case, let \( h'_i \) be the halfspace \( h_i \) rotated to be aligned with \( h \). Then by Proposition 3.3, \( \text{dist}_i(h_i, h'_i) \leq \epsilon \), so
\[
\text{dist}_i(f, h) \leq \text{dist}_i(f, h_i) + \text{dist}_i(h_i, h'_i) + \text{dist}_i(h'_i, h) \leq \epsilon + \epsilon + \text{hdist}_i(t_i, t) \leq 3\epsilon.
\]

**Case 2:** \( |\mathbb{E}_{\mu_i} f| < 1 - \epsilon \). In this case, there must be some \( z \) as specified above, and \( h = h_z \). Let \( h'_i \) be the halfspace aligned with \( h_z \) with threshold \( t_i \). Then \( \alpha(h_i, h_z) \leq \pi \epsilon / 2 \) so by Proposition 3.14 we have \( \text{dist}_i(h_i, h'_i) = \alpha(h_i, h_z) / \pi \leq \epsilon / 2 \). Thus
\[
\text{dist}_i(f, h) \leq \text{dist}_i(f, h_i) + \text{dist}_i(h_i, h'_i) + \text{dist}_i(h'_i, h) \leq \epsilon + \alpha(h_i, h'_i) / \pi + \text{hdist}_i(t_i, t) \leq 3\epsilon.
\]

\[29\]
Acknowledgments

Many thanks to Eric Blais for suggesting this problem and for many helpful discussions. Thanks also to Eric Blais and Amit Levi for comments on the draft of this paper, and to the anonymous reviewers for their careful reading and comments.

A.1 Proofs of the Preliminaries

Proposition 3.3. Let \( f, g \) be \( \pm 1 \)-valued functions with \( |E[f]| \geq 1 - \epsilon \) and \( |E[f] - E[g]| \leq \delta \). Then \( \text{dist}(f, g) \leq \epsilon + \delta/2 \).
Proof. Suppose without loss of generality that $\mathbb{E}[f] \geq 1 - \epsilon$. Then $1 - \epsilon \leq 1 - 2\mathbb{P}[f(x) = -1]$ so $\mathbb{P}[f(x) = -1] \leq \epsilon/2$. Now we have $\delta \geq |\mathbb{E}[f] - \mathbb{E}[h]| = 2|\mathbb{P}[f(x) = -1] - \mathbb{P}[g(x) = -1]|$ so

$$\text{dist}(f, g) = \mathbb{P}[f(x) = 1, g(x) = -1] + \mathbb{P}[f(x) = -1, g(x) = 1] \leq \mathbb{P}[g(x) = -1] + \mathbb{P}[f(x) = -1]$$

$$\leq 2\mathbb{P}[f(x) = -1] + \delta/2 \leq \epsilon + \delta/2.$$

Proposition 3.7. Let $\mu$ be any RI distribution over $\mathbb{R}^n$. $\mu$ is isotropic iff $\mathbb{E}_{x \sim \mu}||x||^2 = n$.

Proof. By rotation invariance we have $\mathbb{E}[x_i^2] = \mathbb{E}[\langle x, u \rangle^2]$ for any unit vector $u$. Then for any such $u$ we have

$$\mathbb{E}[||x||^2] = \mathbb{E}[\langle x, x \rangle] = \sum_i \mathbb{E}[x_i^2] = n\mathbb{E}[\langle x, u \rangle^2].$$

If $\mu$ is isotropic this is $n$; in the opposite direction, if this quantity is $n$ then $\mathbb{E}[\langle x, u \rangle^2] = 1$ so $\mu$ is isotropic.

We need the following proposition:

Proposition A.1. Let $S_n$ denote the surface area of the $n$-sphere. Then $\frac{\sqrt{n-2}}{\sqrt{2\pi}} \leq \frac{S_{n-2}}{S_{n-1}} \leq \frac{\sqrt{n-1}}{\sqrt{2\pi}}$.

Proof. It is well known that $S_{n-1} = \frac{2\pi^{n/2}}{\Gamma(n/2)}$, so the ratio is $\frac{S_{n-2}}{S_{n-1}} = \frac{\Gamma(\frac{n}{2})}{\sqrt{n\pi}\Gamma(\frac{n-1}{2})}$. The conclusion follows from applying the following inequality for $x > 1$, $\epsilon \in [0, 1]$:

$$(x - 1)^\epsilon \Gamma(x - \epsilon) \leq \Gamma(x) \leq (x - \epsilon)^\epsilon \Gamma(x - \epsilon)$$

which can be found in [Wen48, Qi10].

Proposition 3.9. Let $\sigma$ be the uniform distribution of the sphere of radius $r$ over $\mathbb{R}^n$. Let $\sigma_{\pi}$ be the density of the 1-dimensional projection. Then $\sigma_{\pi}(x) \leq \frac{\sqrt{n-1}}{\sqrt{2\pi}r^2} \frac{e^{-\frac{x^2}{2r^2}}}{\sqrt{n}}$, and in particular, for $r = \sqrt{n}$, $\sigma_{\pi}(x) \leq \frac{1}{\sqrt{2\pi}} e^{-x^2/4}$ when $n \geq 4$.

Proof. Using the inequality $\frac{S_{n-2}}{S_{n-1}} \leq \frac{\sqrt{n-1}}{\sqrt{2\pi}}$, we get

$$\sigma_{\pi}(x) = \frac{S_{n-2}(\sqrt{r-x^2})}{S_{n-1}(r)} \leq \frac{S_{n-2}(r-x^2)^{(n-2)/2}}{S_{n-1} r^{n-1}} = \frac{S_{n-2} (1 - (x/r)^2)^{(n-2)/2}}{S_{n-1} r}$$

$$\leq \frac{S_{n-2}}{r S_{n-1}} e^{\frac{x^2(n-2)}{2r^2}} \leq \frac{\sqrt{n-1}}{\sqrt{2\pi}r^2} e^{-\frac{x^2(n-2)}{2r^2}}.$$

Proof. Without loss of generality assume that $w = e_1$. Let $\sigma_r$ be the uniform distribution over the sphere of radius $r$ in $\mathbb{R}^n$ and pick any $\gamma$ such that $|\gamma| \leq r$. Let $x$ be drawn from $\sigma_r$ conditioned on
Then $x_2 \cdots x_n$ is drawn from the uniform distribution over the sphere with radius $\sqrt{r - \gamma^2}$ in $\mathbb{R}^{n-1}$, so for $i > 1$, $\mathbb{E} [x_i \mid x_1 = \gamma] = 0$. Thus $\mathbb{E}_{x \sim \sigma_r} [x \mid x_1 = \gamma] = \gamma e_1$, and

$$
\mathbb{E}_{x \sim \sigma_r} [x \operatorname{sign}(x_1 - t)] = \int_{-r}^r \mathbb{E} [x \operatorname{sign} \gamma - t \mid x_1 = \gamma] d\mathbb{P}[x_1 = \gamma] = \int_{-r}^r \operatorname{sign}(\gamma - t) \gamma e_1 d\mathbb{P}[x_1 = \gamma] = \mathbb{E}_{x \sim \sigma_r} [x_1 \operatorname{sign}(x_1 - t)] \cdot e_1.
$$

Finally, recalling $w = e_1$, $\mathbb{E}_{x \sim \mu} [x h(x)] = \mathbb{E}_{x \sim \mu} [\mathbb{E}_{x \sim \sigma_r} [x h(x)]] = \mathbb{E}_{x \sim \mu} [\langle w, x \rangle h(x)] \cdot w$.

**Proposition 3.14** For any two halfspaces $g(x) = \operatorname{sign}(\langle v, x \rangle - q), h(x) = \operatorname{sign}(\langle u, x \rangle - p)$ (where $u, v$ are unit vectors) and RI distribution $\mu$,

$$\operatorname{dist}_\mu (g, h) \leq \frac{\alpha(g, h)}{\pi} + \operatorname{hdist}_\mu(p, q).$$

**Proof.** Without loss of generality, assume $|p| \geq |q|$, and let $h'$ be the halfspace $h'(x) = \operatorname{sign}(\langle v, x \rangle - p)$. Then by the triangle inequality, $\operatorname{dist}(g, h) \leq \operatorname{dist}(g, h') + \operatorname{dist}(h', h)$. Since $h', h$ have the same normal vector, $\operatorname{dist}(h', h) = \operatorname{hdist}(p, q)$, so it remains to show that $\operatorname{dist}(g, h') \leq \alpha(g, h')/\pi$. It suffices to prove this in the 2-dimensional case, since we may project $\mu$ onto the span of $u, v$ to get another RI distribution $\mu_\pi$ on which $\operatorname{dist}_\mu (g, h') = \operatorname{dist}_\mu (g, h')$. It further suffices to consider the uniform distribution over the unit circle, since any RI distribution in $\mathbb{R}^2$ is a convex combination of scaled circles.

Consider $\sigma$, the uniform distribution over the sphere (circle) in $\mathbb{R}^2$ with radius $r$. Assume $0 \leq p < 1$, since if $p < 0$ we may consider the halfspaces $-g, -h'$ with threshold $-p$ without changing their distance, and if $p \geq 1$ then $g, h'$ are constant on $\sigma$ and the proposition easily holds.

![Figure 2: Proof of Proposition 3.14](image)

Write $\alpha = \alpha(g, h)$ for the angle between $u$ and $v$. Let $a, b, c, d \in \mathbb{R}^2$ be the points on the circle satisfying $\langle a, v \rangle = \langle c, v \rangle = \langle b, u \rangle = \langle d, u \rangle = p, \langle a, u \rangle \leq \langle c, u \rangle, \langle d, v \rangle \leq \langle b, v \rangle$, and $a \neq c, b \neq d$ (see Figure 2); from here we conclude that $\alpha(a, v) = \alpha(c, v) = \alpha(b, u) = \alpha(d, u)$.

In case 1, where the halfspaces intersect, we can see that the difference (bold in Figure 2) is bounded by $(\alpha(a, b) + \alpha(c, d))/2\pi \leq \alpha/\pi$. And in case 2, where the halfspaces are disjoint, the same relation holds with equality, which proves the proposition.

\[\square\]
Proposition 3.15. Let \( h \) be a halfspace with threshold \( t \) and normal vector \( w \). Then for any RI distribution,
\[
|\mathbb{E} [h] | = \mathbb{P} [-|t| \leq \langle w, x \rangle \leq |t|].
\]

**Proof.** Without loss of generality, assume \( t \leq 0 \) (otherwise take \(-h\)). By rotation invariance we have \( \mathbb{P} [\langle w, x \rangle < t] = \mathbb{P} [\langle w, x \rangle > -t] \). Then
\[
|\mathbb{E} [h] | = \mathbb{P} [h(x) = 1] - \mathbb{P} [h(x) = -1] = \mathbb{P} [\langle w, x \rangle \geq t] - \mathbb{P} [\langle w, x \rangle < t]
= \mathbb{P} [\langle w, x \rangle \geq t] - \mathbb{P} [\langle w, x \rangle > -t] = \mathbb{P} [t \leq \langle w, x \rangle \leq t].
\]

Proposition 3.8. Let \( \sigma \) be the uniform distribution over the sphere of radius \( r \), and let \( t \geq 0 \). Then for any unit vector \( u \),
\[
\mathbb{P}_{x \sim \sigma} [\langle u, x \rangle \geq t] \leq \sqrt{2}e^{-t^2(n-2)/2r^2} \leq \sqrt{2}e^{-t^2n/4r^2}
\]
(where the last inequality holds when \( n \geq 4 \)).

**Proof.** Suppose \( \sigma \) is the unit sphere and without loss of generality assume \( u = e_1 \).
\[
\mathbb{P} [x_1 \geq t] = \frac{S_{n-2}}{S_{n-1}} \int_t^1 (1 - t^2)^{(n-2)/2} dt \leq \frac{S_{n-2}}{S_{n-1}} \int_t^\infty e^{-t^2/2} dt = \frac{\sqrt{2\pi}}{S_{n-1} \sqrt{n-2}} \cdot \mathbb{P} [z \geq t] \leq \frac{S_{n-2}}{S_{n-1} \sqrt{n-2}} e^{-t^2/2}
\]
where the final inequality for the Gaussian distribution can be found, for example, in \[BLM13\]. The conclusion then follows from an application of Proposition A.1.

### A.2 Concentration Inequalities and Empirical Estimation

We will make use of two standard concentration inequalities:

**Lemma A.2** (Chebyshev’s Inequality). Let \( X \) be any random variable over \( \mathbb{R} \) and let \( t \geq 0 \). Then \( \mathbb{P} [X \geq t] \leq \frac{\text{Var}[X]}{t^2} \).

**Lemma A.3** (Hoeffding’s Inequality). Let \( \{X_i\}_{i \in [m]} \) be a set of \( m \) independent random variables over \( \mathbb{R} \) and let \( \{a_i, b_i\}_{i \in [m]} \) be pairs of numbers such that for each \( i \in [m], \mathbb{P} [a_i \leq X_i \leq b_i] = 1 \). Then for \( X = \sum_i X_i \), and any \( t \geq 0 \), \( \mathbb{P} [X - \mathbb{E} [X] > t] \leq \exp \left( -\frac{2t^2}{\sum_i (b_i - a_i)^2} \right) \) and the same bound holds for \( \mathbb{P} [\mathbb{E} [X] - X > t] \).

We will use standard empirical estimation techniques, which are easy consequences of Hoeffding’s Inequality. For clarity of presentation, we present this as a subroutine:

**Algorithm 9** ESTIMATE-MEAN(\( \mu, f, \epsilon, \delta \))

1: \( m \leftarrow \frac{4}{\epsilon} \ln(2/\delta) \)
2: Let \( (x_i, f(x_i))_{i \in [m]} \) be a set of random samples.
3: return \( \frac{1}{m} \sum_{i \in [m]} f(x_i) \)
**Lemma A.4.** For any distribution $\mu$ over $\mathbb{R}^n$ and function $f : \mathbb{R}^n \to R$, algorithm Estimate-Mean requires at most $O \left( \frac{1}{\epsilon^2 \log(1/\delta)} \right)$ random samples and will produce an estimate $\tilde{E}$ such that, with probability at least $1 - \delta$, $|\tilde{E} - \mathbb{E}_\mu f| < \epsilon$.

*Proof.* By Hoeffding’s inequality, $\mathbb{P} \left[ |\tilde{E} - \mathbb{E}[f]| \geq \epsilon \right] \leq 2\exp \left( -\frac{m\epsilon^2}{2} \right) = \delta$ when $m = \frac{2}{\epsilon^2 \ln(2/\delta)}$. \qed

The next proposition gives a guarantee on a simple method for estimating thresholds:

**Proposition A.5.** Let $\epsilon, \delta > 0$ and let $\mu$ be some distribution over $\mathbb{R}$. For any $v \in [0,1]$ fix $t$ such that $\mathbb{P} [x \geq t] = v$ and let $X$ be a set of $m = \frac{1}{2\epsilon^2} \ln(2/\delta)$ random samples. Let $p = \max \{ z : \# \{ x \in X : x \geq z \} \geq mv \}$. If $p \leq t$ let $I = [p, t)$, otherwise let $I = [t, p)$. Then

$$\mathbb{P} \left[ \mu(I) > \epsilon \right] \leq \delta .$$

*Proof.* Let $a = \max \{ z : \mu[z, t) \geq \epsilon \}, b = \min \{ z : \mu[t, z) \geq \epsilon \}$, or $a = -\infty, b = \infty$ if no such values exist. The estimation fails if $p \leq a$ or $p \geq b$; note that if $a = -\infty$ or $b = \infty$ the respective inequalities cannot be satisfied, so we are concerned only with the cases where $a, b$ are finite. If $p \leq a$ then $A := \# \{ x \in X : x > a \} < mv$, which, since $\mathbb{E} [A/m] \geq v + \epsilon$, happens with probability

$$\mathbb{P} [A/m < v] \leq \mathbb{P} [A/m < \mathbb{E} [A/m] - \epsilon] \leq \exp \left( -2m\epsilon^2 \right)$$

by Hoeffding’s inequality. The same holds for $B := \# \{ x \in X : x \geq b \}$. Thus, taking the union bound and setting $m = \frac{1}{2\epsilon^2} \ln(2/\delta)$ we see that the failure probability is at most $\delta$. \qed
