The intensity of a monochromatic X-ray beam decreases exponentially with the distance it has traveled inside a material; this behavior is commonly referred to as Beer-Lambert’s law. Knowledge of the materialspecific attenuation coefficient \( \mu \) allows to determine the thickness of a sample from the intensity decrease the beam has experienced. However, classical X-ray tubes emit a polychromatic bremsstrahlung-spectrum. And the attenuation coefficients of all materials depend on the photon energy: photons with high energy are attenuated less than photons with low energy. In consequence, the X-ray spectrum changes while traveling through the medium; due to the relative increase of high energy photons this effect is called beam hardening. For this varying spectrum, the Beer-Lambert law only remains valid if \( \mu \) is replaced by an effective attenuation coefficient \( \mu_{\text{eff}} \) which depends not only on the material, but also its thickness \( x \) and the details of the X-ray setup used. We present here a way to deduce \( \mu_{\text{eff}}(x) \) from a small number of auxiliary measurements using a phenomenological model. This model can then be used to determine an unknown material thickness or in the case of a granular media its volume fraction.

I. INTRODUCTION

If an X-ray photon travels through a material there exists for each atom it encounters a finite probability that it will either be scattered inelastically at one of its electrons, or that it will be absorbed by kicking an electron out of the hull of the atom. These probabilities themselves will depend on both the energy \( E \) of the photon and the type of atoms the material is made of, which is normally quantified by the atomic number \( Z \). In consequence, if a monoenergetic X-ray beam passes through a material, its intensity \( I \) decreases exponentially with the distance \( x \) traveled inside the sample:

\[
I(x) = I_0 \exp(-\mu(E, Z)x).
\]  

In this so-called Beer-Lambert’s law \( I_0 \) is the intensity of the initial beam and \( \mu \) is the attenuation coefficient which depends on \( E \) and \( Z \).

By measuring the ratio of intensities \( I/I_0 \) the thickness \( x \) of the material can be determined. In granular systems this method can be used to determine the average volume fraction \( \phi = x/L \) along the path of the photons where \( L \) is the size of the container. Because the temporal resolution of this method is only limited by the frame rate of the detector, it can also be used to study dynamic systems such as granular flow, impact, vertically vibrated samples, liquid jets, the subsurface swimming of sandfish lizards, fluidized beds, and two-phase flow.

Classical X-ray tubes, which are normally used in scientific, industrial or medical setups, emit a broad energy spectrum originating mostly from the so-called bremsstrahlung. Inside the material, low energy photons are attenuated stronger than high energy photons. In consequence, the relative contribution of the high energy part of the spectrum increases with material thickness, as shown in Fig. 1. This process is known as beam hardening, its most immediate consequence is that Eq. 1 is no longer applicable. In order to quantify the thickness of a material using its X-ray attenuation, beam hardening has to be taken into account.

One way to reduce the effect of beam hardening is the use of a filter, an additional sheet of material (typically a metal such as copper or aluminum) between the X-ray tube and the sample. This filter reduces the ratio of low to high energy photons in the spectrum, i.e. it is effectively narrowing the spectrum. However, this comes at the price of a reduced overall intensity of the beam; without completely removing the problem.

Another option is to replace the X-ray tube with a monoenergetic source. This could either be a synchrotron beamline with a monochromator crystal in the beam path or a \( \gamma \)-ray source such as \( ^{137}\text{Cs} \). However, the first solution suffers from the small sample area of typically 1 cm\(^2\) and the necessity to secure beam time at an user facility via a proposal. In the second approach, the high energies of the \( \gamma \)-rays result in a low contrast for many interesting samples in fields such as soft matter and fluid dynamics.

In many experimental situations the use of a polychromatic photon spectrum cannot be avoided. In consequence, Eq. 1 has to be adapted by the use of an effective attenuation coefficient which depends on the material thickness.

In this work we measure the effective attenuation coefficients for several materials on two different X-ray CT-
sets. We describe all our data with a new heuristic model function which is shown to be more accurate than the models previously used in literature. We demonstrate how the thickness of a material can be deduced from our model and quantify the occurring error.

II. ATTENUATION OF X-RAYS

The intensity of an X-ray beam inside a material decreases due to two processes: scattering and absorption of the photons at the electrons of the material. Because the probability of a photon interacting with an electron depends only on the energies of the photon and the electron, for monoenergetic photons this process is independent of the depth inside the medium. Therefore every slice of thickness \(dx\) attenuates the intensity \(I\) by the same fraction: \(dI/I = -\mu dx\), where the attenuation coefficient \(\mu\) is a material parameter. Integration leads to the Beer-Lambert law shown in Eq. 1.

The attenuation coefficient \(\mu(Z, \rho)\) depends on both the electron configuration of the atoms constituting the material (here summarized by the atomic number \(Z\) of the elements) and on the density \(\rho\) of the material. The former dependence has been precomputed by the National Institute of Standards and Technology (NIST) and can be downloaded from their website using the online tool XCOM\(^{18}\). The \(\rho\) dependence is linear in the number of atoms per volume; considering this dependence explicitly with the so called mass attenuation coefficient \(\mu/\rho\) simplifies the handling of mixtures, molecules, and compressible materials such as gases.

For polychromatic beams photons of energy \(E\) are attenuated according to their own attenuation coefficient \(\mu = \mu(E, Z, \rho)\). Due to the overall decrease of \(\mu\) with \(E\) (cf. Fig. 2 b), the ratio of high to low energy photons increases while the polychromatic beam passes through a material, as shown in Fig. 1. In consequence, the attenuation of a polychromatic X-ray spectrum is not described by the standard Beer-Lambert equation.

In normal X-ray imaging setups the beam intensity is measured by a detector, which responds to photons of different energies according to its spectral sensitivity \(S(E)\). Therefore the grayvalue of any given pixel will depend on three different factors: the emitted X-ray spectrum \(N(E)\), the attenuation coefficient \(\mu(E, Z, \rho)\), the sensitivity curve \(S(E)\), and the material thickness \(x\):

\[
I(x) \propto \int N(E) \exp\{-\mu(E, Z, \rho) x\} S(E) \, dE \quad (2)
\]

An example for the energy dependence of \(N, \mu,\) and \(S\) is shown in Fig. 2. The problem with Eq. 2 is that most users will neither know \(N(E)\) and \(S(E)\) of their X-ray setup, nor will they have the means to measure these two curves. Therefore the tabulated values of \(\mu(E)\) are insufficient to determine the material thickness from the measured intensity.

A. Energy averaged attenuation coefficients

For the description of polychromatic X-ray beams two types of energy averaged attenuation coefficients are used in the literature: a differential attenuation coefficient \(\bar{\mu}\) and an integral versions \(\mu_{\text{eff}}\).\(^{21-25}\) While only \(\mu_{\text{eff}}\) can be measured in experiments, theoretical models have been developed for both versions; we will therefore start by reviewing their relation.

The differential attenuation coefficient \(\bar{\mu}(x)\) describes the intensity change at a given depth \(x\) inside the material\(^{23}\), it is defined by:

\[
\frac{dI(x)}{dx} = -\bar{\mu}(x)I(x). \quad (3)
\]

Measuring \(\bar{\mu}(x)\) directly would require measuring the change in beam intensity \(I(x + dx) - I(x)\) due to an infinitesimally thin slice of material \(dx\), as indicated in Fig. 1. Which is in practice not feasible. One of the main applications of \(\bar{\mu}(x)\) is to calculate the absorbed energy dose in medical applications\(^{23}\).

In order to describe how the beam intensity decreases inside the medium from \(I_0\) to \(I(x)\), we have to integrate Eq. 3:

\[
I(x) = I_0 \exp\left(-\int_0^x \bar{\mu}(x') \, dx'\right). \quad (4)
\]
The differential attenuation coefficient, $\mu(x)$, can however be measured indirectly: Eq. 4 can be rewritten as

$$-\ln \frac{I(x)}{I_0} = \int_0^x \mu(x')dx'.$$

(5)

By differentiation we obtain:

$$\frac{d}{dx} \left(-\ln \frac{I(x)}{I_0}\right) = \mu(x).$$

(6)

This means that $\mu(x)$ can be obtained as the slope of the tangent if the data is plotted as in Fig. 3.

In contrast to $\mu(x)$, which describes the attenuation only at a certain depth inside the material, the integral or effective attenuation coefficient $\mu_{\text{eff}}$ averages over the whole sample of thickness $x$\textsuperscript{21,22}.

$$I(x) = I_0 \exp(-\mu_{\text{eff}}(x)x).$$

(7)

In consequence, it is easy to determine single $\mu_{\text{eff}}$ values by comparing the X-ray intensities before and after a material of known thickness. And if the functional dependence of $\mu_{\text{eff}}$ on the material thickness $x$ is known, the width of an unknown object can be computed from a single radiogram, as shown in section V.

Eq. 7 can be rewritten as

$$-\ln \frac{I(x)}{I_0} = \mu_{\text{eff}}(x)x.$$

(8)

This implies that in Fig. 3 $\mu_{\text{eff}}(x)$ can be visualized as the slope of the secant which connects the origin with the datapoint at thickness $x$.

There exists a generic lower bound for $\mu_{\text{eff}}(x)$ provided that the monoenergetic attenuation coefficient $\mu$ is a monotonic decreasing function of the photon energy; which is normally the case in the experimentally relevant energy range. A simple gedankenexperiment shows then that the effect of beam hardening will stop when the only photons remaining from the initial spectrum are the ones with the highest energy $\mu(E_{\text{max}})$, i.e. the acceleration voltage of the X-ray tube. Therefore $\mu_{\text{eff}}(x)$ has to be larger than $\mu(E_{\text{max}})$. 

Figure 3. A graphical comparison of $\mu$ and $\mu_{\text{eff}}$, both for an $x$ value of 1.2 cm (following ref. 25). The experimental data (red squares) correspond to the logarithm of the intensity decrease of an X-ray beam (60 kV, tungsten anode) passing through borosilicate glass slabs of different thickness. A smooth representation of the data is obtained by a fit with Eq. 13 (red line). $\mu$ in the depth 1.2 cm is the slope of the tangent to the fit curve at $x=1.2$ cm (green dashed line, Eq. 6). $\mu_{\text{eff}}$ of a glass slab of thickness 1.2 cm is the slope of the blue secant connecting the origin with the data point at $x=1.2$ cm (Eq. 8). Finally, $\mu_{\text{60keV}}$ indicates the attenuation a monochromatic beam of 60 keV energy would experience in borosilicate glass\textsuperscript{26} (black short dashed line). Due to the monotonic decrease of $\mu(E)$, no amount of beam hardening can result in a slope of $\mu_{\text{eff}}$ smaller than $\mu_{\text{60keV}}$.
The conversion between the two types of attenuation coefficients is straightforward\textsuperscript{23,25}: By inserting Eq. 7 into Eq. 3 we obtain:

\[
\bar{\mu}(x) = \mu_{\text{eff}}(x) + \frac{d\mu_{\text{eff}}(x)}{dx} x. \quad (9)
\]

The reverse relationship follows from Eq. 4 and 7:

\[
\mu_{\text{eff}}(x) = \frac{\int_0^x \bar{\mu}(x')dx'}{x}. \quad (10)
\]

**B. Modeling of \( \mu_{\text{eff}} \)**

Eq. 2 summarizes the essence of the effect of beam hardening: The measured intensity does not only depend on the type and thickness of the sample material, but also on the shape of the initial beam spectrum \( N(E) \) and the sensitivity curve of the detector \( S(E) \). Most users of an X-ray setup have no information about the exact shape of \( N(E) \) and \( S(E) \) and in consequence the integral in Eq. 2 cannot be solved.

Given this situation, a number of models, either completely heuristic, or based on some physical arguments of \( N(E) \), have been suggested for \( \bar{\mu}(x) \) and \( \mu_{\text{eff}}(x) \). Because all of these models omit at least part of the physics contained in Eq. 2, their merit can only be assessed by comparing them with experimental data. We will present such a comparison, with focus on energy scales and materials used in typical Computed Tomography X-ray setups, in section IV.

The first models for beam hardening were introduced by Bj"{a}rgvand & Shackford\textsuperscript{21}, and Yu et al.\textsuperscript{22} in order to improve dose calculations for medical applications. They gathered data for water and aluminum at linear accelerators for radiotherapy at acceleration voltages of 6 MV and 25 MV and fitted \( \mu_{\text{eff}} \) with:

\[
\mu_{\text{eff}}(x) = \mu_0 - \lambda x \quad \text{(BS)}
\]

\[
\mu_{\text{eff}}(x) = \frac{\mu_0}{1 + \lambda x} \quad \text{(Yu 1)}
\]

\[
\mu_{\text{eff}}(x) = \frac{\mu_0}{(1 + \lambda x)^\beta} \quad \text{(Yu 2)}
\]

where \( \mu_0, \lambda, \) and \( \beta \) are all fit parameters.

Kleinschmidt\textsuperscript{23,27} computed \( \bar{\mu} \) values from numerical data and suggested as fit function:

\[
\bar{\mu} = \mu(E_{\text{max}}) + \frac{\mu_1}{1 + \lambda_1 x + \lambda_2 x^2}, \quad (11)
\]

with \( \mu_1, \lambda_1 \) and \( \lambda_2 \) as free parameters. In order to compare Eq. 11 with our experimental data, we transform it using Eq. 10 to:

\[
\mu_{\text{eff}}(x) = \mu(E_{\text{max}}) + \frac{2\mu_1}{x \sqrt{-\lambda_1^2 + 4\lambda_2}} \times \left[ \arctan \left( \frac{\lambda_1 + 2\lambda_2 x}{\sqrt{-\lambda_1^2 + 4\lambda_2}} \right) - \arctan \left( \frac{\lambda_1}{\sqrt{-\lambda_1^2 + 4\lambda_2}} \right) \right] \quad \text{(KS)}
\]

Alles & Mudde\textsuperscript{24} derived an expression for \( \bar{\mu} \), which contains ten summands in a compound fraction; it is based on four free parameters which have to be determined by fits to experimental data. In later publications Mudde and coworkers\textsuperscript{28–30} analyzed their data with a simpler expression for the intensity decay at the detector:

\[
\frac{I}{I_0} = A + B \exp(-x/C), \quad (12)
\]

where \( A, B \) and \( C \) are fit parameters. For the comparison with our experimental data we combined Eq. 7 with Eq. 12. to obtain an equivalent \( \mu_{\text{eff}}(x) \) as:

\[
\mu_{\text{eff}}(x) = -\frac{1}{x} \ln[A + B \exp(-x/C)] \quad \text{(MU)}
\]

Another model, which is based on the Lambert-W function, was suggested by Mathieu et al.\textsuperscript{31}. However, its underlying assumption is not compatible with our experimental data, as shown in the appendix. We will therefore not include it in our discussion.

Finally, we suggest here a purely heuristic model for \( \mu_{\text{eff}}(x) \):

\[
\mu_{\text{eff}}(x) = a + \frac{b}{x^\alpha}, \quad (13)
\]

where \( a, b \) and \( \alpha \) are free parameters. In section IV A we compare Eq. 13 to the former models, namely Eq.s BS, Yu 1, Yu 2, KS, and MU.

**III. EXPERIMENTAL PROCEDURE**

In order to create samples with a well defined thickness \( x \) in the range \( 2 - 40 \) mm, we stack up to 20 borosilicate plates of thickness \( 2 \pm 0.05 \) mm in the self-made sample-holder shown in Fig. 4 a). Samples are placed between an X-ray tube and a camera and radiograms of the type shown in 4 b) are captured. The effective attenuation coefficient \( \mu_{\text{eff}} \) is then measured using Eq. 8. The values of \( I(x) \) and \( I_0 \) are extracted from the radiograms; they correspond to the mean gray values of regions where the

![Figure 4. Creating borosilicate samples of varying material thickness. a) glass plates of 2 mm thickness are stacked in a brass sample holder. b) radiogram of the sample. The intensities \( I_0 \) and \( I(x) \) are measured in the blue and red framed areas.](image)
beam is transmitted through respectively passes above the plates, as shown in Fig. 4 b).

Measurements are performed in a standard X-ray to- mograph typical for scientific and industrial applications. It contains an X-ray-worx tube (XWT-160-TCHE Plus) with a tungsten transmission target and a PerkinElmer DEXELA 1512 14 bit flat panel detector \(^{32}\). In section IV D we compare the \(\mu_{\text{eff}}\) values computed with this setup with values gathered from a second setup using a different camera and source.

The intensity of an X-ray beam is mainly diminished by two effects: photoelectric absorption and Compton scattering. Some fraction of the scattered photons will also hit the detector, just not at the position predicted by geometrical optics. This contribution to the image intensity will not only depend on the X-ray spectrum and the sample material, but also on the sample shape; in general it will be impractical to predict it. However, if the geometry of the test samples used to quantify beam hardening resembles the geometry of the samples used in the actual measurements, the effect of scattering will be captured by the heuristic approximation presented here.

Absorption measurements are often performed using wedges \(^{31}\) and step wedges \(^{33}\) as single samples providing a variety of material thicknesses. However, because wedges have a broken spatial symmetry in direction perpendicular to the X-ray beam, the undefined scattering contributions limit the accuracy of such measurements.

In contrast, the plate stack configuration shown in Fig. 4 a) is symmetric with respect to the center beam. Together with a small geometric magnification this reduces the contribution of scattering to an area in the vicinity of the rim of the plates. The area in the center of the plates, where \(I\) is measured, can be chosen such that it is free of spatial gradients \(^{22}\). The obvious disadvantage of the plate stack is the requirement of a larger number of individual measurements. However, we will show in section VA that three measurements are sufficient.

IV. COMPARISON MODEL AND EXPERIMENT

In this section we present measurements of the effective attenuation coefficient \(\mu_{\text{eff}}\), as defined in Eq. 7, for different acceleration voltages of the X-ray tube and sample materials. We also describe how \(\mu_{\text{eff}}\) changes due to pre-filtering of the beam and using another camera and X-ray tube. All experimental data can be described with Eq. 13 which is also shown to be more accurate than the best fit at both acceleration voltages. At 60 kV our model deviates less than 0.05 \(/\text{cm}\) from the experimental \(\mu_{\text{eff}}\) over the full range of sample thickness studied, at 140 kV less than 0.01 \(/\text{cm}\).

The main result of Figs. 5 and 6 is that Eq. 13 provides the best fit to the experimental data. a) For visual clarity we fit only a subset of the model functions to experimental data gathered for borosilicate glass plates at an acceleration voltage of 60 kV. b) \(\Delta \mu_{\text{eff}}\) is the difference between a given model and the experimental data. The figure includes all fit-functions discussed in section II B; for the model acronyms see there. Lines in panel a) are fits to the measured data, in panel b) lines are guides to the eye.

When optimizing an X-ray imaging setup, one needs to choose the optimal acceleration voltage. Lower energies deliver typically a stronger contrast between different materials, as it is e.g. beneficial for composite or soft materials. Higher energies result in a lower effective attenuation and therefore the possibility to image thicker or denser samples.

In order to cover both cases, we present in Figs. 5 and 6 measurements for \(\mu_{\text{eff}}\) performed with 60 kV and 140 kV acceleration voltage. Both figures compare the experimental results with fits of the models discussed in section II B. For reasons of readability the direct comparisons (Fig. 5a and 6a) do not include all models; but the plots of the \(\mu_{\text{eff}}\) differences between model and data (Figs. 5b and 6b) do include them all.

The main result of Figs. 5 and 6 is that Eq. 13 provides the best fit at both acceleration voltages. At 60 kV our model deviates less than 0.05 \(/\text{cm}\) from the experimental \(\mu_{\text{eff}}\) over the full range of sample thickness studied, at 140 kV less than 0.01 \(/\text{cm}\).

The rather poor performance of model Eq. BS is not surprising given that it was developed for much higher
B. Effect of pre-filtering

As described in the introduction, a common method to reduce the effect of beam hardening is to insert a small metal plate into the beam path, directly in front of the X-ray tube. These metal filters remove more photons from the low energy part of the spectrum, effectively narrowing the range of energies in the beam. This leads indeed to a decrease in beam hardening as shown in Fig. 7. The dependence of $\mu_{\text{eff}}$ on $x$ decreases with increasing thickness and increasing atomic number of the filter inserted into the beam. A second effect is that the values of $\mu_{\text{eff}}$ also decrease the more the spectrum is shifted towards the high energy range, in agreement with Fig. 2b. Most important in our context is however that Eq. 13 continues to provide a good model for the experimental data, independent of the applied filter.

The major disadvantage of filtering is invisible in Fig. 7: the narrowing in the energy spectrum is accompanied by an overall decrease in intensity. For our measurements $I_0$ decreases to 65% of the unfiltered intensity when adding the 2mm Al filter. For the 4mm Al filter this number becomes 48%, and for the 1mm Cu only 23% of the unfiltered intensity remains.

C. Material independence of Eq. 13

Fig. 8 demonstrates that our model (Eq. 13) provides a good fit to $\mu_{\text{eff}}$ for a variety of different materials. As in the case for the borosilicate glass, the measurements for copper and aluminum are made with stacks of 2 mm thick plates, cf. Fig. 4. The absolute values of $\mu_{\text{eff}}$ require some explanation. For small values of $x$, copper attenuates much stronger than borosilicate glass and aluminum, which is in agreement with the higher atomic number of copper. However, for larger values of $x$ all three materials approach similar values of $\mu_{\text{eff}}$. This seems to imply that aluminum and copper would be equally appropriate choices for shielding against X-rays; which is objectively not the case. This apparent similarity of $\mu_{\text{eff}}$ is an artifact resulting from the limitations of our experimental setup: the intensity $I$ behind the material decreases so much that the dark field noise of the camera starts to become a significant part of the signal, and this dark field noise is obviously not material-dependent. A second spurious contribution to $I$ comes from photons scattered in the air.
Figure 8. Eq. 13 (solid lines) provides a good fit for \( \mu_{\text{eff}}(x) \) measurements of borosilicate glass (squares), aluminum (circles) and copper (triangles). All experimental data are measured at an acceleration voltage of 140 kV.

and other parts of the setup. This underlines again that \( \mu_{\text{eff}}(x) \) is not a material property alone, but also dependent on the details of the experimental setup. However, within these limits fits with Eq. 13 describe the data well and provide therefore the opportunity to compute the material thickness \( x \) from measured values of \( I \) and \( I_0 \); which is our actual goal.

D. Device independence of Eq. 13

As shown in Eq. 2, the measured intensity \( I(x) \) and therefore also \( \mu_{\text{eff}}(x) \) will depend on the type of X-ray tube and detector used in a given setup. This is demonstrated in fig. 9 which compares two data sets: the aluminum data already shown in Fig. 8 and another data set captured with the a setup consisting of a GE 225HP 225kV HighPower X-ray tube and an XEye 2020 detector with a 300 \( \mu \)m thick CsI scintillator. Even for the same acceleration voltage, the absolute values of \( \mu_{\text{eff}}(x) \) differ up to the factor of two. However, both data set are again well described by a fit with Eq. 13.

V. DETERMINING THE MATERIAL THICKNESS \( x \)

Aim of this work is to measure the thickness \( x \) of a material based on the intensity values extracted from a radiogram. As shown in section IV, equation 13 provides the best known approximation of the effective absorption coefficient \( \mu_{\text{eff}}(x) \).

Because \( \mu_{\text{eff}}(x) \) depends on details of the setup such as acceleration voltage and camera type, we need to calibrate our setup/material combination in addition to the actual measurement. I.e. we need to determine the three parameters \( a, b \) and \( \alpha \) in equation 13 by taking radiograms of objects of known thickness \( x \) and made from the material we are interested in, using the same setup we then use for the actual measurements. We will show in subsection VA that three calibration measurements, which can e.g. be gathered from a scalene cuboid made of the sample material, are sufficient to determine \( a, b \) and \( \alpha \).

The actual measurement of \( x \) consists of determining the gray values \( I \) and \( I_0 \) at positions in the radiogram where the beam has either traveled through or passed next to the object (cf. Fig. 4). Rewriting Eq. 7 we obtain

\[
-\ln \left( \frac{I}{I_0} \right) = \mu_{\text{eff}}(x)x
\]

(14)

inserting \( \mu_{\text{eff}}(x) \) from Eq. 13 leads to

\[
ax + bx^{1-\alpha} + \ln \left( \frac{I}{I_0} \right) = 0.
\]

(15)

Because Eq. 15 cannot be solved analytically for \( x \), we have to determine the material thickness indirectly: We can either compute a look-up table for the right hand side of equation 14 and interpolate \( x \) with the desired accuracy. Or we can solve Eq. 15 numerically, using e.g. Newton’s method. The latter method will converge, if \( x \) is restricted to the range \( 0 < x \leq x_{\text{max}} \) where \( x_{\text{max}} \) is the maximal thickness of the sample. \( x = 0 \) needs to be excluded, because Eq. 13 diverges at that point.

A. Number of calibration measurements required

Section IV demonstrates that Eq. 13 provides a good fit to our data, provided the fit is based on 20 data points.
VI. EXAMPLE: MEASURING THE VOLUME FRACTION IN A GRANULAR SHEAR BAND

When dense granular systems are sheared, the strain is often localized in so-called shear bands. One way to create such a shear band is to fill a rectangular box with sand while maintaining a free surface, cf. figure 11 a). If the box is then shaken horizontally, the upper part of the sample material sloshes back and forth between the outer walls while the bottom part of the sample moves stationary with the box; between these two parts a shear band forms.

Using high-speed X-ray radiography we can show that the formation of these shear bands is accompanied by dilatancy, i.e. a reduction in the volume fraction \( \phi \) (which measures the locally averaged ratio of particle volume to total volume). Figure 11 b) shows the corresponding setup: an X-ray beam is traveling perpendicular to the shaking direction through the sample cell. The corresponding radiogram (figure 11 d) displays brighter horizontal stripes; these correspond to the shear bands with their lower value of \( \phi \).

For a quantitative analysis of the radiograms shown in figure 11 d) we need to first convert the intensities in the radiogram to lengths \( x_{\text{sand}} \) that the X-rays travel through the actual sample material while passing through the box (here we assume that we can neglect the \( \mu_{\text{eff}} \) of the interstitial air). This step requires the knowledge of \( \mu_{\text{eff}}(x) \) of the sample material, using the method described in this paper. Figure 11 c) shows a fit of equation 13 to the intensity ratios measured with an cuboidal box filled with sand of a known volume fraction. The volume fraction averaged along the beam path can then be computed as \( \phi = x_{\text{sand}}/L \), where \( L \) is the inner wall to wall distance in beam direction.

Figure 11 c) shows the volume fraction as a function of height, measured and horizontally averaged inside the blue box in panel d), the arrow indicates the position of the shear band. Further information on the dynamics of these shear bands can be found in reference 35.
VII. CONCLUSION

In all X-ray imaging setups working with a broad energy spectrum, which is all setups using a classical X-ray tube, the attenuation has to be described by an effective attenuation coefficient which does depend on both the type of material and its thickness. The latter dependence originates from beam-hardening, the change of the energy spectrum within the material. Because both the intensity of the X-ray tube and the sensitivity of the detector are energy dependent, the properties of the experimental setup will influence how the effective attenuation depends on the sample thickness. The new phenomenological equation for the effective attenuation introduced in this work provides a good fit to experimental data gathered for a variety of materials and experimental conditions. It also allows reliable measurements of the sample thickness using as little as three calibration measurements to determine the effective attenuation. However, due to the large number of possible experimental configurations, a general applicability cannot be guaranteed.

ACKNOWLEDGMENTS

We wish to thank Jonathan Kollmer for his help with Figure 11. This work was funded by the German Federal Ministry for Economic Affairs and Energy, grant number 50WM 1653.

Appendix: Excluding the model by Mathieu et al.

Mathieu and coworkers\(^{31}\) proposed an attenuation model based on the Lambert W function. According to this model the measured intensities should be described by the following equation:

\[
\frac{\ln(I(x)/I_0)}{x} = \mu_0 + \frac{I(x)}{I_0}, \tag{A.1}
\]

However, our data clearly deviate from eq. A.1 as shown in Fig. 12 where it would correspond to straight lines with slope \(\lambda\).

REFERENCES

2. If the energy of the x-ray photon exceeds 1.022 MeV it can also be transformed into an electron-positron pair.

Kleinschmidt also used equations BS and Yu 1 of Björgard & Shackford and Yu et al., but interpreted them as functions for the differential attenuation coefficient \( \bar{\mu} \).

The fit was performed with gnuplot, http://gnuplot.sourceforge.net/.

Figure 11. Measuring the volume fraction in granular shear bands. a) A polycarbonate box with inner dimensions 100 by 50 by 50 mm\(^3\) is filled with sand with a mean diameter of 265±70 \(\mu\)m. b) Radiograms are taken while the box is shaken horizontally on a linear translation stage with a frequency of 18 Hz. From the radiograms (panel d) the average volume fraction inside the sample can be computed (panel c), provided \(\mu_{eff}(x)\) of the sand is known (panel f). The latter was determined from attenuation measurements of a box with side lengths 2, 3, and 4 cm which was filled with sand at a volume fraction of 0.6. For further information see\(^{35}\).

Figure 12. The model by Mathieu et al. does not describe our experimental data: Equation A.1 predicts the data of our borosilicate glass measurements to be on straight lines.
