Abstract: Stein’s formula states that a random variable of the form $z^\top f(z) - \text{div} f(z)$ is mean-zero for all functions $f$ with integrable gradient. Here, $\text{div} f$ is the divergence of the function $f$ and $z$ is a standard normal vector. This paper aims to propose a Second Order Stein formula to characterize the variance of such random variables for all functions $f(z)$ with square integrable gradient, and to demonstrate the usefulness of this Second Order Stein formula in various applications.

In the Gaussian sequence model, a remarkable consequence of Stein’s formula is Stein’s Unbiased Risk Estimate (SURE), an unbiased estimate of the mean squared risk for almost any given estimator $\hat{\mu}$ of the unknown mean vector. A first application of the Second Order Stein formula is an Unbiased Risk Estimate for SURE itself (SURE for SURE): an unbiased estimate provides information about the squared distance between SURE and the squared estimation error of $\hat{\mu}$. SURE for SURE has a simple form as a function of the data and is applicable to all $\hat{\mu}$ with square integrable gradient, for example the Lasso and the Elastic Net.

A second application of the Second Order Stein formula is an exact formula for the variance of the divergence of the function $f(z)$ along with an upper bound through a single application of the Gaussian Poincaré inequality to the exact formula. A consequence of this application, which is naturally of great interest in and of itself, is a novel bound on the variance of the size of the model selected by the Lasso. The variance bound, which holds when the design is in general position, implies that the size of the selected model is concentrated around its mean when the mean is of greater order than $\log p$.

A third application of the Second Order Stein formula, which is again of great independent interest, is a general semi-parametric scheme to de-bias an almost differentiable initial estimator for the statistical inference of a low-dimensional projection of the unknown regression coefficient vector. The de-biased estimator is asymptotically normal when the variance provided by the Second Order Stein formula is of the same order as the prediction error of the initial estimator as long as the initial estimator is persistent.

Key words: Stein’s formula, variance estimate, risk estimate, SURE, SURE for SURE, Lasso, Elastic Net, model selection, variance of model size, de-biased
estimation, regression.

1. A Second Order Stein formula

The multivariate version of Stein’s formula [Ste81] can be described as follows. Let \( z = (z_1, \ldots, z_n) \) be a standard normal \( N(0, I_n) \) random vector. Let \( f_1, \ldots, f_n \) be functions \( \mathbb{R}^n \to \mathbb{R} \) and denote by \( f \) the column vector in \( \mathbb{R}^n \) with \( i \)-th component equal to \( f_i \). We say that a random variable \( X \) is in \( L_1 \) if \( \mathbb{E}|X| < +\infty \), and that \( X \) is in \( L_2 \) if \( \mathbb{E}[X^2] < +\infty \). If each \( f_i \) is the indefinite integration of its \( i \)-th partial derivative and the \( i \)-th partial derivative of \( f_i \) is in \( L_1 \) as a function of \( z \sim N(0, I_n) \) for each \( i \), then

\[
\mathbb{E}[z^\top f(z)] = \mathbb{E}[\text{div} f(z)]
\]

holds, where the divergence of \( f \) is \( \text{div} f = \sum_{i=1}^n (\partial / \partial x_i) f_i \). We refer the reader to the book [CGS10] for a recent survey on Stein’s formula and its applications to normal approximation.

In other words, Stein’s formula (1.1) states that the random variable

\[
z^\top f(z) - \text{div} f(z)
\]

is mean-zero. The topic of the current paper is the following Second Order Stein formula, which provides an identity for the variance of the random variable (1.2) with \( f \) in the Sobolev space \( W^{1,2}(\gamma_n) \) with respect to the standard Gaussian measure \( \gamma_n \) in \( \mathbb{R}^n \). Let \( C^\infty_0(\mathbb{R}^n) \) be the space of infinitely differentiable functions \( \mathbb{R}^n \to \mathbb{R} \) with compact support. The Sobolev space \( W^{1,2}(\gamma_n) \) is defined as the completion of the space \( C^\infty_0(\mathbb{R}^n) \) with respect to the norm

\[
\|g\|_{1,2} = \mathbb{E}[|g(z)|^2]^{1/2} + \mathbb{E}[(|\nabla g(z)|^2)^{1/2}] \quad g \in C^\infty_0(\mathbb{R}^n)
\]

where \( z \sim N(0, I_n) \). By [Bog98, Proposition 1.5.2], the space \( W^{1,2}(\gamma_n) \) corresponds to functions \( g : \mathbb{R}^n \to \mathbb{R} \) that are weakly differentiable and \( \mathbb{E}[|g(z)|^2] + \mathbb{E}[(|\nabla g(z)|^2)^{1/2}] < +\infty \) for \( z \sim N(0, I_n) \). We refer to Section 1.5 in [Bog98] for a complete description of the space \( W^{1,2}(\gamma_n) \).

**Theorem 1.1.** Let \( z = (z_1, \ldots, z_n) \) be a standard normal \( N(0, I_n) \) random vector. Let \( f_1, \ldots, f_n \) be functions \( \mathbb{R}^n \to \mathbb{R} \) and \( f \) be the column vector in \( \mathbb{R}^n \) with \( i \)-th component equal to \( f_i \). Assume throughout that each \( f_i \) is square integrable, i.e. \( \mathbb{E}[f_i(z)^2] < \infty \).

(i) Assume that each \( f_i \) is twice continuously differentiable and that its first and second order derivatives have sub-exponential growth. Then

\[
\mathbb{E}[(z^\top f(z) - \text{div} f(z))^2] = \mathbb{E}\sum_{i=1}^n f_i^2(z) + \mathbb{E}\sum_{i=1}^n \sum_{j=1}^n \frac{\partial f_i}{\partial x_j}(z) \frac{\partial f_j}{\partial x_i}(z).
\]

An equivalent version of (1.4) for functions of \( y = N(\mu, \sigma^2 I) \), in vector notation, is given in (1.8) below.

(ii) If \( f : \mathbb{R}^n \to \mathbb{R} \) is \( L \)-Lipschitz for \( L < +\infty \), then (1.4) holds.

(iii) If each component \( f_i \) of \( f \) belongs to \( W^{1,2}(\gamma_n) \), then (1.4) holds.
Here is a proof of Theorem 1.1(i). Extensions (ii) and (iii) are proved in Appendix A.

**Proof of Theorem 1.1 (i).** When the functions \( f_i \) and \( (\partial/\partial x_j)f_i \) are treated as random variables, their argument is always \( z \) through the proof, so we simply write \( f_i \) for \( f_i(z) \) and similarly for the partial derivatives. A sum \( \sum_i \) or \( \sum_k \) always sums over \( \{1, ..., n\} \).

Write the left hand side in (1.4) as

\[
E \sum_i \left( z_i f_i - \frac{\partial f_i}{\partial x_i} \right) \left( \sum_j z_j f_j - \sum_i \frac{\partial f_i}{\partial x_i} \right).
\]

By a first application of Stein’s formula for each term \( z_i \), the identity

\[
(1.5) \quad E \left[ (z_i f_i(z) - \frac{\partial f_i}{\partial x_i}(z)) g(z) \right] = E \left[ f_i(z) \frac{\partial g}{\partial x_i}(z) \right]
\]

holds for any differentiable function \( g : \mathbb{R}^n \to \mathbb{R} \) with sub-exponential growth. Hence the left hand side in (1.4) equals

\[
E \sum_i f_i^2 + E \sum_i f_i \sum_j z_j \frac{\partial f_j}{\partial x_i} - E \sum_i f_i \sum_j \frac{\partial^2 f_i}{\partial x_i \partial x_j}.
\]

We again apply Stein’s formula to each \( z_j \) in the second term above to obtain

\[
E \sum_i f_i^2 + E \sum_i \sum_j f_i \frac{\partial f_j}{\partial x_i} + E \sum_i f_i \sum_j \frac{\partial^2 f_j}{\partial x_j \partial x_i} - E \sum_i f_i \sum_j \frac{\partial^2 f_i}{\partial x_i \partial x_j}.
\]

Since \( f \) is twice continuously differentiable, by Schwarz Theorem on the symmetry of the second derivatives we have \( \sum_j (\partial/\partial x_j)(\partial/\partial x_i)f_j = \sum_j (\partial/\partial x_i)(\partial/\partial x_j)f_j \) and the proof of (1.4) is complete. \( \square \)

Throughout the paper, \( \| \cdot \| \) is the Euclidean norm and \( \| \cdot \|_F \) the Frobenius norm, and \( f : \mathbb{R}^n \to \mathbb{R}^m \) is L-Lipschitz if \( \|f(u) - f(v)\| \leq L\|u - v\| \), \( \forall u, v \). For \( f : \mathbb{R}^n \to \mathbb{R}^n \) with components \( f_i \), denote by \( \nabla f_i \) the gradient of each \( f_i \), and by \( \nabla f \) the matrix in \( \mathbb{R}^{n \times n} \) with columns \( \nabla f_1, ..., \nabla f_n \). The Second Order Stein formula (1.4) can then be rewritten as

\[
(1.6) \quad E \left[ (z^T f(z) - \text{div } f(z))^2 \right] = E \left[ \|f(z)\|^2 + \text{trace } \left( (\nabla f(z))^2 \right) \right].
\]

By the Cauchy-Schwarz inequality,

\[
(1.7) \quad E \left[ (z^T f(z) - \text{div } f(z))^2 \right] \leq E \sum_{i=1}^n f_i^2(z) + E \sum_{i=1}^n \sum_{j=1}^n \left( \frac{\partial f_i}{\partial x_j}(z) \right)^2,
\]

\[
= E \left[ \|f(z)\|^2 + \|\nabla f(z)\|_F^2 \right].
\]
If \( \nabla f(z) \) is almost surely symmetric, then 
\[
\text{trace}(\nabla f(z))^2 = \|\nabla f(z)\|_F^2
\]
and the above inequality is actually an equality. However the inequality in (1.7) is strict otherwise.

If \( y = \mu + \varepsilon \) with \( \varepsilon \sim N(0, \sigma^2 I_n) \) and \( f : \mathbb{R}^n \to \mathbb{R}^n \) satisfies one of the assumption of Theorem 1.1, then
\[
E[(\varepsilon^T f(y) - \sigma^2 \text{div} f(y))^2] = \sigma^2 E[\|f(y)\|^2] + \sigma^4 E[\text{trace}((\nabla f(y))^2)]
\]
is easily obtained by setting \( z = \varepsilon/\sigma \) and applying Theorem 1.1 to \( f(x) = \sigma f(\mu + \sigma x) \). Theorem 1.1 is also applicable under the central limit theorem. Let \( \varepsilon_m = m^{-1/2} \sum_{i=1}^m x_i \) with iid \( x_i \in \mathbb{R}^n, E[x_i] = 0 \) and \( E[x_i^T x_i] = \Sigma \). If \( \{\|f(\varepsilon_m)\|^2, \|\nabla f(\varepsilon_m)\|^2, (\Sigma f(\varepsilon_m))^2, m \geq 1 \} \) is uniformly integrable and \( \nabla f \) is almost everywhere continuous, then
\[
E[\varepsilon_m^T f(\varepsilon_m)] = E[\text{trace}(\Sigma \nabla f(\varepsilon_m))] + o(1)
\]
and
\[
\text{Var}(\varepsilon_m^T f(\varepsilon_m) - \text{trace}(\Sigma \nabla f(\varepsilon_m)))
\]
\[
= E[\|\Sigma^{1/2} f(\varepsilon_m)\|^2] + E[\text{trace}((\Sigma \nabla f(\varepsilon_m))^2)] + o(1)
\]
as \( m \to \infty \), where \( o(1) \) becomes 0 for all \( n \) when \( x_i \sim N(0, \Sigma) \).

We provide in the next sections several applications of the Second Order Stein formula (1.4). Section 2 leverages the above formula to construct an unbiased risk estimate for Stein’s Unbiased Risk Estimate (SURE) in the Gaussian sequence model. We shall call this general method SURE for SURE. Section 3 provides bounds on the variance of random variables of the form \( \text{div} f \) for functions \( f \) as in the above result. Section 4 provides new bounds on the variance of the size of the model selected by the Lasso in sparse linear regression. Section 5 provides SURE for SURE formulas for the Lasso and E-net. Section 6 provides a scheme to de-bias a general class of estimators in linear regression where one wishes to estimate a low-dimensional projection of the unknown regression coefficient vector. Section 7 develops a Monte Carlo scheme to approximate the divergence of a general differentiable estimator when the analytic form of the divergence is unavailable.

2. SURE for SURE

In the Gaussian sequence model, one observes \( y = \mu + \varepsilon \) where the noise \( \varepsilon \sim N(0, I_n) \) is standard normal and \( \mu \) is an unknown mean. Given an estimator \( \hat{\mu}(y) \) of the form \( \hat{\mu} = y + f(y) \) where \( f : \mathbb{R}^n \to \mathbb{R}^n \) is some known almost differentiable function with \( \nabla f \) in \( L_1 \), SURE provides an unbiased estimate of the mean squared risk \( E[\|\hat{\mu} - \mu\|^2] \) given by
\[
\text{SURE} = \|f(y)\|^2 + 2 \text{div} f(y) + n.
\]
The fact that this quantity is an unbiased estimate of \( E[\|\hat{\mu} - \mu\|^2] \) is a consequence of the identity
\[
\|\hat{\mu} - \mu\|^2 = \|\varepsilon + f(y)\|^2 = \|f(y)\|^2 + 2\varepsilon^T f(y) + \|\varepsilon\|^2
\]
with $E[\|\varepsilon\|^2] = n$ and Stein’s formula (1.1) which asserts that $E[\varepsilon^\top f(y)] = E[\text{div } f(y)]$ whenever all partial derivatives of $f$ are in $L_1$. The random variable $\text{div } f(y)$ can be computed from the observed data since it only involves $y$ as well as the partial derivatives of $f$. The quantity $\hat{d} = n - \text{div } f(y)$ is an estimator sometimes referred to as the empirical degrees of freedom of the estimator $\hat{\mu}$.

Here, we define the mean squared risk of the scalar estimator $\hat{\text{SURE}}$ by

$$R_{\text{sure}} = E\left[\left(\hat{\text{SURE}} - \|\hat{\mu} - \mu\|^2\right)^2\right].$$

This means we treat $\hat{\text{SURE}}$ as an estimate of the squared prediction error $\|\hat{\mu} - \mu\|^2$ as well. This is reasonable as the actual squared loss $\|\hat{\mu} - \mu\|^2$ is often a more relevant target than its expectation. One may also wish to treat $\hat{\text{SURE}}$ as an estimate of the deterministic $E[\|\hat{\mu} - \mu\|^2]$ and consider the estimation of $\text{Var}(\|\hat{\mu} - \mu\|^2)$ or $\text{Var}(\hat{\text{SURE}})$, but these would be different problems to which our method may not be directly applicable. Let us mention, though, that if estimation of the deterministic quantity $E[\|\hat{\mu} - \mu\|^2]$ is essential, inequality

$$E\left[\left((\hat{\text{SURE}})^{1/2} - E[\|\hat{\mu} - \mu\|^2]^{1/2}\right)^4\right]^{1/4} \leq R_{\text{sure}}^{1/4} + 3$$

holds if the function $y \rightarrow \hat{\mu}$ is 1-Lipschitz, a property that is shared by all convex-regularized least-squares estimators [BT17]. Hence up to an additive absolute constant, $R_{\text{sure}}$ bounds from above the quartic risk of $\text{SURE}^{1/2}$ when the estimation target is $E[\|\hat{\mu} - \mu\|^2]^{1/2}$. The proof of (2.3) is given in Appendix E.

$\text{SURE}$ is widely used in practice to estimate $\|\hat{\mu} - \mu\|^2$ or $E[\|\hat{\mu} - \mu\|^2]$ either because it is of interest to estimate the prediction error of $\hat{\mu}$, or because several estimators of the mean vector $\mu$ are available and the statistician hopes to use the $\hat{\text{SURE}}$ of each estimator in order to compare them on equal footing. Although $\text{SURE}$ provides an unbiased estimate of the loss $\|\hat{\mu} - \mu\|^2$ and its expectation, such estimate may end up being unusable, or provide spurious estimates, if the quantity (2.2) is too large. For estimators of interest where $\text{SURE}$ is used in practice, it is important to understand the risk of $\hat{\text{SURE}}$ given by (2.2) in order to provide some uncertainty quantification about the success of $\hat{\text{SURE}}$. For instance, one should expect $\hat{\text{SURE}}$ to be successful if $R_{\text{sure}}^{1/2}$ is negligible compared to $\text{SURE}$, i.e., $R_{\text{sure}}^{1/2} \ll \text{SURE}$. On the other hand, if $R_{\text{sure}}^{1/2} \gg \text{SURE}$ then we would expect that estimates from $\hat{\text{SURE}}$ would be spurious with constant probability and $\text{SURE}$ should not be trusted. Under the square integrability condition on the first and second partial derivatives of $f(y)$, [Ste81] proposed an unbiased estimate of the risk (2.2). However, the twice differentiability condition typically fails to hold for estimators involving less smooth regularizers such as the Lasso. [DJ95] studied the performance of $\text{SURE}$ optimized separable threshold estimator (SureShrink) and thus the accuracy of $\text{SURE}$ in this special case. [DKF+13] derives an identity for the quantity (2.2) in the special case of of the Lasso. In a general study of $\text{SURE}$
tuned estimators, [TR18] developed a correction for the excess optimism with the nominal SURE in such schemes. Section 5 in [JM18] establishes consistency of SURE for the Lasso with random design and identity covariance matrix if the tuning parameter is large enough. The Second Order Stein identity

$$E \left[ \left( \|z\|^2 - n + \gamma(z) \right) \right] = E \left[ 2p + 2\Delta \gamma(z) + \gamma(z)^2 \right],$$

where $$\Delta = \sum_{i=1}^{n} (\partial / \partial x_i)^2$$ is the Laplacian, was used in [Joh88] to prove the inadmissibility of SURE for the estimation of the squared loss of the James-Stein estimator when $$n \geq 5$$.

The following result, which extends Theorem 3 of [Ste81] to allow application to the Lasso and other estimators only one-time differentiable, computes the expectation of the quantity (2.2) as well as an unbiased estimator of it directly through Theorem 1.1.

**Theorem 2.1.** Let $$\varepsilon \sim N(0, I_n)$$ and $$y = \mu + \varepsilon$$. Let $$\hat{\mu} = f(y) + y$$ be an estimator of $$\mu$$ with $$f : \mathbb{R}^n \to \mathbb{R}^n$$ satisfying the assumptions of Theorem 1.1, and define SURE by (2.1). Then

$$E \left[ \left( \hat{\text{SURE}} - \|\hat{\mu} - \mu\|^2 \right) \right] = E \left[ 2n + 4\|f(y)\|^2 \right],$$

(2.4)

$$= E \left[ 2n + 4\|f(y)\|^2 \right],$$

(2.5)

Thus, SURE for $$\hat{R}_{\text{SURE}} = 2n + 4\|f(y)\|^2$$ is an unbiased estimate of the risk of SURE in (2.2).

As the quantities in (2.4) and (2.5) are identical without taking the expectation, SURE for SURE is also given by

$$\hat{R}_{\text{SURE}} = 2n + 4\|f(y)\|^2$$

(2.6)

$$= 2n + 4\|f(y)\|^2 + 4\|f(y)\|^2$$

(2.7)

**Proof.** For brevity, write $$\text{div} f$$ for $$\text{div} f(y)$$ and $$f$$ for $$f(y)$$. By simple algebra

$$\left( \|\hat{\mu} - \mu\|^2 - \text{SURE} \right) = \left( \|\hat{\mu} - \mu\|^2 - (n + 2\text{div} f + \|f\|^2) \right)$$

$$= \left( (\|\varepsilon\|^2 - n) + 2(\varepsilon^\top f - \text{div} f) \right).$$

The variance of $$\|\varepsilon\|^2$$ is $$2n$$ hence $$E[(\|\varepsilon\|^2 - n)^2] = 2n$$. By Theorem 1.1 we get

$$4E[(\varepsilon^\top f - \text{div} f)^2] = 4E\|f\|^2 + 4E\text{trace}(\nabla f^2).$$

For the cross-term, applying Stein’s formula twice we get

$$4E \left[ \sum_{i=1}^{n} \sum_{j=1}^{n} \varepsilon_j f_j \left( \varepsilon_j f_j - \frac{\partial f_j}{\partial x_j} \right) \right] = 8E \sum_{j=1}^{n} \varepsilon_j f_j = 8E[\text{div} f].$$
This completes the proof of the first equality. The second equality is obtained by observing that $f(y) = \hat{\mu}(y) - y$, hence
\[
\nabla f(y) = \nabla \hat{\mu} - I_n, \quad \text{div } f(y) = \text{trace}[\nabla \hat{\mu}] - n,
\]
4-trace\left( (\nabla f(y))^2 \right) + 8 \text{div } f(y) = 4 \text{trace}\left( (\nabla \hat{\mu}(y))^2 \right) - 4n.
\]

\[\Box\]

Remark 2.1. In the Gaussian sequence model where the noise $\varepsilon$ has distribution $N(0, \sigma^2 I_n)$ with $\sigma \neq 1$, the estimator SURE has the form
\[
(2.8) \quad \text{SURE} = na^2 + 2\sigma^2 \text{div } f(y) + \|f\|^2,
\]
\[
= \|y - \hat{\mu}\|^2 + 2\sigma^2 \text{div } \hat{\mu} - \sigma^2 n.
\]
The same argument as above implies that in this setting, SURE for SURE is
\[
(2.9) \quad \hat{R}_{\text{mle}} = 4\|y - \hat{\mu}\|^2 + 4\sigma^4 \text{trace}\left( (\nabla \hat{\mu})^2 \right) - 2n\sigma^4,
\]
as its expectation is identical to $\mathbb{E}\left[ (\text{SURE} - \|\hat{\mu} - \mu\|^2)^2 \right]$.

While SURE for SURE provides an unbiased point estimator for the (mean) squared difference between SURE and the squared loss $\|\hat{\mu} - \mu\|^2$, we may also use the Second Order Stein formula to derive interval estimates for $\|\hat{\mu} - \mu\|^2$ based on SURE. As we are not compelled to directly use the $\hat{R}_{\text{mle}}$ in (2.9) to construct such interval estimates, we present the following simpler approach.

\textbf{Theorem 2.2.} Let $y$, $\mu$, $\hat{\mu} = \hat{\mu}(y)$ and $\text{SURE}$ be as in (2.8). Then,
\[
(2.10) \quad \mathbb{E}\left[ (\text{SURE} - \|\mu - \hat{\mu}\|^2 - \|\varepsilon\|^2 + \sigma^2 n)^2 \right]
\quad = \quad 4\sigma^2 \mathbb{E}\left[ \|\hat{\mu} - \mu\|^2 \right] + 4\sigma^4 \mathbb{E}\left[ \text{trace}\left( (\nabla \hat{\mu})^2 \right) \right].
\]
If the right-hand side of (2.10) is bounded by $\sigma^4 v_0^2 2n \epsilon_n$ with a constant $v_0$, then
\[
(2.11) \quad \mathbb{P}\left\{ |\text{SURE} - \|\mu - \hat{\mu}\|^2| \leq \sigma^2 (v_\alpha + v_0) \sqrt{2n} \right\} \geq 1 - \alpha - \epsilon_n
\]
for all $\alpha \in (0, 1)$, where $v_\alpha$ is defined by $\mathbb{P}\{ (2n)^{-1/2} |\chi_n^2 - n| > v_\alpha \} = \alpha$, and
\[
(2.12) \quad \mathbb{P}\left\{ \|\mu - \hat{\mu}\|^2 \leq \text{SURE} + \sigma^2 (v_{-\alpha} + v_0) \sqrt{2n} \right\} \geq 1 - \alpha - \epsilon_n,
\]
where $v_{-\alpha}$ is defined by $\mathbb{P}\{ (2n)^{-1/2} (n - \chi_n^2) > v_{-\alpha} \} = \alpha$.

While the left-hand side of (2.10) is quartic in $\|\hat{\mu} - \mu\|$, the right-hand side is quadratic. Thus, SURE provides an accurate estimate of $\|\mu - \hat{\mu}\|^2$ when the squared error is of greater order than $\|\varepsilon\|^2 - \sigma^2 n \approx \sigma^2 (2n)^{1/2} N(0, 1)$, provided that the second term on the right-hand side of (2.10) is of no greater order than $\max\{ \sigma^2 n, \sigma^2 \mathbb{E}[\|\hat{\mu} - \mu\|^2] \}$. Specifically, in such scenarios, (2.11)
implies that SURE is within a small fraction of \(\|\mu - \hat{\mu}\|^2\) when \(\sqrt{\|\mu - \hat{\mu}\|^2/n}\) is of greater order than \(\sigma n^{-1/4}\), and (2.11) and (2.12) provide confidence regions for the entire vector \(\mu\). As \(\sigma n^{-1/4}\) is known to be a lower bound for the error in the estimation of the average loss in the estimation of \(\mu\) \({[Li89, NvdG13]}\), (2.11) implies the rate optimality of the upper bound (2.12) for the squared estimation error \(\|\mu - \hat{\mu}\|^2\) and thus the rate optimality of the resulting confidence region for \(\mu\). We will verify in Theorems 4.3 and 4.5 in Section 4 that the condition for (2.11) and (2.12) holds for the Lasso under commonly imposed regularity conditions in sparse regression theory.

**Proof.** Assume \(\sigma = 1\) without loss of generality. As \(f(y) = \hat{\mu} - y = (\hat{\mu} - \mu) - \varepsilon\),

\[
\text{SURE} - \|\mu - \hat{\mu}\|^2 = \|\hat{\mu} - y\|^2 - \|\mu - \hat{\mu}\|^2 + 2\text{div}(\hat{\mu} - y) + n
\]

so that (2.10) is a direct consequence of Theorem 1.1. By the Markov inequality,

\[
\mathbb{P}\left\{\|\hat{\mu} - \mu\| - \text{div}(\hat{\mu} - \mu) \geq \sqrt{v_0 n/2}\right\} \leq \mathbb{E}\left[\|\hat{\mu} - \mu\|^2 + \text{trace}(\nabla \hat{\mu}(y))^2)/(v_0^2 n/2)\right] \leq \epsilon_n.
\]

The conclusion then follows from the definition of \(\epsilon_n\) and the union bound.

As we have briefly discussed above the statement of Theorem 2.1, SURE is often used to optimize among different estimators. Consider for simplicity the comparison between two estimates \(\mu^{(1)}\) and \(\mu^{(2)}\) of \(\mu\). In this setting,

\[
R^{(\text{diff})}_{\text{SURE}} = \mathbb{E}\left[\left(\|\mu^{(1)} - \mu\|^2 - \|\mu^{(2)} - \mu\|^2 - \text{SURE}^{(\text{diff})}\right)^2\right]
\]

is the proper risk for SURE, where \(\mu^{(1)}\) and \(\mu^{(2)}\) are two estimates of \(\mu\), and

\[
\text{SURE}^{(\text{diff})} = \hat{\mu}^{(1)} - \hat{\mu}^{(2)}
\]

is the difference in SURE between \(\mu^{(1)}\) and \(\mu^{(2)}\). When the loss \(\|\hat{\mu} - \mu\|^2\) is of smaller order than \(n^{1/2}\), SURE may produce a spurious estimator due to the estimation of \(\|\varepsilon\|^2\) by \(n\) in (2.1). However, due to the cancellation of this common chi-square type error, the risk of the estimator (2.14) could be of smaller order than the risk of SURE for both \(\hat{\mu}^{(j)}\). Parallel to Theorem 2.1, the Second Order Stein formula leads to the following.

**Theorem 2.3.** Let \(\varepsilon \sim N(0, I_n)\), \(y = \mu + \varepsilon\), and \(\mu^{(1)}\) and \(\mu^{(2)}\) be estimates of \(\mu\) based on \(y\). Let \(\text{SURE}^{(\text{diff})}\) and \(R^{(\text{diff})}_{\text{SURE}}\) be as in (2.13) and (2.14) and \(f(y) = \hat{\mu}^{(1)} - \hat{\mu}^{(2)}\). Suppose \(f : \mathbb{R}^n \rightarrow \mathbb{R}^n\) satisfies the assumptions of Theorem 1.1. Then,

\[
R^{(\text{diff})}_{\text{SURE}} = \mathbb{E}\left[4\|f(y)\|^2 + 4\text{trace}\left(\left(\nabla f(y)\right)^2\right)\right].
\]
Consequently, SURE for SURE, given by

\begin{equation}
\hat{R}_{\text{SURE}}^{(d)} = 4\|f(y)\|^2 + 4\text{trace}\left((\nabla f(y))^2\right).
\end{equation}

is an unbiased estimate of the risk of \( \text{SURE}^{(d)} \) in (2.13).

**Proof.** By algebra,

\[ \|\hat{\mu}^{(1)} - \mu\|^2 - \|\hat{\mu}^{(2)} - \mu\|^2 - \text{SURE}^{(d)} = 2\varepsilon^T f(y) - 2\text{div} f(y). \]

The conclusion follows directly from Theorem 1.1. \qed

Beyond pairwise comparisons, the following result provides guarantees on the SURE-tuned estimate \( \hat{\mu} \), which is obtained by selecting the estimator among \( \{\hat{\mu}^{(1)},...,\hat{\mu}^{(m)}\} \) with smallest SURE, i.e., \( \hat{\mu} = \hat{\mu}^{(k)} \) where \( k = \arg\min_{j\in[m]} \text{SURE}^{(j)} \) and \( \text{SURE}^{(j)} = \|\hat{\mu}^{(j)} - y\|^2 + 2\sigma^2 \text{trace} \nabla \hat{\mu}^{(j)} - n\sigma^2 \) when \( \varepsilon \sim N(0,\sigma^2) \).

**Theorem 2.4.** Consider the sequence model \( y = \mu + \varepsilon \) with \( \varepsilon \sim N(0,\sigma^2 I_n) \). If \( \hat{\mu}^{(1)},...,\hat{\mu}^{(m)} \) are all 1-Lipschitz functions of \( y \) and \( \hat{\mu} \) is the estimate among \( \{\hat{\mu}^{(1)},...,\hat{\mu}^{(m)}\} \) with the smallest SURE, then

\[
\mathbb{E}\left[ \left(n^{-1/2}\|\hat{\mu} - \mu\| - \min_{j\in[m]} n^{-1/2}\|\hat{\mu}^{(j)} - \mu\| \right)^2 \right]^{1/2} \leq \sigma \left\{ (32m/n)^{1/4} + (44m/n)^{1/2} + \left(8 \log(mn)/n \right)^{1/2} \right\}.
\]

The proof is given in Appendix D. The assumption that the estimators \( \hat{\mu}^{(j)} \) are 1-Lipschitz functions of \( y \) is mild: for instance this property is satisfied for all convex regularized least-squares [BT17]. Under this assumption, Theorem 2.4 implies that for \( m \leq n \)

\[ n^{-1/2}\|\hat{\mu} - \mu\| - \min_{j\in[m]} n^{-1/2}\|\hat{\mu}^{(j)} - \mu\| = O_\varepsilon(\sigma(m/n)^{1/4}). \]

Theorem 2.4 can also be understood in terms of sample size requirement: If \( \varepsilon > 0 \) is a fixed precision target and \( \alpha \in (0,1) \) then \( n \gtrsim m/(\varepsilon^4\alpha^2) \) samples are sufficient to ensure \( \mathbb{P}(n^{-1/2}\|\hat{\mu} - \mu\| - \min_{j\in[m]} n^{-1/2}\|\hat{\mu}^{(j)} - \mu\| \leq \varepsilon) \geq 1 - \alpha \). We are not aware of a previous result of this form that applies with the above level of generality, i.e., with no restriction on the nature of the estimators \( \{\hat{\mu}^{(1)},...,\hat{\mu}^{(m)}\} \) beyond the 1-Lipschitz requirement.

3. Upper bounds on the variance of the divergence

The Second Order Stein formula (1.4) lets us derive upper bounds of the variance of random variables of the form \( \text{div} f(z) \) where \( z \sim N(0,\mathbb{I}_n) \) and \( f \) is as in Theorem 1.1.
Proposition 3.1. Let $f$ be as in Theorem 1.1. Then the variance of the random variable $\text{div } f(z)$ satisfies

\begin{equation}
\text{Var}[\text{div } f(z)] = \mathbb{E}[\text{trace } \left((\nabla f(z))^2\right)] + \text{Var}[z^\top f(z)] - \mathbb{E}[\|f(z)\|^2] - 2\mathbb{E}[f(z)^\top (\nabla f(z))z].
\end{equation}

Consequently,

\begin{equation}
\text{Var}[\text{div } f(z)] \leq \mathbb{E}[\text{trace } \left((\nabla f(z))^2\right)] + \mathbb{E}[\|\nabla f(z)\|^2].
\end{equation}

Proof. Define the function $g$ by $g(x) = x^\top f(x)$ for any $x \in \mathbb{R}^n$. When the functions $g, f_i, (\partial/\partial x_j)f_i$ and $(\partial/\partial x_j)g$ are treated as random variables, their argument is always $z$ through the proof, so we simply write $f_i$ for $f_i(z)$ and similarly for $g$ and the partial derivatives. We have $(\partial g/\partial x_i)(z) = f_i(z) + \sum_{j=1}^n z_j(\partial f_j/\partial x_i)(z)$ so that $\nabla g(z) = f(z) + (\nabla f(z))z$. Recall that by convention, $\nabla f$ is the matrix with columns $\nabla f_1, ..., \nabla f_n$. By (1.5),

\begin{equation}
\mathbb{E}[(z^\top f)(z^\top f - \text{div } f)] = \mathbb{E} \sum_i f_i \frac{\partial g}{\partial x_i} = \mathbb{E}\|f\|^2 + \mathbb{E}[f^\top (\nabla f)z].
\end{equation}

Since $\mathbb{E}[\text{div } f] = \mathbb{E}[z^\top f]$ by (1.1), using $a^2 - b^2 = (a - b)^2 - 2b(b - a)$ we get

\begin{equation}
\text{Var}[\text{div } f] - \text{Var}[z^\top f] = \mathbb{E}[(\text{div } f)^2] - \mathbb{E}[(z^\top f)^2],
\end{equation}

\begin{equation}
= \mathbb{E}[(\text{div } f - z^\top f)^2] - 2\mathbb{E}[(z^\top f)(z^\top f - \text{div } f)].
\end{equation}

Using (1.4) for the first term and (3.3) for the second term implies (3.1).

Next, by the Gaussian Poincaré inequality applied to $g$,

\begin{equation}
\text{Var}[g(z)] \leq \mathbb{E}[\|\nabla g(z)\|^2] = \mathbb{E}[\|f(z) + (\nabla f(z))z\|^2]
\end{equation}

\begin{equation}
= \mathbb{E}[[f(z)]^2 + \|(\nabla f(z))z\|^2 + 2f(z)^\top (\nabla f(z))z].
\end{equation}

Combined with (3.1), this completes the proof of (3.2). \qed

A striking feature of the above upper bound is that the variance of the random variable $\text{div } f(z)$, defined using the first order derivatives of $f$, can be bounded from above using only first order partial derivatives of $f$. In particular, the second partial derivatives of $f$ may be arbitrarily large or may not exist. This feature will be used in the next section to study the variance of the size of the model selected by the Lasso in linear regression, which takes the form $\text{div } f$ for a certain function $f$.

It can be seen from the proof that the inequality (3.2) involves a single application of the Gaussian Poincaré inequality to $z^\top f(z)$. Thus, it holds with equality if and only if $f(z)$ is deterministic.

Finally, we obtain the following corollary by applying Proposition 3.1 to $z \rightarrow f(z) - \mathbb{E}[^\top \nabla f(z)]z$.

Corollary 3.2. Let $f$ be as in Theorem 1.1. Then

\begin{equation}
\text{Var}[\text{div } f(z)] \leq \mathbb{E}[\text{trace } \left((\nabla f(z) - \mathbb{E}[\nabla f(z)])^2\right)] + \mathbb{E}[\|(\nabla f(z) - \mathbb{E}[\nabla f(z)])z\|^2].
\end{equation}

Proof. By Proposition 3.1 with $\tilde{f}(z) = f(z) - \mathbb{E}[\nabla f(z)]z$ we have $\nabla \tilde{f} = \nabla f - \mathbb{E}[\nabla f(z)]$ and $\text{div } \tilde{f}(z) = \text{div } f(z) - \text{trace } \mathbb{E}[\nabla f(z)] = \text{div } f(z) - \mathbb{E}[^\top \text{div } f(z)].$ \qed
4. The variance of the model size of the Lasso

Consider a linear regression model

\[ y = X\beta + \varepsilon, \]

where \( \beta \) is the true coefficient vector, \( \varepsilon \sim N(0, \sigma^2 I_n) \) is the noise and \( X \) is a deterministic design matrix. Consider the penalized Lasso \( \hat{\beta}^{(\lambda)} \) which solves the optimization problem

\[ \hat{\beta}^{(\lambda)} = \arg\max_{b \in \mathbb{R}^p} \{ \|Xb - y\|^2/(2n) + \lambda\|b\|_1 \}. \]

Let \( \hat{S} = \{ j \in [p] : (\hat{\beta}^{(\lambda)}_{\text{lasso}})_j \neq 0 \} \) be the support of the Lasso. We are interested in the size of \( \hat{S} \) denoted by \( |\hat{S}| \). Even though the Lasso and sparse linear regression have been studied extensively in the last two decades, little is known about the stochastic behavior of the discrete random variable \( |\hat{S}| \). Under the sparse Riesz or similar conditions, \( |\hat{S}| \lesssim \|\beta\|_0 \) with high probability [ZH08, Zha10, ZZ12] but such results only imply a bound of the form \( \text{Var}(|\hat{S}|) \lesssim \|\beta\|_0^2 \) on the variance; we will see below that the variance of \( |\hat{S}| \) is typically much smaller. There are trivial situations where the behavior of \( |\hat{S}| \) is well understood: if \( \lambda \) is very large for instance, \( |\hat{S}| = 0 \) with high probability. Or, under strong conditions on \( X \) and \( \beta \) that grants support recovery (cf. for instance, the conditions given in [MB06, ZY06, Tro06, Wai09]), \( \hat{S} = \text{supp}(\beta) \) holds with probability at least \( 1 - 1/p^2 \) and in this case \( \text{Var}(|\hat{S}|) \leq \mathbb{E}[(|\hat{S}| - s_0)^2] \leq 1. \)

Outside of these situations, studying \( |\hat{S}| \) appears delicate; for instance, our previous attempts at studying the variance of \( |\hat{S}| \) went as follows. Let \( (e_1, \ldots, e_p) \) be the canonical basis in \( \mathbb{R}^p \) and let \( x_j = Xe_j \) for all \( j = 1, \ldots, p \). The KKT conditions of the Lasso are given by

\[ x_j^\top(y - X\hat{\beta}^{(\lambda)}_{\text{lasso}})/(n\lambda) \begin{cases} \text{sgn}((\hat{\beta}^{(\lambda)}_{\text{lasso}})_j) & \text{if } (\hat{\beta}^{(\lambda)}_{\text{lasso}})_j \neq 0, \\ \in [-1, 1] & \text{if } (\hat{\beta}^{(\lambda)}_{\text{lasso}})_j = 0. \end{cases} \]

At a given point \( y \), to understand the stability of \( \hat{S} \), a natural avenue is to identity how close the quantities \( x_j^\top(y - X\hat{\beta}^{(\lambda)}_{\text{lasso}})/(n\lambda) \) are from \( \pm 1 \) for the indices \( j \notin \hat{S} \). If many indices \( j \notin \hat{S} \) are such that \( x_j^\top(y - X\hat{\beta}^{(\lambda)}_{\text{lasso}})/(n\lambda) \) is extremely close to \( \pm 1 \), then a tiny variation in \( y \) may push some of the quantities \( x_j^\top(y - X\hat{\beta}^{(\lambda)}_{\text{lasso}})/(n\lambda) \) towards \( \pm 1 \) resulting in many new variables entering the support for this tiny variation in \( y \). The current model size \( |\hat{S}| \) is non-informative about how many indices \( j \notin \hat{S} \) are such that \( x_j^\top(y - X\hat{\beta}^{(\lambda)}_{\text{lasso}})/(n\lambda) \) is extremely close to \( \pm 1 \) and the random variable \( |\hat{S}| \) appears prone to instability.

With the Second Order Stein formula (1.4) and the tools developed in the previous section, the variance of \( |\hat{S}| \) can be bounded as follows. First, we need to describe a condition on the deterministic matrix \( X \) which ensures that the
KKT conditions of the Lasso hold strictly with probability 1. We say that the KKT conditions hold strictly if

\[ \forall j \notin \hat{S}, \quad -1 < \frac{1}{\lambda h} x_j^\top (y - X \hat{\beta}_\text{lasso}^{(\lambda)}) < 1. \tag{4.3} \]

**Assumption 4.1.** For all \( \delta_1, ..., \delta_p \in \{-1, 1\} \) and \( 1 \leq j_0 < j_1 < \cdots < j_n \leq p \),

\[ \text{rank} \left( \begin{array}{cccc} x_{j_0} & x_{j_1} & \cdots & x_{j_n} \\ \delta_{j_0} & \delta_{j_1} & \cdots & \delta_{j_n} \end{array} \right)_{(n+1) \times (n+1)} = n + 1. \]

**Proposition 4.1.** If \( X \) satisfies the above assumption then the set \( B = \{ j \in \mathbb{N} : |x_j^\top (y - X \hat{\beta}_\text{lasso}^{(\lambda)})| = \lambda n \} \) is such that \( X_B \) has rank \( |B| \) and the solution \( \hat{\beta}_\text{lasso}^{(\lambda)} \) to the optimization problem (4.2) is unique. Furthermore, if \( \mathbb{P}[v^\top \varepsilon = c] = 0 \) for all vectors \( v \neq 0 \) and real \( c \), then the KKT conditions of the Lasso \( \hat{\beta}_\text{lasso}^{(\lambda)} \) hold strictly with probability 1, i.e., (4.3) holds with probability 1.

Expositions of the results in the first part of the above proposition exist in the literature, see for instance [Zha10, Section 3] or [TT12, Tib13]. Compared with previous versions of the condition on the design, Assumption 4.1, which clearly holds with probability 1 when \( X \) is the realization of a continuous distribution over \( \mathbb{R}^{n \times p} \), gives a natural interpretation in terms of the rank of specific matrices. The fact that the KKT conditions of the Lasso hold strictly with probability one is known although it is difficult to pinpoint an existing result in the literature. We provide a short proof in Appendix B for completeness.

Next define the function \( f : \mathbb{R}^n \to \mathbb{R}^n \) by

\[ f : \varepsilon \to X (\hat{\beta}_\text{lasso}^{(\lambda)} - \beta). \tag{4.4} \]

Then the function \( f : \mathbb{R}^n \to X (\hat{\beta}_\text{lasso}^{(\lambda)} - \beta) \) is 1-Lipschitz and this property holds true for all convex penalized Least-Squares estimators [BT17, Proposition 3]. Consequently the partial derivatives of \( f \) exist almost everywhere and are bounded. It is enough to compute the gradient of \( f \) Lebesgue almost everywhere and by the above Proposition, the KKT conditions holds strictly for almost every point \( \varepsilon_0 \in \mathbb{R}^n \).

If the KKT conditions of the Lasso hold strictly for \( \varepsilon_0 \), then by Lipschitz continuity of \( \varepsilon \to X \hat{\beta}_\text{lasso}^{(\lambda)} \), the KKT conditions also hold strictly in small enough nontrivial neighbourhood of \( \varepsilon_0 \). In this small neighborhood, the sign and support of \( \hat{\beta}_\text{lasso}^{(\lambda)} \) are unchanged and we have for \( \| h \| \) small enough

\[ X \hat{\beta}_\text{lasso}^{(\lambda)} (\varepsilon_0 + h) = X_{\hat{S}} (X^\top X)^{-1}_{\hat{S}, \hat{S}} (X_{\hat{S}}^\top (\varepsilon_0 + X \beta) - \lambda \text{sign}(\hat{\beta}_\text{lasso}^{(\lambda)} (\varepsilon_0 + h))) \]

where \( \hat{S} \) denotes the locally constant support equal to the support of \( \hat{\beta}_\text{lasso}^{(\lambda)} (\varepsilon_0) \). In this neighbourhood the map \( h \to X \hat{\beta}_\text{lasso}^{(\lambda)} (\varepsilon_0 + h) \) as well as the map \( h \to X (\hat{\beta}_\text{lasso}^{(\lambda)} (\varepsilon_0 + h) - \beta) \) are locally affine with linear part equal to the orthogonal projection

\[ P_{\hat{S}} = X_{\hat{S}} (X^\top X)^{-1}_{\hat{S}, \hat{S}} X_{\hat{S}}. \tag{4.5} \]

We conclude this calculation with the following lemma.
Proposition 4.2. Let $\hat{\beta}_{\text{lasso}}^{(\lambda)}$ be the Lasso estimator (4.2) with data $(X, y)$ satisfying $y = X\beta + \varepsilon$. Define $f(\varepsilon) = X(\hat{\beta}_{\text{lasso}}^{(\lambda)} - \beta)$ as in (4.4). Suppose Assumption 4.1 holds and $P\{v^T\varepsilon = c\} = 0$ for all deterministic $v \in \mathbb{R}^n$ and real $c$. Then almost surely

$$\nabla \hat{\beta}_{\text{lasso}}^{(\lambda)} = \left( (X^T X)^{-1} \hat{S}^T \hat{X} \right)_{\hat{S}^T \times n}$$

as well as

$$\nabla f(\varepsilon) = \hat{P}_{\hat{S}} \quad \text{and} \quad \text{div } f(\varepsilon) = \|P_{\hat{S}}\|_F^2 = \text{trace } P_{\hat{S}} = |\hat{S}|,$$

where $\hat{S} = \text{supp}(\hat{\beta}_{\text{lasso}}^{(\lambda)})$ and $P_{\hat{S}}$ is as in (4.5).

By Proposition 3.1 we obtain the following.

Theorem 4.3. Consider the linear model (4.1) and $\hat{\beta}_{\text{lasso}}^{(\lambda)}$ in (4.2), with deterministic design $X$ satisfying Assumption 4.1, true target vector $\beta$ and noise $\varepsilon \sim N(0, \sigma^2 I_n)$. Then the variance of the size of the selected support satisfies

$$\text{(4.6)} \quad \text{Var}[|\hat{S}|] \leq E[|\hat{S}|] + E[\|P_{\hat{S}}\varepsilon\|^2 / \sigma^2].$$

Consequently, $\text{Var}[|\hat{S}|] \leq 2n$ as well as

$$\text{(4.7)} \quad \text{Var}[|\hat{S}|] \leq 3E[|\hat{S}|] + 4E \left[ |\hat{S}| \log \left( \frac{ep}{1 \vee |\hat{S}|} \right) \right] \leq 3E[|\hat{S}|] + 4E[|\hat{S}|] \log \left( \frac{ep}{1 \vee E[|\hat{S}|]} \right).$$

A significant feature of the above theorem, and Proposition 3.1 as well, is the requirement of no condition on the true $\beta$, the penalty level $\lambda$ or the design matrix $X$ beyond Assumption 4.1. In particular, the restricted eigenvalue condition is not required.

An implication of Theorem 4.3 is the confidence interval

$$\frac{|\hat{S}|}{E[|\hat{S}|]} + \frac{E[|\hat{S}|]}{|\hat{S}| \vee 1} - 2 \leq C_\alpha \left( \frac{3}{|\hat{S}| \vee 1} + \frac{4 \log(ep)}{|\hat{S}| \vee 1} \right)$$

for $E[|\hat{S}|]$ with conservative $C_\alpha = 1/\alpha^2$, although $E[|\hat{S}|]$ is not a conventional parameter due to its dependence on the specific choice of $\hat{\beta}$. It is known that $\mathbb{P}\{|\hat{S}| \geq k\} \approx 1$ when $X$ has iid $N(0, \Sigma)$ rows with $(\Sigma)_{jj} = 1$, $\beta = 0$ and $\lambda = \lambda(k) = (\sigma/n^{1/2})\{L(k/p) - 1\}$ under a mild side condition on $\Sigma$, where $L(t)$ is defined by $\mathbb{P}\{N(0, 1) > L(t)\} = t$ [SZ13][Proposition 14(ii)]. As $|\hat{S}|$ is expected to be larger when $\beta \neq 0$, it would be reasonable to expect $E[|\hat{S}|] \gg \log p$ when $\lambda = \lambda(k_n)$ with $k_n \gg \log p$. 
An informative benchmark to study the tightness of inequality (4.7) for the support of the Lasso is the case \( X = \sqrt{n} I_p \) which reduces to the Gaussian sequence model. Then \( \hat{\beta}_{\text{lasso}}^{(x)} \) is the soft-thresholding operator and \( |\hat{S}| \) is the sum of \( p \) iid Bernoulli random variables with parameters \( q_1, \ldots, q_p \in (0, 1) \) and \( \text{Var}[|\hat{S}|] = \sum_{j=1}^{p} q_j (1 - q_j) \). Under mild assumption on the probabilities \( q_j \) (e.g., \( q_j \leq 1/2 \) for all \( j \)), the variance \( \text{Var}[|\hat{S}|] \) is of the same order as \( \mathbb{E}[|\hat{S}|] \). Hence the bound (4.7) is sharp up to a logarithmic factor.

**Proof.** Assume \( \sigma = 1 \) without loss of generality due to scale invariance. The first claim follows from (4.5) and the discussion leading to it, combined with Proposition 3.1. Next we first use the rough bounds \( |\hat{S}| \leq n \) and \( \| P_{\hat{S}} \| \leq \| \varepsilon \| \) to obtain \( \text{Var}[|\hat{S}|] \leq 2n \). For the right term of the minimum, for a fixed \( A \subset [p] \), the random variable \( \| P_A \varepsilon \| \) has chi-squared distribution with at most \( |A| \) degrees of freedom and a classical tail bound (cf. for instance [LM00, Lemma 1]) states that

\[
\mathbb{P}(\| P_A \varepsilon \|^2 > |A| + 3x) \leq \mathbb{P}(\| P_A \varepsilon \|^2 > |A| + 2\sqrt{|A| + 2x}) \leq e^{-x}.
\]

Consequently, by the union bound over all \( (p^m) \leq (\frac{ep}{m})^m \) supports \( A \) of size \( m \),

\[
\mathbb{P}\left( \max_{\hat{A} \subset [p]: |\hat{A}| = m} \| P_{A} \varepsilon \|^2 > 2m + 3 \left( m \log \left( \frac{ep}{m} \right) + x \right) \right) \leq e^{-x}.
\]

By a second union bound over all possible support sizes \( m = 1, \ldots, p \),

\[
\mathbb{P}\left( \max_{A \subset [p]} \left\{ \| P_A \varepsilon \|^2 - 2|A| - 3 \left( |A| \log \left( \frac{ep}{|A| \lor 1} \right) \right) \right\} > 3(\log p + x) \right) \leq e^{-x}.
\]

Finally, let \( X = (1/3) \max_{A \subset [p]} \{ \| P_A \varepsilon \|^2 - 2|A| - 3(\log p + x) \} \) so that \( \mathbb{P}(X > x) \leq e^{-x} \) holds. The identity \( \mathbb{E}[\max(X, 0)] = \int_0^{\infty} \mathbb{P}(X > x) dx \leq 1 \) yields

\[
\mathbb{E}[\| P_{\hat{S}} \varepsilon \|^2] \leq 2\mathbb{E}[|\hat{S}|] + 3\mathbb{E}[|\hat{S}| \log \left( \frac{ep}{|\hat{S}| \lor 1} \right) + \log(ep)]
\]

\[
(4.8)
\]

The proof is complete as the second inequality in (4.7) follows from the concavity of the function \( x \to x \log(ep/(x \lor 1)) \).

A sequence of non-negative random variables \((Z_q)_{q \geq 1}\) is said to be relatively stable if \( Z_q/\mathbb{E}[Z_q] \) converges to 1 in probability. A direct consequence of Theorem 4.3 is that the model size \( |\hat{S}| \) is relatively stable provided that \( \mathbb{E}[|\hat{S}|] \) is not pathologically small.

**Corollary 4.4.** Let the setting and assumptions of Theorem 4.3 be fulfilled. Then

\[
\mathbb{E}\left[ \left( \frac{|\hat{S}|}{\mathbb{E}[|\hat{S}|]} - 1 \right)^2 \right] \leq \frac{3}{\mathbb{E}[|\hat{S}|]} + \frac{4 \log(ep/\mathbb{E}[|\hat{S}|])}{\mathbb{E}[|\hat{S}|]} \leq \frac{3 + 4 \log(ep)}{\mathbb{E}[|\hat{S}|]}.
\]
Consequently, if one considers a sequence of regression problems such that $E[|\hat{S}|/\log(ep) \to +\infty$, then $|\hat{S}|/E[|\hat{S}|]$ converges to 1 in $L_2$ and in probability.

From (4.7), we can also obtain more explicit bounds on the variance of $|\hat{S}|$ by bounding from above $E[|\hat{S}|]$. We provide below upper bounds on $E[|\hat{S}|]$ under two assumptions on $X$: the Sparse Riesz Condition (SRC) $[ZH08, Zha10]$ and the Restricted Eigenvalue (RE) condition $[BRT09]$. Under both conditions, if the tuning parameter of the Lasso is large enough then the squared risk $\lambda$ for $x \in \mathbb{R}^p$ results. Throughout the rest of this section, denote by $s_0 = |\beta|_0$ the number of nonzero coefficients, or sparsity, of the unknown coefficient vector $\beta$.

The Sparse Riesz Condition (SRC) $[ZH08, Zha10]$ on the design $X$ holds if for certain positive reals $\{c_*, c^*\}$,

$$
(4.9) \quad c_* \|u\|^2 \leq \|Xu\|^2/n \leq c^* \|u\|^2 \quad \forall u \in \mathbb{R}^p : |\text{supp}(u) \setminus S| \leq (c^*/c_* - 1)s_0,
$$

where $S$ denotes the support of $\beta$ and $s_0 = |S|$. Let $c_*(d) = \min\{\|Xu\|^2/n : ||u|| = 1, ||u||_0 = d\}$ and $c^*(d) = \max\{\|Xu\|^2/n : ||u|| = 1, ||u||_0 = d\}$ be bounds for the sparse eigenvalues of the Gram matrix $X^T X/n$. Given $d$, the SRC can be viewed as a sparsity condition on $\beta$ as it holds when $||\beta||_0 \leq dc_*(d)/c^*(d)$. When $X$ has iid $N(0, \Sigma)$ rows, we may take $d = a_1 n/\log p$ such that $c_*(d) = (1 - a_2)\phi_{\min}(\Sigma)$ and $c^*(d) = (1 + a_2)\phi_{\max}(\Sigma)$ are valid bounds for the sparse eigenvalues with probability $1 - e^{-a z^2}$ for some small positive constants $a_1$ and $a_2$ $[ZH08]$.

A bound on $E[|\hat{S}|]$ can be obtained under the (SRC) as follows. Let $P_A$ be the orthogonal projection onto the span of the columns of $X_A$ for any $A \subset [p]$. Then, by $[Zha10, \text{Lemma 1 (ii)}]$ with $d^* = (c^*/c_*)s_0$, $K^* = c^*/c_* - 1$, $m = m^* = [s_0(c^*/c_*) - 1]$ and $\alpha = 1/2$, on the event

$$
(4.10) \quad \lambda \geq 2\sqrt{c^*} \max_{A \subset [p]: |A \setminus S| = m} \|P_A - P_S\|\varepsilon\|/\sqrt{nm},
$$

we have $|\hat{S} \setminus S| \leq m$. For each $A$ with $|A \setminus S| \leq m$, we have $P(||(P_A - P_S)\varepsilon|| > \sigma\sqrt{m} + \sigma\sqrt{2x}) \leq e^{-x}$. By the union bound over all possible $(p - s_0) \leq m \log (p\sqrt{m})$ sets $A$, we get

$$
P \left( \max_{A \subset [p]: |A \setminus S| = m} \|P_A - P_S\|\varepsilon\|/\sqrt{nm} > \sigma(1 + \sqrt{2x + 2\log(ep/m)}) \right) \leq e^{-x}.
$$

With $x = \log p$, this implies that (4.10) holds with probability at least $1 - 1/p$ for

$$
(4.11) \quad \lambda = 2\sqrt{c^*}\sigma(1 + 2\sqrt{\log(ep/m)}).
$$

If $\Omega$ denotes this event of probability at least $1 - 1/p$, then

$$
E[|\hat{S}|] \leq s_0 + m + E[I_{\Omega^c} ||\hat{S}||] \leq s_0 + m + 1 = (c^*/c_*)s_0 + 1.
$$
Combined with Theorem 4.3, this provides a bound on the variance of $|\hat{S}|$.

The expectation $\mathbb{E}[|\hat{S}|]$ can also be bounded from above if both Assumption 4.1 and the Restricted Eigenvalue (RE) condition [BRT09] hold.

**Theorem 4.5.** Consider the linear model (4.1) with $\varepsilon \sim N(0, \sigma^2 I_n)$ and $s_0 = \|\beta\|_0$. Let $\tau, \gamma > 0$, $\omega = \sigma(1+\tau)/\sqrt{n}$ and $\hat{\beta}_\text{lasso}$ be as in (4.2) with

$$\lambda = \sigma(1 + \tau)(1 + \gamma)\sqrt{(2/n) \log(ep/(s_0 \lor 1))}. \tag{4.12}$$

Assume that the columns of $X$ are normalized such that $\max_{j \in \beta} \|X e_j\|^2 \leq n$. Let $\hat{S}$ be the support of $\hat{\beta}_\text{lasso}$. Then the Lasso satisfies

$$\mathbb{E} \left[ 2\tau e^\top X (\hat{\beta}_\text{lasso} - \beta) + \|X (\hat{\beta}_\text{lasso} - \beta)\|^2 \right]/n \leq \frac{s_0 (\lambda^2 + \omega^2) + (s_0 \lor 1) \omega^2 + \omega^2/2}{\text{RE}^2(S, c_0)},$$

where $\text{RE}(S, c_0) = \inf_{u \in \mathbb{R}^p : \|u\|_1 \leq c_0 \sqrt{n} \|\sqrt{\|u\|} \mathbb{E}[(X u)/\|u\|]}} (n^{-1/2}) \|\mathbb{E} X u/\|u\| \|$ and $S$ is the support of $\beta$, provided that $c_0 \geq \gamma^{-1} \sqrt{2(1 + 2\omega^2/\lambda^2)}$, e.g. $c_0 = 2/\gamma$. If in addition Assumption 4.1 holds, then

$$\mathbb{E} \left[ |\hat{S}| + \|X (\hat{\beta}_\text{lasso} - \beta)\|^2/(2\sigma^2 \tau) \right] \leq \left( \sqrt{\tau} + 1/\sqrt{\tau} \right)^2 \left( \frac{(1 + \gamma) \{ s_0 \log(ep/(s_0 \lor 1)) + (s_0 \lor 1) \}}{\text{RE}^2(S, 2/\gamma)} + \frac{1}{4} \right). \tag{4.13}$$

The proof of Theorem 4.5 is given in Appendix C. The Gaussian concentration theorem is used in [BT17, BLT18] to obtain bounds on $\mathbb{E}[\|X (\hat{\beta}_\text{lasso} - \beta)\|^2]$ as well as higher order moments of the squared risk; similar arguments are used to derive Theorem 4.5. If $X$ satisfies Assumption 4.1 then $\mathbb{E} [e^\top X (\hat{\beta}_\text{lasso} - \beta)] = \mathbb{E} [|\hat{S}|]$, so that the argument leads to (4.13). Informally, this implies $\mathbb{E} [|\hat{S}|] \lesssim 1 + s_0 \log(ep/(s_0 \lor 1))$ up to a multiplicative constant that depends only on $\gamma, \tau$ and the restricted eigenvalue. To our knowledge, this bound on the size of the model selected by the Lasso under the RE condition is new. Previous upper bounds of the form $|\hat{S}| \lesssim s_0$ require that both maximal and minimal sparse eigenvalues of $X^\top X/n$ are bounded away from 0 and $+\infty$, cf. [ZH08], [Zha10, Lemma 1], [BRT09, (7.9)], [BCW14, Theorem 3] among others. The major difference between such conditions and the RE condition is that the RE condition does not require any bounds on the maximal sparse eigenvalues of $X^\top X/n$. Inequality (4.13) reveals that the RE condition is sufficient to control $\mathbb{E}[|\hat{S}|]$ by $s_0$ times a logarithmic factor. Under the RE condition, assumptions on the maximal sparse eigenvalues of $X^\top X/n$ are unnecessary to control $\mathbb{E}[|\hat{S}|]$.

The discussions above under the SRC or the RE condition yield the following bounds on the variance of $|\hat{S}|$.

**Corollary 4.6.** Let the setting and the assumptions of Theorem 4.3 be fulfilled. Let $s_0 = \|\beta\|_0$.

(i) If $\lambda$ is as in (4.12) for some $\gamma, \tau > 0$ and $\max_{j=1,\ldots,p} \|X e_j\|^2 \leq n$ then

$$\mathbb{E}[|\hat{S}|] \leq \frac{C(s_0 \lor 1)}{\text{RE}^2(S, 2/\gamma)} \log \left( \frac{ep}{1 \lor s_0} \right)^2.$$
where $C = C(\gamma, \tau) > 0$ and $c_0$ only depends on $\gamma, \tau$ and \text{RE}(S, c_0)$ is the constant defined in Theorem 4.5.

(ii) Assume that $X$ satisfies the SRC condition (4.9) for some positive reals $\{c^*, c_\ast\}$. If $\lambda$ is as in (4.11) then

$$\text{Var}[|\hat{S}|] \leq C^\prime \left( 1 + \left( s_0 (c^*/c_\ast) + 1 \right) \log \left( \frac{ep}{s_0 (c^*/c_\ast) + 1} \right) \right)$$

for some absolute constant $C^\prime > 0$.

In other words, under the SRC or the RE condition on the design matrix $X$, the standard deviation of the size of the model $|\hat{S}|$ is smaller than $\sqrt{s_0}$ up to logarithmic factors. The bound is sharper under the SRC by a logarithmic factor.

Note that the above techniques are not specific to the Lasso. For instance, any estimator defined as the solution of a convex optimization problem of the form

$$(4.14) \quad \hat{\beta} = \arg \max_{b \in \mathbb{R}^p} \|Xb - y\|^2 / 2n + h(b)$$

for some proper convex function $h$ is such that the map $f : \varepsilon \to X\hat{\beta}$ is 1-Lipschitz, see for instance [BT17]. Hence the partial derivatives of $f(\varepsilon) = X(\hat{\beta} - \beta)$ exist almost surely and the bound

$$E[(\sigma^2 \text{div } f(\varepsilon) - \varepsilon^\top f(\varepsilon))^2] \leq \sigma^2 E\|X(\hat{\beta} - \beta)\|^2 + \sigma^4 E\|\nabla f(\varepsilon)\|^2_F$$

(4.15)

holds by Theorem 1.1 and the fact that the operator norm of $\nabla f(\varepsilon)$ is bounded by 1 thanks to the 1-Lipschitzness of $f$. Similarly, the bound

$$\text{Var}[\text{div } f] = E[(\text{div } f(\varepsilon) - E[\text{div } f(\varepsilon)])^2]$$

(4.16)

$$\leq E\|\nabla f(\varepsilon)\|^2_F + E\|\nabla f(\varepsilon)\varepsilon\|^2 / \sigma^2$$

$$\leq 2n$$

holds by Proposition 3.1.

5. SURE for SURE in high-dimensional linear regression

Again we consider linear regression with deterministic design.

The Lasso

We have derived in the previous section the gradient of $\varepsilon \to X\hat{\beta}^{(\lambda)}_{\text{lasso}}$ almost everywhere under Assumption 4.1. It is instructive to use these calculations to make explicit SURE for SURE from Section 2 in the Lasso case. With the notation of Section 2, consider the sequence model $y = \mu + \varepsilon$ where
\( \varepsilon \sim N(0, \sigma^2 \mathbf{I}_n) \) and the unknown mean is \( \mu = \mathbf{X}\beta \), as in the linear model (4.1). Set \( \hat{\mu}(y) = \mathbf{X}\hat{\beta}^{(\lambda)} \) with the Lasso estimator (4.2). Under Assumption 4.1, \( |\hat{S}| = \text{div} \hat{\mu} = \text{trace}((\nabla \hat{\mu})^2) \) by Proposition 4.2, so that Stein’s Unbiased Risk Estimate is

\begin{equation}
\text{SURE} = \| \mathbf{y} - \mathbf{X}\hat{\beta}^{(\lambda)} \|^2 + \sigma^2(2|\hat{S}| - n)
\end{equation}

as in (2.8). Moreover, by Theorem 2.1, SURE for SURE in the Lasso case is

\begin{equation}
\hat{\mu}^{(\lambda)} = 4\sigma^2\| \mathbf{y} - \mathbf{X}\hat{\beta}^{(\lambda)} \|^2 + \sigma^4(4|\hat{S}| - 2n)
\end{equation}

which is an unbiased estimator of \( R_{\text{SURE}} = \mathbb{E}[(\text{SURE} - \| \mathbf{X}(\hat{\beta}^{(\lambda)} - \beta) \|^2)^2] \). The identity \( \mathbb{E}[\hat{R}_{\text{SURE}}] = R_{\text{SURE}} \) for the Lasso appeared previously in \([DKF+13]\).

Let \( \{\tau, \gamma, \lambda\} \) be as in Theorem 4.5 and define \( C_{\tau, \gamma} = \max(1, 2\tau)(\sqrt{\tau} + 1/\sqrt{\tau})^2(4(1 + \gamma)^2 + 5) \). Under the conditions of Theorem 4.5 including Assumption 4.1, (4.13) implies that the right-hand side of (2.10) is bounded by \( \sigma^4 2\nu \epsilon_n^2 \) with \( \epsilon_n^2 = C_{\tau, \gamma}(s_0 \lor 1)\{\log(p/(s_0 \lor 1))\}/\{nR\epsilon^2(\hat{S}, 2/\gamma)\} \), so that

\[ \mathbb{P}\{\text{SURE} - \| \mu - \hat{\mu} \|^2 \leq 1.96\sigma^2\sqrt{2n}\} \approx 95\% \]

by Theorem 2.2 when \( \epsilon_n = o(1) \), with \( v_n^2 = \epsilon_n = \sqrt{\epsilon_n} \), and similarly

\[ \mathbb{P}\{\| \mu - \hat{\mu} \|^2 \leq \text{SURE} + 1.645\sigma^2\sqrt{2n}\} \approx 95\%. \]

For the comparison of two Lasso estimators \( \hat{\beta}^{(\lambda_1)} \) and \( \hat{\beta}^{(\lambda_2)} \) with \( \lambda_1 \neq \lambda_2 \),

\begin{equation}
\text{SURE}^{(\text{diff})} = \| \mathbf{X}\hat{\beta}^{(\lambda_1)} - \mathbf{y} \|^2 - \| \mathbf{X}\hat{\beta}^{(\lambda_2)} - \mathbf{y} \|^2 + 2\sigma^2(\| \hat{S}^{(\lambda_1)} \| - \| \hat{S}^{(\lambda_2)} \|)
\end{equation}

provides \( \mathbb{E}[\text{SURE}^{(\text{diff})}] = \mathbb{E}[\| \mathbf{X}(\hat{\beta}^{(\lambda_1)} - \beta) \|^2 - \| \mathbf{X}(\hat{\beta}^{(\lambda_2)} - \beta) \|^2] \), and

\begin{equation}
\hat{\mu}^{(\lambda_1, \lambda_2)} = 4\sigma^2\| \mathbf{X}(\hat{\beta}^{(\lambda_1)} - \beta) \|^2 + 4\sigma^4 \text{trace} \left( (\mathbf{P}_{\hat{S}^{(\lambda_1)}} - \mathbf{P}_{\hat{S}^{(\lambda_2)}})^2 \right)
\end{equation}

provides \( \mathbb{E}[\hat{\mu}^{(\lambda_1, \lambda_2)}] = \mathbb{E}[\| \mathbf{X}(\hat{\beta}^{(\lambda_1)} - \beta) \|^2 - \| \mathbf{X}(\hat{\beta}^{(\lambda_2)} - \beta) \|^2] \), where \( \hat{S}^{(\lambda_1)} = \text{supp}(\hat{\beta}^{(\lambda_1)} \mathbf{X}_A) \) and \( \mathbf{P}_A \) is the projection onto the column space of \( \mathbf{X}_A \).

**Elastic Net**

Similar computations can be carried out for other estimators such as the Group Lasso or the Elastic Net. For instance, consider the Elastic Net estimator \( \hat{\beta}_{\text{EN}} \) defined as the solution of the optimization problem

\begin{equation}
\hat{\beta}_{\text{EN}} = \arg \max_{\mathbf{b} \in \mathbb{R}^p} \| \mathbf{X}\mathbf{b} - \mathbf{y} \|^2 / 2n + \lambda\| \mathbf{b} \|_1 + \gamma\| \mathbf{b} \|^2 / 2.
\end{equation}
where $\lambda, \gamma > 0$. Set $\hat{\mu}(y) = X\hat{\beta}_{\text{EN}}$. Then by similar arguments as in the Lasso case, the KKT conditions of the optimization problem (5.5) hold strictly almost everywhere in $y$. By differentiating the KKT conditions on a neighbourhood where the KKT conditions hold strictly (the details are omitted), the gradient of $y \rightarrow \hat{\beta}_{\text{EN}}$ is given by

$$\nabla \hat{\beta}_{\text{EN}} = \left( (\gamma I_S + X_S^T X_S)^{-1} X_S^T \right)_{p \times n},$$

and the gradient of $y \rightarrow X\hat{\beta}_{\text{EN}}$ is given by

$$\nabla (X\hat{\beta}_{\text{EN}}) = X\hat{\beta}_{\text{EN}} = X(S\gamma I_S + X_S^T X_S)^{-1}X_S^T.$$

where $\hat{S} \subset [p]$ is the set of nonzero coefficients of $\hat{\beta}_{\text{EN}}$. Stein’s Unbiased Risk Estimate is given by

$$\text{SURE} = ||y - X\hat{\beta}_{\text{EN}}||^2 + 2\sigma^2 \text{trace} \left[ X\hat{\beta}_{\text{EN}} - X\hat{\beta}_{\text{EN}} \right] - \sigma^2 n,$$

and SURE for SURE in the Elastic Net case is

$$\hat{R}_{\text{sure}} = 4\sigma^2 ||X\hat{\beta}_{\text{EN}} - y||^2 + 4\sigma^4 ||X\hat{\beta}_{\text{EN}}||^2 / \sigma^2.$$

By Theorem 2.1, this is an unbiased estimate of $\mathbb{E}[(\text{SURE} - ||X(\beta - \hat{\beta}_{\text{EN}})||^2)^2]$. SURE for SURE $\hat{R}_{\text{sure}}$ for the difference between two E-nets or between the Lasso and E-net can be derived similarly as in (5.4). We omit the details.

**Remark 5.1.** Let $\hat{d} = \text{trace}[X_S^T (\gamma I_S + X_S^T X_S)^{-1}X_S^T]$. Since $\hat{d}$ is the divergence of the function $\varepsilon \rightarrow X(\hat{\beta}_{\text{EN}} - \beta)$, Proposition 3.1 implies that

$$\text{Var}[\hat{d}] \leq \mathbb{E}[||X_S^T (\gamma I_S + X_S^T X_S)^{-1}X_S^T||_F^2] + \mathbb{E}[||X_S^T (\gamma I_S + X_S^T X_S)^{-1}X_S^T\varepsilon||^2] / \sigma^2.$$

If $P_S$ is the orthogonal projection onto the span of the columns of $X_S$ then the second term satisfies $\mathbb{E}[||X_S^T (\gamma I_S + X_S^T X_S)^{-1}X_S^T\varepsilon||^2] / \sigma^2 \leq \mathbb{E}[(||P_S\varepsilon||^2 / \sigma^2].$

Since (4.8) holds for any random $S$, we obtain

$$\text{Var}[\hat{d}] \leq \mathbb{E}[||X_S^T (\gamma I_S + X_S^T X_S)^{-1}X_S^T ||_F^2] + \mathbb{E}[2|\tilde{S}| + 4|\tilde{S}| \log(ep/\{1 \lor |\tilde{S}|\})] \leq 3\mathbb{E}[|\tilde{S}|] + 4\mathbb{E}[|\tilde{S}| \log(ep/\{1 \lor |\tilde{S}|\})].$$

6. **De-biasing nonlinear estimators in linear regression**

Consider a linear regression model

$$y = X\beta + \varepsilon$$
with an unknown target vector $\beta \in \mathbb{R}^p$, a Gaussian noise vector $\varepsilon \sim N(0, \sigma^2 I_n)$, and a Gaussian design matrix $X \in \mathbb{R}^{n \times p}$ with iid $N(0, \Sigma)$ rows. We assume that the covariance matrix $\Sigma$ is known and invertible.

This section explains how to construct an estimate of a linear contrast

$$\theta = \langle a_0, \beta \rangle$$

(6.2)

from an initial estimator $\hat{\beta}$. Here and in the sequel, $\langle \cdot, \cdot \rangle$ denotes the scalar product in $\mathbb{R}^n$. Define

$$u_0 = \Sigma^{-1} a_0 / \langle a_0, \Sigma^{-1} a_0 \rangle, \quad z_0 = X u_0 \quad Q_0 = I_{p \times p} - u_0 a_0^\top$$

(6.3)

and assume for simplicity that $a_0$ is normalized such that

$$\langle a_0, \Sigma^{-1} a_0 \rangle = 1.$$

By definition of $u_0$, $z_0 \sim N(0, I_n)$ and $z_0$ is independent of $X Q_0$.

We assume throughout this section that we are given an initial estimator $\hat{\beta}$.

Since $X = z_0 a_0^\top + X Q_0$ and the two random vectors $z_0, X Q_0$ are independent, we view $\hat{\beta}$ as a function with three arguments $\hat{\beta}(y, z_0, X Q_0)$ and we assume that the partial derivatives $(\partial / \partial y) \hat{\beta}$ and $(\partial / \partial z_0) \hat{\beta}$ exist almost everywhere.

The estimator $\hat{\beta}$ provides an initial estimate of the unknown parameter $\theta$ (6.2) by the plug-in $\langle a_0, \hat{\beta} \rangle$. However, this estimator may be biased, and a first attempt to fix the bias is the following one-step MLE correction in the direction given by the one dimensional model

$$\{ \hat{\beta} + t u_0, t \in \mathbb{R} \}$$

(6.4)

$$\langle a_0, \hat{\beta} \rangle + \frac{\langle z_0, y - X \hat{\beta} \rangle}{\| z_0 \|^2}.$$

Variants of the above de-biasing scheme have been considered in [Zha11, ZZ14, BCH14, Büh13, VdGBRD14, JM14, JM18], among others. We multiply by $\| z_0 \|^2$ to avoid random denominators; the random variables $\| z_0 \|^2$ is chi-square with $n$ degrees of freedom, equal to $n + O(\sqrt{n})$ with overwhelming probability so that $\| z_0 \|^2 \approx n$ describes the number of observations.

When constructing the estimator (6.4) above by the one-step MLE correction, the statistician hopes that the quantity

$$\frac{\| z_0 \|^2 \langle a_0, \hat{\beta} - \beta \rangle + \langle z_0, y - X \hat{\beta} \rangle}{\sigma \sqrt{n}}$$

(6.5)

is asymptotically standard normal; this is the ideal result to construct confidence intervals for the unknown parameter (6.2) at the $\sqrt{n}$-adjusted rate.

By simple algebra we have

$$\frac{\| z_0 \|^2 \langle a_0, \hat{\beta} - \beta \rangle + \langle z_0, y - X \hat{\beta} \rangle}{\sigma \sqrt{n}} = \frac{z_0^\top \varepsilon}{\sigma \sqrt{n}} - \frac{z_0^\top X Q_0 (\hat{\beta} - \beta)}{\sigma \sqrt{n}}.$$

(6.6)
The random variable \( (z_0^\top \epsilon)/(\sigma \sqrt{n}) \) is asymptotically standard normal. It remains to understand whether the random variable
\[
\frac{z_0^\top XQ_0(\hat{\beta} - \beta)}{\sigma \sqrt{n}}
\]
is negligible or not, compared to \( (z_0^\top \epsilon)/(\sigma \sqrt{n}) \). For the derivation below, we will argue conditionally on \((\epsilon, XQ_0)\). We also define \( f : \mathbb{R}^n \to \mathbb{R}^n \) by
\[
f(z_0) = XQ_0(\hat{\beta} - \beta).
\]
The quantity (6.7) is still biased and Stein’s formula lets us quantify the remaining bias exactly as follows
\[
E \left[ \frac{z_0^\top XQ_0(\beta - \beta)}{\sigma \sqrt{n}} \middle| XQ_0, \epsilon \right] = E \left[ \frac{z_0^\top f(z_0)}{\sigma \sqrt{n}} \middle| XQ_0, \epsilon \right] = E \left[ \frac{\text{div} f(z_0)}{\sigma \sqrt{n}} \middle| XQ_0, \epsilon \right].
\]
The partial derivatives \( (\partial/\partial z_0) f_i \) where \( f_i \) is the \( i \)-th coordinate of \( f \) can be computed by the chain rule
\[
\frac{\partial f_i}{\partial z_{0i}} = e_i^\top XQ_0 \left[ \langle a_0, \beta \rangle \frac{\partial \hat{\beta}}{\partial y_i} + \frac{\partial \hat{\beta}}{\partial z_{0i}} \right].
\]
Hence, the divergence of \( f \), which quantifies the remaining bias in (6.7) is
\[
\text{div} f = \langle a_0, \beta \rangle \hat{\nu} + \hat{B},
\]
where
\[
\hat{\nu} = \text{trace} \left( XQ_0 \frac{\partial \hat{\beta}}{\partial y} \right), \quad \hat{B} = \text{trace} \left( XQ_0 \frac{\partial \hat{\beta}}{\partial z_0} \right).
\]
It will be convenient to write \( \text{div} f \) instead as
\[
\text{div} f = \langle a_0, \beta - \hat{\beta} \rangle \hat{\nu} + \hat{A} \quad \text{where} \quad \hat{A} = \hat{B} + \langle a_0, \hat{\beta} \rangle \hat{\nu}.
\]
The quantities \( \hat{\nu}, \hat{A} \) and \( \hat{B} \) above can be constructed from the observed data since they only depend on \( X, Q_0, y \) and the derivatives of \( \hat{\beta} \). However, the quantity \( \langle a_0, \beta \rangle \) is unknown; it is the parameter of interest that we wish to estimate. This motivates the estimator of \( \theta = \langle a_0, \beta \rangle \) defined by
\[
\hat{\theta} = \langle a_0, \hat{\beta} \rangle + \frac{z_0^\top (y - X\hat{\beta}) + \hat{A}}{\|z_0\|^2 - \hat{\nu}}
\]
with \( \hat{A} \) and \( \hat{\nu} \) as in (6.9) and (6.10). This estimator \( \hat{\theta} \) is constructed so that the random variable
\[
\frac{\|z_0\|^2 - \hat{\nu})(\hat{\theta} - \theta)}{\sigma \sqrt{n}} - \frac{z_0^\top \epsilon}{\sigma \sqrt{n}}
\]
\[ \hat{A} + \hat{\nu}\langle a_0, \beta - \hat{\beta} \rangle - z_0^\top f(z_0) \]

(6.12)

\[ \frac{\text{div} f(z_0) - z_0^\top f(z_0)}{\sigma \sqrt{n}} \]

is exactly mean-zero by the first-order Stein’s formula (1.1). Furthermore, the variance of this random variable can be expressed exactly in terms of the derivatives of \( f \) thanks to the Second Order Stein formula (1.4). Similarly, the above equality can be rewritten as

\[ (\|z_0\|^2 - \hat{\nu})(\hat{\theta} - \theta) = \text{div} f(z_0) - z_0^\top (f(z_0) - \varepsilon), \]

(6.13)

which is equal to \( \text{div} g(z_0) - z_0^\top g(z_0) \) for \( g(x) = f(x) - \varepsilon \) since \( f \) and \( g \) have the same divergence. Hence the random variable (6.13) is exactly mean zero by the first-order Stein’s formula, and the Second Order Stein formula (1.4) provides an exact identity for its variance. We gather the above derivation in the following theorem.

**Theorem 6.1.** Let \( \hat{\beta} \) be an estimator such that, if we write it as a function \( \hat{\beta}(y, z_0, XQ_0) \), all partial derivatives of the function \( XQ_0 \hat{\beta} \) with respect to \( y \) and \( z_0 \) exist and are in \( L_2 \). Define the estimator \( \hat{\theta} \) of \( \theta = \langle a_0, \beta \rangle \) by (6.11), with \( \hat{\nu} \) and \( \hat{A} \) as in (6.9) and (6.10). Then the random variable

\[ \frac{(\|z_0\|^2 - \hat{\nu})(\hat{\theta} - \theta)}{\sigma \sqrt{n}} - \frac{z_0^\top \varepsilon}{\sigma \sqrt{n}} \]

(6.14)

is exactly mean-zero and its variance is exactly equal to

\[ \frac{1}{n\sigma^2} \left( \mathbb{E} \left[ \|XQ_0(\hat{\beta} - \beta)\|^2 \right] + \mathbb{E} \left[ \text{trace}((\nabla f(z_0))^2) \right] \right) \]

(6.15)

where \( f(z_0) = XQ_0(\hat{\beta} - \beta) \). Furthermore, the random variable \( (\|z_0\|^2 - \hat{\nu})(\hat{\theta} - \theta) \) is also mean-zero with variance equal to

\[ \mathbb{E} \left[ \|\varepsilon - XQ_0(\hat{\beta} - \beta)\|^2 \right] + \mathbb{E} \left[ \text{trace}((\nabla f(z_0))^2) \right]. \]

Theorem 6.1 is a direct consequence of the Second Order Stein formula (1.4) and the analysis summarized in (6.12).

The random variable \( \frac{z_0^\top \varepsilon}{(\sigma \sqrt{n})} \) is asymptotically standard normal. Indeed, if \( Z_n = \frac{\varepsilon^\top z_0}{(\sigma \|z_0\|)} \) then \( Z_n \) has standard normal distribution and is independent of \( \|z_0\| \) so

\[ \mathbb{E} \left[ \left( \frac{z_0^\top \varepsilon}{\sigma \sqrt{n}} - Z_n \right)^2 \right] = \mathbb{E} \left[ Z_n^2 \right] \mathbb{E} \left[ \left( \frac{\|z_0\|}{\sqrt{n}} - 1 \right)^2 \right] \]

(6.17)

\[ = 2(n - \sqrt{n}\mathbb{E}[\|z\|])/n \]

\[ \leq 2(1 - (1 - 1/n)^{1/2}) \]

\[ \leq 2/n. \]
For the last two inequalities, we used that $\sqrt{n-1} \leq E\|z\|$, which holds thanks to the Gaussian Poincaré inequality $E[\|z_0\|^2] = n \leq (E\|z\|)^2 + 1$, and the elementary inequality $1 - \sqrt{1-x} \leq x$ for all $x \in (0, 1)$.

It follows that the random variable (6.14) converges to 0 in $L^2$ if and only if (6.15) converges to 0. If this is the case, the random variable

$$\frac{(\|z_0\|^2 - \hat{\nu})(\hat{\theta} - \theta)}{\sigma \sqrt{n}}$$

converges in $L^2$ to a standard normal.

The above construction provides a general scheme to de-bias an initial estimator $\hat{\beta}$ for the estimation of a linear contrast $\theta = \langle a_0, \beta \rangle$ when the covariance matrix $\Sigma$ is known.

A notable feature of the above result is the random variable $\hat{\nu}$ whose role is to adjust multiplicatively the random variable $(\hat{\theta} - \theta)$ so that $(\|z_0\| - \hat{\nu})(\hat{\theta} - \theta)$ is exactly mean-zero. This adjustment accounts for the degrees-of-freedom of the initial estimator $\hat{\beta}$. We refer to our concurrent paper [BZ18] for theory of degrees-of-freedom adjustment in semi-parametric inference about a preconceived one-dimensional parameter $\theta = \langle a_0, \beta \rangle$.

7. Monte Carlo approximation of divergence

The Second Order Stein formula and the techniques presented in this paper also suggest a Monte Carlo method to approximate the divergence in the general case.

Suppose we are interested in the approximation of $\text{div } f(y)$ at the currently observed vector $y$. Assume that the function $f(\cdot)$ is 1-Lipschitz and its value can be quickly computed for small perturbations of $y$, say, $f(y + az)$ for small $az$. When $f(y) = X\beta$ in the linear model with a convex regularized least-squares estimator $\hat{\beta}$, the 1-Lipschitz condition holds automatically [BT17], and if $\hat{\beta}(y)$ has already been computed by an iterative algorithm, the computation of $\hat{\beta}(y + az)$ would typically be fast as one can use $\hat{\beta}(y)$ as a starting point (“warm start”) to compute $\hat{\beta}(y+az)$. Next, with the 1-Lipschitz function $h(z) = a^{-1}(f(y + az) - f(y))$ and $z \sim N(0, I_n)$ independent of $y$, if $E_z$ denotes the expectation with respect to $z$ conditionally on $y$, we have by the Gaussian Poincaré inequality that

$$E_z[(z^\top h(z) - D_0)^2] \leq E_z[\|h(z) + \nabla h(z)z\|^2] \leq 4n$$

with $D_0 = E_z \text{div } h(z) = \int_{\mathbb{R}^n}(2\pi)^{-n/2}e^{-\|x\|^2/2} \text{div } f(y + ax)dx$. Hence If we compute $f(y + az_j)$ at $m$ independent Gaussian perturbations $z_1, ..., z_m \sim N(0, I_n)$, inequality

$$E\left[\left(\frac{1}{m} \sum_{j=1}^m z_j^\top h(z_j) - D_0\right)^2\right] \leq \frac{4n}{m}$$
holds. Here the function $y \rightarrow \text{div}(y)$ is locally integrable and almost surely bounded by $n$ thanks to the Lipschitzness of $f$. For almost every $y$, $y$ is a Lebesgue point of $\text{div} f$ so that $D_0 \rightarrow \text{div}(y)$ as $a \rightarrow 0$ by the Lebesgue differentiation theorem. Hence $D_0 \approx \text{div}(y)$ for small enough $a > 0$ and $\frac{1}{m} \sum_{j=1}^{m} z_j h^\top h(z_j)$ provides a useful approximation of the divergence thanks to $|\frac{1}{m} \sum_{j=1}^{m} z_j h(z_j) - D_0| = O_p(\sqrt{n/m})$ where $O_p(\cdot)$ is with respect to the probability distribution of $z_1, \ldots, z_m$. For large $m$, more precise results can be obtained by the Central Limit Theorem.

We apply this probabilistic procedure to the Elastic-Net and Singular Value Thresholding (SVT) [CSLT13] for which explicit formulae for $\hat{df} = \text{trace}[\nabla f(y)]$ are available. Indeed, the gradient $\nabla f(y)$ for the elastic net is given in Section 5 of the submission, and [CSLT13, Equation (1.8)] provides an explicit formula for the degrees-of-freedom of SVT with tuning parameter $\lambda$: If $\hat{B}$ soft-thresholds the singular values of an observed matrix $Y \in \mathbb{R}^{m \times n}$ with tuning parameter $\lambda$, the divergence of $\hat{B}$ with respect to $Y$ is given by

$$
\hat{d}f = \sum_{i=1}^{\sqrt{n}} \{I(\sigma_i > \lambda) + |q - n|(1 - \lambda/\sigma_i)_+\} + 2 \sum_{i=1}^{\sqrt{n}} \sum_{j=1, j \neq i}^{\sqrt{n}} \frac{\sigma_i(\sigma_i - \lambda)_+}{\sigma_i^2 - \sigma_j^2}
$$

where $\sigma_1, \ldots, \sigma_{\sqrt{n}}$ are the singular values of $Y$. We then compare on simulated data this exact formula to the above random approximation scheme. For $n = 100, q = 101, \lambda = 10.0$, with $Y$ being the sum of standard normal noise plus a ground-truth rank-10 matrix, we apply the above algorithm with $m$ perturbations $(Y + aZ_j)_{j=1, \ldots, m}$ for various values of $m$ and compute $\hat{d}f_{\text{approx}} = \frac{1}{m} \sum_{j=1}^{m} \text{trace}(Z_j h(Z_j))$ where $h(Z_j) = a^{-1}(\hat{B}(Y + aZ_j) - B(Y))$ with $a = 0.0001$ as explained above. The results are in Figure 1.

In the case of the Elastic-Net with $\ell_1$ parameter $\lambda > 0$ and $\ell_2$ parameter $\gamma > 0$, we draw a similar experiment with the exact formula for degrees-of-freedom being given by $\hat{d}f = \text{trace}[X_S(X_S^\top X_S + n\gamma)^{-1}X_S^\top]$. With $n = 500, p = 400$, and again $a = 0.001$, $X$ having independent symmetric $\pm 1$, $\lambda = 0.8\sqrt{4\log(p)/n}$, $\gamma = 0.2\sqrt{4\log(p)/n}$, we obtain the standard errors and boxplots in Figure 2.

The experiments show that the above approximation scheme provides good approximations in these special cases where exact formula are available. Hence it could also be useful for estimators where no exact formula is available for the divergence.

Appendix A: Non-smooth functions

Proof of Theorem 1.1 (ii) for Lipschitz functions. If $f$ is Lipschitz, then each component $f_i$ of $f$ is also Lipschitz. Hence $f_i$ belongs to the space $W^{1,2}(\gamma_n)$ defined above (1.3) and the weak gradient of $f_i$ is equal almost everywhere to its gradient in the sense of Frechet differentiability (cf., e.g. [Eva97, Theorem 4-6 pp 279-281]). Thus (ii) is a consequence of (iii). □

Proof of Theorem 1.1 (iii) for $f_i \in W^{1,2}(\gamma_n)$. Since $W^{1,2}(\gamma_n)$ is the completion with respect to the norm (1.3) of the space $C_0^\infty(\mathbb{R}^n)$ of smooth functions with
compact support, for each coordinate $i = 1, \ldots, n$ there exists a sequence $(g_i, q)_{q \geq 1}$ of $C^\infty_0(\mathbb{R}^n)$ functions with $\max_{i=1, \ldots, n} E[(f_i - g_i, q) + \|\nabla f_i - \nabla g_i, q\|^2] \to 0$ as $q \to +\infty$. Define $g_0 : \mathbb{R}^n \to \mathbb{R}^n$ as the function with components $g_1, q, \ldots, g_n, q$. 

By considering a subsequence, we may assume that for all $q \to +\infty$.

Cantelli lemma. Let $X$.

This completes the proof.

Appendix B: Strictness of the KKT condition

Proof of Proposition 4.1. Assume that $X_B$ has rank strictly less than $|B|$. Then there must exist some $j \in B$ and $A \subseteq B \setminus \{j\}$ with $x_j = \sum_{k \in A} \gamma_k x_k$ and $\text{rank}(X_A) = \min(|A|, n)$. By the definition of $B$

$$\lambda n \delta_j = x_j^\top (y - \hat{X} \hat{\beta}_\text{lasso}^\lambda) = \lambda n \sum_{k \in A} \gamma_k \delta_k$$

where $\delta_k = x_k^\top (y - \hat{X} \hat{\beta}_\text{lasso}^\lambda)/(\lambda n) \in \{-1, 1\}$. This is impossible by Assumption 4.1 on $X$. Hence $X_B$ has rank $|B|$. For the uniqueness, consider
two Lasso solutions $\hat{\beta}^{(\lambda)}_{lasso}$ and $\hat{b}$ of (4.2). It is easily seen that $X\hat{\beta}^{(\lambda)}_{lasso} = X\hat{b}$ by the strict convexity of the squared loss in $Xb$ in (4.2); actually the function $y \to X\hat{\beta}^{(\lambda)}_{lasso}$ is 1-Lipschitz (cf. for instance [BLT18]). Furthermore both $\hat{\beta}^{(\lambda)}_{lasso}, \hat{b}$ must be supported on $B$. Hence $X_B(\hat{\beta}^{(\lambda)}_{lasso})_B = X_B \hat{b}_B$ which implies that $\hat{b}_B = (\hat{\beta}^{(\lambda)}_{lasso})_B$ because $X_B$ has rank $|B|$.

It remains to show that for any $j \notin \hat{S}$, the KKT condition on coordinate $j$ holds strictly with probability one. As $X_B$ has rank $|B|$, it suffices to consider the case of $|\hat{S}| < n$. By the KKT condition, $(\hat{\beta}^{(\lambda)}_{lasso})_{\hat{S}} = (X_{\hat{S}}^T X_{\hat{S}})^{-1}(X_{\hat{S}}^T y - n\lambda sgn((\hat{\beta}^{(\lambda)}_{lasso})_{\hat{S}}))$. As $P[v^T y = c] = 0$ for all deterministic $v \neq 0$ and real $c$,

$$E\left(\mathbb{P}\left[|y - X_S(X_S^T X_S)^{-1}(X_S^T y - n\lambda u_S)/n| = \pm \lambda |X|\right]\right) = 0$$

for all deterministic $\{S, j, u\}$ satisfying rank$(X_S) = |S| < n$, rank$(X_{S,(j)}) = |S| + 1$ and $u_S \in \{\pm 1\}^S$. Hence, $P[|B| > |\hat{S}|] = 0$, which means that the KKT conditions of $\hat{\beta}^{(\lambda)}_{lasso}$ must hold strictly with probability one. \hfill \qed

Appendix C: Upper bound on the sparsity of the Lasso under the RE condition

Before proving Theorem 4.5 we need the following lemma.

**Lemma C.1.** (i) Let $Z$ be a standard normal random variable. Then,

$$\mathbb{P}[Z > t] \leq \frac{e^{-t^2/2}}{(2\pi t^2 + 4)^{1/2}}, \quad \forall \ t \geq 0,$$

and

$$(C.1) \quad E\left([|Z| - t]^2\right) \leq \frac{4e^{-t^2/2}}{(t^2 + 2)(2\pi t^2 + 4)^{1/2}}, \quad \forall \ t \geq 0.$$

(ii) Let $g_1, ..., g_p$ be centered normal random variables with variance at most $\omega^2$ and let $S \subset [p]$ of size $|S| = s_0$. Then for any $\lambda, \mu \geq 0$

$$E\left[\sum_{j \in S} (g_j - \lambda)^2 + \sum_{j \notin S} (|g_j| - \mu)^2\right] \leq s_0(\lambda^2 + \omega^2) + \frac{4\omega^2(\mu - s_0)e^{-(\mu/\omega)^2/2}}{((\mu/\omega)^2 + 2)(2\pi(\mu/\omega)^2 + 4)^{1/2}}.$$

Furthermore, if $\mu \geq \omega \sqrt{2\{\log((p - s_0)/(s_0 \vee 1))\}^+}$ the right hand side is bounded from above by $s_0(\lambda^2 + \omega^2) + (s_0 \vee 1)\omega^2$.\hfill 

**Remark** Compared with the usual tail probability bounds for standard Gaussian, the upper bounds in Lemma C.1 is sharp at both $t = 0$ and $t \to \infty$.

**Proof.** (i) Let $t > 0$. Let $\varphi(t)$ and $\Phi(t)$ respectively be the density and cumulative distribution function of $Z$. With $u = tx + x^2/2$ and $du = (t + x)dx$,

$$\frac{\Phi(-t)}{\varphi(t)} = \int_0^\infty e^{-tx - x^2/2}dx = \int_0^\infty \frac{e^{-u}du}{(t^2 + 2u)^{1/2}} = \int_0^\infty f_i(u^{-1/2})e^{-u}du,$$
Thus,
\[ f_t(x) = (t^2 + 2/x^2)^{-1/2} = x(t^2 x^2 + 2)^{-1/2} \]
is a concave function of \( x \).

This gives the tail probability bound.

Define \( J_k(t) = \int_0^\infty x^k e^{-x-t^2/(2t^2)} dx \). For the second tail moment, we have \( \mathbb{E}[(|Z| - t)^2] = 2\varphi(t) J_2(t)/t^3 = 2 \Phi(-t) J_2(t)/\{t^2 J_0(t)\} \). As in Proposition 10 (i) in [SZ13] and its proof, we have \( J_2(t)/J_0(t) \leq 1/(1/2 + t^2) \) for \( k \geq 0 \) due to the recursion \( J_{k+1}(t) + t^2 J_{k+2}(t) = (k + 1)J_k(t) \).

(ii) This is a variation of Proposition D.1 in [Bel18] which is sharper for small \( \mu \) thanks to (C.1). By scale invariance we may assume that \( \omega = 1 \). For \( j \in S \) it is clear that \( \mathbb{E}[(g_j - \lambda)^2] \leq \lambda^2 + 1 \). For \( j \notin S \), using that \( g_j \) has variance at most 1 and the monotonicity of the expectation as a function of the variance, the proof is completed by applying the upper bound for \( \mathbb{E}[(|Z| - \mu)^2] \) in Part (i).

Proof of Theorem 4.5. Let \( \mu = (1 + \tau)\sigma \sqrt{2 \log(ep/(s_0 \lor 1))/n} \) and \( \lambda = (1 + \gamma)\mu \). For each \( j \in [p] \) set \( g_j = (\tau + 1)e^T X e_j/n \). By the KKT conditions of the Lasso we have

\[
(\tau e^T X h + \|Xh\|^2)/n \leq g^T h - \lambda\|h_S\|_1 - \lambda \text{sgn}(\beta_S)^T h_S,
\]

where \( h = \hat{\beta}_{\text{lasso}} - \beta \). Define \( T = \{u \in \mathbb{R}^p : \|u_S\|_1 < c_0 \sqrt{s_0 \lor 1}\|u\|\} \) as well as

\[
f_{\lambda,\mu}(\varepsilon) = \sup_{u \in T} \frac{g^T u - \mu\|u_S\|_1 - \lambda \text{sgn}(\beta)^T u_S}{\|u\|},
\]

\[
g_{\lambda,\mu}(\varepsilon) = \sup_{u \notin T, \|X u\| > 0} \frac{(g^T u - \mu\|u_S\|_1 - \lambda \text{sgn}(\beta)^T u_S - \gamma c_0 \sqrt{s_0 \lor 1}\|u\|_1)}{\|X u\|/\sqrt{n}}
\]

where \( a_+ = \max(a,0) \) for any real \( a \). Let \( \Omega \) be the event \( \Omega = \{h \in T\} \) and \( I_\Omega \) be its indicator function. Using the elementary inequality \( 2ab - b^2 \leq a^2 \) we get

\[
(2\tau e^T X h + \|X h\|^2)/n \leq I_\Omega f_{\lambda,\mu}(\varepsilon)^2/\text{RE}(S,c_0)^2 + I_{\Omega^c} g_{\lambda,\mu}(\varepsilon)^2.
\]

We now bound the expectation \( \mathbb{E}[f_{\lambda,\mu}(\varepsilon)^2] \). By simple algebra on each coordinate and the Cauchy-Schwarz inequality,

\[
f_{\lambda,\mu}(\varepsilon)^2 = \sum_{j \in S} (g_j - \lambda \text{sgn}(\beta_j))^2 + \sum_{j \notin S} (|g_j| - \mu)^2.
\]

Each \( g_j \) is centered, normal with variance at most \( \omega^2 = (1 + \tau)^2 \sigma^2/n \), hence Lemma C.1 implies that \( \mathbb{E}[f_{\lambda,\mu}(\varepsilon)^2] \leq s_0(\lambda^2 + \omega^2) + (s_0 \lor 1)\omega^2 \), which is then bounded by \( 2^{-1}(\gamma c_0)^2(s_0 \lor 1)\lambda^2 \) by the condition on \( c_0 \).

Note that by construction, the function \( \varepsilon \to g_{\lambda,\mu}(\varepsilon) \) is \((1 + \tau)/\sqrt{n})\)-Lipschitz, so that by the Gaussian concentration inequality (see, e.g., [BLM13, Theorem 10.17]),

\[
\mathbb{E}[g_{\lambda,\mu}(\varepsilon)^2] = \int_0^{+\infty} \mathbb{P}[g_{\lambda,\mu}(\varepsilon) > \sqrt{t}] dt \leq \int_0^{+\infty} \mathbb{P}[\omega N(0,1) > \sqrt{t}] dt = \omega^2/2,
\]
provided that the median of $g_{\lambda,\mu}(\varepsilon)$ is zero. We now prove that the median is indeed zero. The event \{\(f_{\lambda,\mu}(\varepsilon)^2 \leq 2E[f_{\lambda,\mu}(\varepsilon)^2]\) has probability at least 1/2 thanks to Markov’s inequality. Furthermore, we proved above that \(2E[f_{\lambda,\mu}(\varepsilon)^2] \leq (c_0\gamma)^2(s_0 \lor 1)^2\). On this event of probability at least 1/2, for any \(u \in T\) we have
\[
(g^\top u - \mu u_s)\|1 - \lambda \text{sgn}(\beta_S)^\top u_s - (c_0\gamma)\lambda \sqrt{s_0 \lor 1}\|u\|_+ = 0.
\]

We have established that the median of $g_{\lambda,\mu}$ is non-positive and the proof is complete. \qed

Appendix D: Proof of Theorem 2.4

The proof requires the following lemma.

**Lemma D.1.** Consider the sequence model \(y = \mu + \varepsilon\) with \(\varepsilon \sim N(0, \sigma^2 I_n)\). Let \(\hat{\mu}^{(1)}, \hat{\mu}^{(2)}\) be two estimators that are 1-Lipschitz functions of \(y\) and let \(f(y) = \hat{\mu}^{(2)} - \hat{\mu}^{(1)}\). Let \(\hat{\mu}\) be the estimator among \(\{\hat{\mu}^{(1)}, \hat{\mu}^{(2)}\}\) with the smallest SURE. Then either
\[
E[\Delta^4] \leq 8\sigma^4 E\text{trace}\{(\nabla f(y))^2\} \quad \text{or} \quad E[\Delta^2] \leq 4\sigma^2
\]
holds, where \(\Delta = \|\hat{\mu} - \mu\| - \min_{j=1,2} \|\hat{\mu}^{(j)} - \mu\|\).

**Proof of Lemma D.1.** Let \(\xi = \|\hat{\mu}^{(1)} - \mu\|^2 - \|\hat{\mu}^{(2)} - \mu\|^2 - \overline{\text{SURE}}^{(1)} + \overline{\text{SURE}}^{(2)}\) and \(X = \|\xi\|/E[\xi^4]\). By definitions of \(\hat{\mu}\) and \(\Delta\),
\[
|\xi| = X E[4\sigma^2 \|f(y)\|^2 + 4\sigma^4 \text{trace}\{(\nabla f(y))^2\}]^{1/2} \\
\geq \|\hat{\mu} - \mu\|^2 - \min_{j=1,2} \|\hat{\mu}^{(j)} - \mu\|^2 \\
= \left\{\|\hat{\mu}^{(1)} - \mu\| + \|\hat{\mu}^{(2)} - \mu\|\right\}\Delta
\]
thanks to the formula for \(R_{\text{unb}}^{(\text{def})}\). Next, we distinguish two cases.

- In the case \(E[\|f(y)\|^2] \leq \sigma^2 E\text{trace}\{(\nabla f(y))^2\}\), thanks to \(E[X^2] = 1\), the previous display yields \(E[\Delta^4] \leq 8\sigma^4 E\text{trace}\{(\nabla f(y))^2\}\).
- In the case \(E[\|f(y)\|^2] > \sigma^2 E\text{trace}\{(\nabla f(y))^2\}\), let \(T = E[\|f(y)\|^2]^{1/2} - \|f(y)\|\). The previous displayed inequality implies that
\[
\Delta \leq \frac{X \sqrt{8} \sigma \langle f(y) \rangle + T}{\|\hat{\mu}^{(1)} - \mu\| + \|\hat{\mu}^{(2)} - \mu\|} \leq X \sqrt{8} \sigma \left(1 + \frac{T}{\|f(y)\|}\right).
\]
For \(T < \|f(y)\|\) we have \(\Delta < 2\sqrt{8} \sigma X\) by the previous display, and for \(T \geq \|f(y)\|\) we have \(\Delta \leq T\) by the triangle inequality, which gives \(\Delta^2 \leq \max(32\sigma^2 X, T^2)\). Let \(\text{med}_f\) be the median of \(\|f(y)\|\). Since \(\|f(y)\|\) is 2-Lipschitz, \(E(\|f(y)\| - \text{med}_f)^2) \leq 2\sigma^2\), so that
\[
E[T^2] \leq E\left[(E(\|f(y)\| - \text{med}_f)^2)^{1/2} + \text{med}_f - \|f(y)\|\right]^2 \leq 12\sigma^2.
\]
Since \(E[X^2] = 1\) we conclude that \(E[\Delta^2] \leq 32\sigma^2 + 12\sigma^2 = 44\sigma^2\).
Proof of Theorem 2.4. Let $j_0 = \arg\min_{j=1,\ldots,m} \mathbb{E}\|\hat{\mu}^{(j)} - \mu\|$. For $k \in [m]$, let

$$\Delta_k = I_k(\|\hat{\mu}^{(k)} - \mu\| - \|\hat{\mu}^{(j_0)} - \mu\|)_+,$$

where $I_k$ is the indicator of the event that the SURE of $\hat{\mu}^{(k)}$ is smaller than the SURE of $\hat{\mu}^{(j_0)}$. Then by Lemma D.1, either $\mathbb{E}[\Delta_k^2] \leq 44\sigma^2$ or $\mathbb{E}[\Delta_k] \leq 32\sigma^4n$ holds, where we use that the function $f(y) = \hat{\mu}^{(j_0)} - \hat{\mu}^{(k)}$ is 2-Lipschitz which grants trace$(\nabla f(y))^2 \leq 4n$ almost surely. Let $S = \{k \in [m] : \mathbb{E}[\Delta_k^2] \leq 44\sigma^2\}$ and $S' = \{k \in [m] : \mathbb{E}[\Delta_k^4] \leq 32\sigma^4n\}$. By Lemma D.1, $[m] = S \cup S'$ and by Jensen’s inequality for the maximum over $S'$,

$$\mathbb{E}[\max_{k \in m} \Delta_k^2] \leq \mathbb{E}[\max_{k \in S} \Delta_k^2] + \mathbb{E}[\max_{k \in S'} \Delta_k^4]^{1/2} \leq 44\sigma^2m + \sigma^2(32mn)^{1/2}.$$

Finally we have by the triangle inequality

$$\mathbb{E}\left[\|\hat{\mu} - \mu\| - \min_{k \in [m]} \|\hat{\mu}^{(k)} - \mu\|\right]_+^{1/2} \leq \sigma(44m)^{1/2} + \sigma(32mn)^{1/4} + \mathbb{E}\left[\max_{k \in [m]} W_k^2\right]^{1/2}$$

where $W_k = (\|\hat{\mu}^{(j_0)} - \mu\| - \|\hat{\mu}^{(k)} - \mu\|)_+$. For each $k \in [m]$, the function $y \rightarrow \|\hat{\mu}^{(j_0)} - \mu\| - \|\hat{\mu}^{(k)} - \mu\|$ is 2-Lipschitz with negative expectation so that $\mathbb{P}(W_k > 2\sigma\sqrt{2x}) \leq e^{-x}$ for all $x > 0$ by Gaussian concentration and $\mathbb{P}(\max_{k \in [m]} W_k^2 > 8\sigma^2(x + \log m)) \leq e^{-x}$ by the union bound. Finally, $\mathbb{E}[\max_{k \in [m]} W_k^2] \leq 8\sigma^2 \log(em)$ follows by integration. \qed

Appendix E: Proof of (2.3)

By the triangle inequality

$$\mathbb{E}\left[\text{SURE} + \mathbb{E}[\|\hat{\mu} - \mu\|^2]^{1/2}\right]^{1/4} \leq \mathbb{E}[\|\hat{\mu} - \mu\|^2]^{1/4} + \mathbb{E}\left[(\|\hat{\mu} - \mu\|^2 - \mathbb{E}[\|\hat{\mu} - \mu\|^2])^{1/4}\right].$$

If $y \rightarrow \hat{\mu}$ is a 1-Lipschitz function then $\varepsilon \rightarrow \|\hat{\mu} - \mu\|$ is also 1-Lipschitz and the second term above is bounded from above as follows:

$$\mathbb{E}[\|\hat{\mu} - \mu\|^2]^{1/4} \leq \mathbb{E}[\|\hat{\mu} - \mu\|^2]^{1/4} + \mathbb{E}[\|\hat{\mu} - \mu\|^2]^{1/4} = 3/4.$$

by $\int_0^\infty \mathbb{P}(\|\hat{\mu} - \mu\| > x)4x^3dx < 1$ for the first term, and by $0 \leq \mathbb{E}[\|\hat{\mu} - \mu\|^2]^{1/4} \leq 1$ thanks to the Gaussian Poincaré inequality for the second term.
