Abstract

We propose Shared Entangled State (SES) as an alternative to Shared Reference Frame (SRF). Although not a universal substitute, we show that there are certain tasks where shared entangled state is a more effective resource than a shared reference frame. We study in detail three such tasks.

PACS: 03.67.-a ,03.65.Ud

1 Introduction

Almost in any protocol of quantum communication, a shared reference frame is indispensable [1, 2, 3, 4] otherwise measurements of the states by the participants will not produce any useful correlation. However this basic initial default brings about practical problems and challenges. In short distance experiments done in a single laboratory, some of the noise that occur in the process of quantum protocols like an unstable fiber communication link or instability in the sending and receiving apparatus is equivalent to an unknown or varying reference frame of the receiver compared with that of the sender. To remedy this, most Quantum Key Distribution (QKD) protocols [5, 6] are supplemented by an active alignment of reference frames to eliminate the slow rotation of reference frames induced by the environment [7, 8, 9, 10, 11, 12]. The active aligning of reference frames usually is a complicated practical task and causes new problems such as lowering the secure key generation rate.

In long distance communication, i.e. between earth and satellites [13, 14, 15, 16, 17], atmospheric turbulence, rotation and revolution of the satellite with respect to the earth, makes it necessary to constantly align reference frames to a high precision which is again very difficult and costly.
On the theoretical side, precise alignment of reference frames raises basic questions: “How much quantum resources is required for aligning a direction between two distant parties with a given precision?” This problem has been studied from different points of view [18, 19, 20, 21, 22, 23, 24, 25]. In particular, it was shown in [26] that one party (say Alice) can share a direction with another party (say Bob) by sending \( N \) polarized parallel spins, where the error vanishes as \( O(1/N) \). However this scaling of error is achieved only if Bob uses \( N - \) particle entangled measurements which is extremely difficult from experimental point of view. In this sense we can say that establishing aligned reference frames with arbitrary precision and by using purely quantum mechanical means needs an exceedingly large amount of resources.

As an alternative method, the authors of the present article proposed in [27] a method which is based on single particle measurements on entangled states shared between the two parties. In this method which is a converse of the standard QKD protocol, the players make measurements on their fixed directions and use the imperfect correlations in the publicly announced results to find the angle between their respective directions and align them accordingly. By repeating this they can eventually fully align their coordinate systems with a precision which is as good as the method of [26].

The above discussion shows that establishing an exact shared reference frame is equivalent to the consumption of infinite quantum resources, i.e. this infinite resource is the necessary prerequisite of all frame dependent quantum protocols.

Later the problem of classical and quantum communication in the absence of shared reference frames was studied in a series of works [28, 29, 30], where it was shown that in the absence of an SRF, it is still possible to communicate classical and quantum information if one encodes a classical bit into two and four qubits respectively. In [29] it was also shown that certain relative informations can be communicated, albeit with lower efficiency, in the absence of SRF.

In this paper we try to study the problem from another point of view and focus on this question: Can we find an alternative resource instead of a shared reference frame? We suggest that at least for certain tasks, shared entangled states can compensate for the lack of a common reference frame. We consider three different tasks and show that shared entangled state not only can compensate for the lack of a SRF, but also works more efficiently. One of the tasks is the determination of the angle between two spins sent to two observers far from each other and the other two tasks are discrimination between two different two-qubit states, again when the two particles are sent to two distant observers.

The structure of this paper is as follows: In section 2 we explore the task of retrieving the relative angle of two qubits and compare the efficiency of the task when the players share a reference frame or an entangled state. In section 3 we investigate another task, namely discrimination between two two-qubit states sent by Alice to Bob and Charlie, where each of them receive one of the qubits. Finally in section 4, we consider the discrimination task between a pair of parallel spins versus a pair of anti-parallel spins. In all tasks, the superiority of shared entangled state to shared reference frame is proved by using appropriate figure of merits. We will then conclude the paper with a discussion in section 5.

2 Task I: Retrieving the relative angle of two spins

Suppose Alice holds two spins in her lab which have an angle \( \alpha \) with each other. Alice sends one of these two spins to Bob and the other one to Charlie. We assume that these two spins are parallel transported to Bob and Charlie who do not have a shared reference frame with Alice. We consider two different scenarios based on two different resources. In the first one, they share a reference frame with
each other and in the second one, they do not have a SRF and only share an entangled state in the form of a singlet state, see figure 1. In both scenarios they can do single and two qubit measurements and can communicate the results of these measurements to each other. The question is: In which scenario they obtain more information about the angle $\alpha$?

Figure 1: (Color online) Task I: Alice transports two spins to Bob and Charlie who are supposed to estimate the angle between the two spins. a) when they have a shared reference frame (SRF), b) when they only have a shared entangled state (SES).

We assume that Alice prepares the product state $\rho_\alpha$ with a prior probability distribution $P(\alpha)$. Bob and Charlie perform POVM’s with elements $\{E_\lambda\}$ and $\{E_\lambda'\}$ and obtain the results

$$P(\lambda, \lambda'|\alpha) := \text{tr} ((E_\lambda \otimes E_\lambda')\rho_\alpha).$$

(1)

They then update their knowledge of the probability distribution by using the Bayesians rule

$$p(\alpha|\lambda\lambda') = \frac{\text{tr}((E_\lambda \otimes E_\lambda')\rho_\alpha)p(\alpha)}{p(\lambda\lambda')}.$$

(2)

where

$$p(\lambda\lambda') = \int \text{tr}((E_\lambda \otimes E_\lambda')\rho_\alpha)p(\alpha)d\alpha.$$

(3)

The information gain of Bob and Charlie, when they obtain the results $\lambda$ and $\lambda'$ (for short $\lambda\lambda'$) is given by
\[ I_{\lambda\lambda'} = \int p(\alpha|\lambda\lambda') \log_2 \left[ \frac{p(\alpha|\lambda\lambda')}{p(\alpha)} \right] d\alpha. \] (4)

The average information gain for all measurement results will then be

\[ I_{\text{avg}} = \Sigma_{\lambda,\lambda'} p(\lambda\lambda') I_{\lambda\lambda'}. \] (5)

This is the figure of merit which is used for comparison of the two resources. For the optimum measurements we use the basic result of [29] according to which in the absence of reference frames, the optimal measurements are projective measurements on total spins. We will elaborate more on this in due course. Finally note that Bob and Charlie have to collaborate in order to be able to read the information of \( \alpha \). They have to communicate to each other the results of their measurements.

Remark 1: We emphasize that here we are not proposing a quantum secret sharing scheme and so we are not concerned with problems of security or cheating either among the participants or by outside adversaries. Our goal is merely to provide examples where shared entangled state can be a better resource than shared reference frames.

### 2.1 Shared reference frame as a resource

Alice prepares a product state of two spin \( \frac{1}{2} \) particles, say \( |n_1\rangle \otimes |n_2\rangle \), where \( |n_i\rangle \) is the eigenstate of \( \vec{\sigma}.n_i \) with positive eigenvalue and encodes her desired information in the relative angle \( \alpha = \cos^{-1}(n_1,n_2) \). Then she sends one qubit to Bob and the other to Charlie. Bob and Charlie seek to estimate the angle \( \alpha \) while Bob and Charlie have a shared reference frame (but they do not have a SRF with Alice).

This problem has been studied in [29] and they showed that measuring each qubit along the same (arbitrary) axis and registering whether the outcomes are the same or not is the optimal measurement for Bob and Charlie. In [29] the maximum average information gain when parties have a SRF is calculated for two different prior distributions. In the case of parallel and anti-parallel distribution,

\[ p(\alpha = 0) = p(\alpha = \pi) = \frac{1}{2}, \] (6)

the average information gain is 0.08 bits and in the case of uniform distribution \( p(\alpha) = \frac{1}{2} \sin(\alpha) \), this information gain decreases to the value of 0.027 bits.

In the next subsection we explore the same task when Bob and Charlie have a SES instead of a SRF and then compare the information gain of two resources.

### 2.2 Shared entangled state as resource

In this case Bob and Charlie do not share a reference frame, instead they share an entangled state in the form of a singlet \( |\psi_-\rangle = \frac{1}{\sqrt{2}} (|0,1\rangle - |1,0\rangle) \) which is known to be rotationally invariant. The most general measurement that Bob and Charlie can perform on their own qubits is a Positive Operator Valued Measurement (POVM) represented by a set of operators \( \{ E_\lambda \} \) and \( \{ E_{\lambda'} \} \) respectively. In the absence of an SRT, \( E_\lambda \) and \( E_{\lambda'} \) should be rotationally invariant and the only rotationally invariant one-qubit operator is the identity, which obviously leads to zero information gain about the relative parameter. On the other hand, when they share a singlet state, there are rotationally invariant POVM's
other than unit operators at their disposal. In fact any two-qubit rotationally invariant positive operator is a positive-weighted expansion of $\Pi_0$ and $\Pi_1$ [29]:

$$E_\lambda = a_\lambda \Pi_0 + b_\lambda \Pi_1,$$

(7)

where

$$\Pi_0 = |\psi_-\rangle\langle\psi_-|,$$

(8)

is the projective measurement onto the antisymmetric subspace ($J = 0$) and $\Pi_1 = I - \Pi_0$ is the projector onto the symmetric subspace ($J = 1$).

In [29] an argument is used to find the optimal measurement which is also valid in our case: "In order to ensure $\Sigma_\lambda E_\lambda = I$, one needs that $\Sigma_\lambda a_\lambda = 1$ and $\Sigma_\lambda b_\lambda = 1$, so $\{a_\lambda\}$ and $\{b_\lambda\}$ are probability distributions over $\lambda$. $E_\lambda$ can be obtained by random sampling of the projective measurement elements $\Pi_0, \Pi_1$, and such a sampling cannot increase the information about the relative parameters (quantified by some concave function such as the average information gain). Thus, the most informative rotationally-invariant POVM for Bob is simply the projective measurement on the basis of total spin". The same argument is true for the measurement elements of Charlie.

The four-qubit state provided for Bob and Charlie is

$$|\chi\rangle = |n_1\rangle_A |\psi^-\rangle_{AA} |n_2\rangle_A,$$

(9)

in which the first two qubits are with Bob and the third and forth ones are with Charlie. In (9), we have labeled the first and the last qubits by $A$ to emphasize that they have been prepared in the frame of reference of Alice and the singlet has also been labeled by $AA$ due to the rotational invariance of singlets. In the rest of the paper we omit these labelings for simplicity. We can set $n_1 = z$ which gives:

$$|\chi\rangle = |0\rangle_A \left( \frac{1}{\sqrt{2}} |01\rangle - \frac{1}{\sqrt{2}} |10\rangle \right)_{AA} \left( \cos(\frac{\alpha}{2}) |0\rangle + \sin(\frac{\alpha}{2}) \exp(i\phi) |1\rangle \right)_A,$$

(10)

where $\alpha = \cos^{-1}(z n_2)$ and $|\psi^-\rangle$ has the same form in all bases due to its rotational invariance.

The elements of projective measurements of Bob and Charlie on the four qubits can be written as the product projectors as follows where the first projector refers to Bob and the second to Charlie, i.e. $\Pi_{0,1}$ projects the two particles of Bob to spin 0 and the two particles of Charlie to spin 1:

$$\Pi_{0,0} = \Pi_0 \otimes \Pi_0, \quad \Pi_{0,1} = \Pi_0 \otimes \Pi_1, \quad \Pi_{1,0} = \Pi_1 \otimes \Pi_0, \quad \Pi_{1,1} = \Pi_1 \otimes \Pi_1.$$

(11)

Note that each of the above simple projectors like $\Pi_0$ is a two qubit measurement.

**Remark 2:** Note that neither Bob nor Charlie do not have any common reference frame with Alice and with each other. Nevertheless their projective measurements on total spins of their two particles does not require any shared frame of reference with Alice. The reason is the rotational invariance of these particular projectors. More precisely, for any state $|i,j\rangle_{AA}$, and any projector on total spin $s$ by say Bob on his two particles, $\Pi_s^{B,B}$, we have the following equality

$$A,A \langle i,j| \Pi_s^{B,B} |i,j\rangle_{A,A} = B,B \langle i,j| \Pi_s^{B,B} |i,j\rangle_{B,B}, \quad \text{abbreviated to} \quad \langle i,j| \Pi_s |i,j\rangle.$$

(12)

The same argument applies also to the measurements of Charlie. Hereafter we do not write the labels A, B and C explicitly and note that this argument applies to all the calculations in the manuscript.
The conditional probabilities of different outcomes can be calculated with accord to $p(\Pi_{i,j}|\alpha) = \langle \chi|\Pi_{i,j}|\chi\rangle$. One directly calculates the matrix elements to obtain
\begin{align}
p(\Pi_{0,0}|\alpha) &= \frac{1}{8} \sin^2\left(\frac{\alpha}{2}\right),
p(\Pi_{1,0}|\alpha) &= \frac{1}{4} - \frac{1}{8} \sin^2\left(\frac{\alpha}{2}\right),
p(\Pi_{1,1}|\alpha) &= \frac{1}{2} + \frac{1}{8} \sin^2\left(\frac{\alpha}{2}\right).
\end{align}
(13)

The posterior distribution and average information gain depend on Bob and Charlie’s prior knowledge of $\alpha$. We consider two different choices for the prior probability distribution.

**Case 1: Parallel and antiparallel distribution**

In this case the prior probabilities of $\alpha$ are
\begin{align}
p(\alpha = 0) &= p(\alpha = \pi) = \frac{1}{2},
\end{align}
(14)
which by insertion into (3) will give
\begin{align}
p(\Pi_{0,0}) = \frac{1}{16}, \quad p(\Pi_{0,1}) = p(\Pi_{10}) = \frac{3}{16}, \quad p(\Pi_{1,1}) = \frac{9}{16}.
\end{align}
(15)

Using equations (13) and (15) and inserting them into (2) the posterior probabilities are found to be:
\begin{align}
p(\alpha = 0|\Pi_{0,0}) &= 0, \quad p(\alpha = \pi|\Pi_{0,0}) = 1, 
p(\alpha = 0|\Pi_{1,0}) &= \frac{2}{3}, \quad p(\alpha = \pi|\Pi_{1,0}) = \frac{1}{3}, 
p(\alpha = 0|\Pi_{0,1}) &= \frac{2}{3}, \quad p(\alpha = \pi|\Pi_{0,1}) = \frac{1}{3}, 
p(\alpha = 0|\Pi_{0,1}) &= \frac{4}{9}, \quad p(\alpha = \pi|\Pi_{0,1}) = \frac{5}{9}.
\end{align}
(16)

Inserting all quantities in (4), and doing the numerical integration, we find:
\begin{align}
I_{\Pi_{0,0}} &= 1, \quad I_{\Pi_{1,0}} = I_{\Pi_{0,1}} = 0.08, \quad I_{\Pi_{1,1}} = 0.008.
\end{align}
(17)

In case of obtaining $\Pi_{00}$, Bob and Charlie gain 1 bit of information (since only an anti-parallel pair of spins can combine with the singlet state to produce spin zero for Both Bob and Charlie) and in the other cases much less information is acquired. The average information gained about the relative angle is found to be
\begin{align}
I_{\text{avg}} = \sum_{i,j} P(i,j)I_{i,j} = 0.09.
\end{align}

This result suggests that the shared entangled state has played a role and the average information gain has been increased from 0 to 0.09 which is slightly higher than the value 0.08 reported in the previous subsection and obtained with shared reference frames [29].

**Case II: Uniform distribution**
Table 1: The average information gain of relative angle $\alpha$ depends on the different resources and different prior distributions

<table>
<thead>
<tr>
<th>Prior Distribution</th>
<th>Resource</th>
<th>SRF</th>
<th>SES</th>
</tr>
</thead>
<tbody>
<tr>
<td>Parallel-antiparallel</td>
<td></td>
<td>0.08</td>
<td>0.09</td>
</tr>
<tr>
<td>Uniform</td>
<td></td>
<td>0.027</td>
<td>0.028</td>
</tr>
</tbody>
</table>

The angle $\alpha$ may be chosen from a uniform distribution in which case we have $p(\alpha) = \frac{1}{2} \sin(\alpha)$. Inserting this distribution in equation (2) will yield to the posterior probabilities

$P(\alpha | \Pi_{0,0}) = \sin^2 \frac{\alpha}{2} \sin \alpha$,

$P(\alpha | \Pi_{0,1}) = P(\alpha | \Pi_{1,0}) = \left(\frac{2}{3} - \frac{1}{3} \sin^2 \frac{\alpha}{2}\right) \sin \alpha$,

$P(\alpha | \Pi_{1,1}) = \left(\frac{4}{9} - \frac{1}{9} \sin^2 \frac{\alpha}{2}\right) \sin \alpha$. (18)

Following the same steps as sec (2.2), the average information gain will be $I_{\text{avg}} = 0.028$ which is again slightly higher than the value 0.027 reported in the last subsection for the case with shared reference frames [29]. These results are summarized in table (2.2).

As can be seen from the results, the average information gain when Bob and Charlie have a SRF is strictly less than those obtained when they have a SES for both prior distributions. Hence for estimating the relative parameter of two qubits, one shared singlet state is a better resource than shared reference frame. In the next two sections we will see this priority of SES to SRF in two other tasks.

3 Task II: Discrimination between parallel spins and a singlet

In this section we will compare SRF and SES with regard to the efficiency they induce in a specific discrimination task. In discrimination tasks, [32] [33] [34] a quantum system is selected from a known ensemble of states, and the goal is to determine with certainty which state has been selected, or to minimize the percentage of the cases where the receiver of states cannot reach a definite conclusion.

Consider the case where Alice chooses with equal probability a state from the following ensemble

$\{ |\psi_- \rangle, |m, m \rangle \}$

where $|\psi_- \rangle$ is the antisymmetric state and $m$ is an arbitrary direction unknown to the receivers. She then sends one of the qubits to Bob and the other to Charlie whose task is to determine which state has been sent to them, (see figure 2).

The appropriate measurements for Bob and Charlie depend on the resources available to them i.e. shared entangled state or shared reference frame. We compare these different resources in the following.
3.1 Shared reference frame as a resource

First note that $|\psi_-\rangle$ is a rotationally invariant state and can be written in the common reference frame of Bob and Charlie as

$$|\psi_-\rangle = \frac{1}{\sqrt{2}}(|z+, z-\rangle - |z-, z+\rangle), \quad (19)$$

where $|z\pm\rangle$ are the eigenstates of $\vec{\sigma}\cdot \vec{z}$ with positive and negative eigenvalues. The other state $|m, m\rangle$ can be written as

$$|m, m\rangle = (\cos(\frac{\theta}{2})|z+\rangle + \exp(i\phi) \sin(\frac{\theta}{2})|z-\rangle) \otimes |z\rangle. \quad (20)$$

where $\theta$ and $\phi$ designate the angular coordinates of the unit vector $m$. In view of the symmetry of both states with respect to exchange of particles, it is obvious that Bob and Charlie should have the same measurement elements to obtain maximum information. So both of them measure their qubits along the same (arbitrary) axis, say $\hat{z}$. The four projectors of Bob and Charlie will then be

$$\Pi_{+,+} = |z+\rangle\langle z+| \otimes |z+\rangle\langle z+|, \quad \Pi_{+, -} = |z+\rangle\langle z+| \otimes |z-\rangle\langle z-|,$$

$$\Pi_{-,+} = |z-\rangle\langle z-| \otimes |z+\rangle\langle z+|, \quad \Pi_{-, -} = |z-\rangle\langle z-| \otimes |z-\rangle\langle z-|. \quad (21)$$

---

Figure 2: (Color online) Task II: Alice randomly sends one of the two states $|\psi_-\rangle$ or $|m, m\rangle$ to Bob and Charlie who are supposed to discriminate between the two states. a) when they share a reference frame, b) when they share only a singlet entangled state.
Table 2: The conditional probabilities of each outcome for different states sent by Alice when Bob and Charlie have a shared reference frame.

| probability     | state          | $|\psi_-\rangle$ | $|m, m\rangle$ |
|-----------------|----------------|------------------|-----------------|
| $P(+, +|\psi\rangle)$ | 0              | $\cos^4 \theta/2$ |                  |
| $P(+, -|\psi\rangle)$ | $1/2$         | $\cos^2 \theta/2 \sin^2 \theta/2$ |                  |
| $P(-, +|\psi\rangle)$ | $1/2$         | $\cos^2 \theta/2 \sin^2 \theta/2$ |                  |
| $P(-, -|\psi\rangle)$ | 0              | $\sin^4 \theta/2$ |                  |

The probabilities of each outcome $p(i, j|\psi\rangle) := \text{tr}(\Pi_{i, j}|\psi\rangle\langle\psi|)$ for $|\psi\rangle = |\psi_-\rangle$ or $|m, m\rangle$ can be obtained by straightforward calculations. These probabilities are shown in table (2). As can be seen from this table, by obtaining the results $+, +$ or $-, -$, Bob and Charlie will be sure that Alice has send the state $|m, m\rangle$, while they will fail to identify the state when they obtain $+, -$ or $-, +$. We use the probability of getting an ambiguous outcome as a figure of failure for comparing two different resources and we call it the inconclusive probability. Hence the inconclusive probability in this case is:

$$P_{\text{inconclusive}} = \frac{1}{2} [P(+ - |\psi_-\rangle) + P(- + |\psi_-\rangle)] + \frac{1}{2} [P(+ - |m, m\rangle) + P(- + |m, m\rangle)]$$

$$= \frac{1}{2} + \frac{1}{4} \sin^2 \theta. \quad (22)$$

We consider the situation that the direction $m$ has been chosen completely random, i.e. from a uniform distribution. This uniform distribution indicated the average probability of uncertainty to be:

$$\bar{P}_{\text{inconclusive}} = \frac{1}{4 \pi} \int \left( \frac{1}{2} + \frac{1}{4} \sin^2 \theta \right) \sin \theta d\theta d\phi = \frac{2}{3}. \quad (23)$$

### 3.2 Shared entangled state as a resource

We now investigate the same discrimination task when Bob and Charlie do not have any shared reference frame but a singlet state $|\psi_-\rangle$. Here each of them can do two-qubit measurements on the particle that he receives from Alice and the share of the entangled state that he holds. Bob and Charlie should carry out rotationally invariant measurements hence they perform total spin measurements. So Bob projects his qubits in the antisymmetric ($\Pi_0 = |\psi_-\rangle\langle\psi_-|$) or symmetric ($\Pi_1 = I - |\psi_-\rangle\langle\psi_-|$) subspaces and Charlie carries out the same measurement on his own qubits. Hence the four product projectors of Bob and Charlie are as (11):

$$\Pi_{0,0} = \Pi_0 \otimes \Pi_0, \quad \Pi_{0,1} = \Pi_0 \otimes \Pi_1, \quad \Pi_{1,0} = \Pi_1 \otimes \Pi_0, \quad \Pi_{1,1} = \Pi_1 \otimes \Pi_1. \quad (24)$$

To see how the conditional probabilities in table (3) are calculated, we proceed as follows. When Alice sends the state $|\psi_-\rangle_{1,2}$, (when the particle 1 goes to Bob and the particle 2 goes to Charlie) the total state of the four particles is $|\Psi\rangle_{\text{tot}} = |\psi_-\rangle_{BC} \otimes |\psi_-\rangle_{1,2}$. Bob measures the total spin of the pair $(B, 1)$ and Charlie measures the total spin of the pair $(C, 2)$. It is obvious that the total spin of the four particles is zero and hence the outcomes $(0, 1)$ and $(1, 0)$ are impossible.

**Remark 3:** In the following lines, $|0\rangle$ and $|1\rangle$ denote the computational basis states, i.e. the two eigenstates of the operator $\sigma_z$. The subscripts 0 and 1 in these kets do not have anything to do with
Table 3: The conditional probabilities of each outcome for different states sent by Alice, when Bob and Charlie have a shared entangled state.

| probability | state | $|\psi^\perp\rangle$ | $|m, m\rangle$ |
|-------------|-------|----------------|----------------|
| $P(0, 0|\psi)$ | 1/4 | 0 | |
| $P(0, 1|\psi)$ | 0 | 1/4 | |
| $P(1, 0|\psi)$ | 0 | 1/4 | |
| $P(1, 1|\psi)$ | 3/4 | 1/2 | |

To find the probabilities of the other two outcomes, we note that

$$|\Psi\rangle_{tot} = \frac{1}{2} \left( |0, 1\rangle - |1, 0\rangle \right)_{B,C} \otimes \left( |0, 1\rangle - |1, 0\rangle \right)_{1,2},$$

which upon rearranging is given by

$$|\Psi\rangle_{tot} = \frac{1}{2} \left[ (|0, 0\rangle - |1, 1\rangle)_{B,C} \otimes (|0, 0\rangle - |1, 1\rangle)_{1,2} \right].$$

Using the notation for the spin-1 triplet ($t$) and spin-0 singlet ($s$) and using

$$|0, 0\rangle = |t_1\rangle,$$
$$|0, 1\rangle = \frac{1}{\sqrt{2}} (|t_0\rangle + |s_0\rangle),$$
$$|1, 0\rangle = \frac{1}{\sqrt{2}} (|t_0\rangle - |s_0\rangle),$$
$$|1, 1\rangle = |t_{-1}\rangle,$$

we find

$$|\Psi\rangle_{tot} = \frac{1}{2} \left[ |t_1\rangle|t_{-1}\rangle - |t_0\rangle|t_0\rangle + |s_0\rangle|s_0\rangle - |t_{-1}\rangle|t_0\rangle \right]_{B,1;C,2}.$$ (28)

Since the two parties are measuring only the total spins, this leads to $P(0, 0|\psi^\perp) = \frac{1}{4}$ and $P(1, 1|\psi^\perp) = \frac{3}{4}$.

Now suppose that Alice sends the state $|m, m\rangle_{1,2}$, so the total state of Bob and Charlie is $|\psi^\perp\rangle_{B,C} \otimes |m, m\rangle_{1,2}$. Bob and Charlie are going to perform the total spin measurement, due to the rotational invariance of both the singlet state and the measurements of Bob and Charlie, the results for the state $|\psi^\perp\rangle_{B,C} \otimes |m, m\rangle_{1,2}$ should be the same as that for $|\psi^\perp\rangle_{B,C} \otimes |z, z\rangle_{1,2}$, therefore we start with:

$$|\Psi\rangle_{tot} = |\psi^\perp\rangle_{B,C} \otimes |z, z\rangle_{1,2} = \frac{1}{\sqrt{2}} \left( |0, 1\rangle - |1, 0\rangle \right)_{B,C} \otimes |0, 0\rangle_{1,2}.$$ (29)

Upon rearranging the labels this is written as

$$|\Psi_{tot\rangle}_{B,1;C,2} = \frac{1}{\sqrt{2}} \left( |00\rangle_{B,1} |10\rangle_{C,2} - |01\rangle_{B,1} |00\rangle_{C,2} \right).$$ (30)

Using (27) we find

$$|\Psi_{tot\rangle}_{B,1;C,2} = \frac{1}{2} \left[ |t_1\rangle|t_0\rangle - |t_0\rangle|t_1\rangle - |t_1\rangle|s_0\rangle - |s_0\rangle|t_1\rangle \right]_{B1,C2}.$$ (31)
This equation will then lead to the probabilities shown in table 3. The zero probabilities in the first three rows of table 3 shows that for these outcomes the two recipients can unambiguously discriminate the states. Only for the forth row they cannot reach a conclusion. Therefore we find

\[ P_{\text{inconclusive}} = \frac{1}{2} P(11|\psi^-) + \frac{1}{2} P(11|m, m) = \frac{5}{8}. \]  \hspace{1cm} (32)

which is definitely smaller than the value of \( \frac{2}{3} \) when Bob and Charlie shared a reference frame and it shows the superiority of SES over SRF in this discrimination task.

In the next section we will consider another even more decisive example which shows this superiority of shared entangled state over shared frame of reference.

4 Task III: Discrimination between parallel and anti-parallel spins

Let Alice choose her states with equal probability from the following ensemble \( \{ |m, m\rangle, |m, m^\perp\rangle \} \), where the direction of \( m \) is arbitrary and as before, Bob and Charlie are to determine which pair has been sent to them, figure 3. It is now better to first consider the case where Bob and Charlie share a singlet.

4.1 Shared entangled state as a resource

The probabilities for the case when Alice sends \( |m, m\rangle \) have already been calculated in previous subsection and are presented in table 3. The same type of analysis as in equations (29-31) can be done for the case when Alice sends \( |m, m^\perp\rangle \), and here the measurement results are the same as that of the case when Alice sends \( |z, z^\perp\rangle \). The calculations are straightforward and instead of (29), we now have

\[ |\Psi_{\text{tot}}\rangle_{B,1;C,2} = \frac{1}{\sqrt{2}} (|01\rangle - |10\rangle)_{B,C} \otimes |01\rangle_{1,2}. \]  \hspace{1cm} (33)

which, after rearranging, in terms of total spins will be written as

\[ |\Psi_{\text{tot}}\rangle_{B,1;C,2} = \frac{1}{2\sqrt{2}} [2|t_1\rangle|t^-\rangle - |t_0\rangle|t_0\rangle - |s_0\rangle|t_0\rangle - |s_0\rangle|s_0\rangle]_{B1;C2}. \]  \hspace{1cm} (34)

This will then easily leads to the probabilities shown in table 4. Since Alice sends her states with equal probability, it is obvious that in 1 out of 16 times, Bob and Charlie obtain the value 00 which definitely lead them to correct statement that the anti-parallel pair of spins has been sent to them. We will now see that when they have a shared reference frame, they can never reach a conclusive result.

| probability | state | \( |m, m\rangle \) | \( |m, m^\perp\rangle \) |
|-------------|-------|-----------------|-----------------|
| \( P(0, 0|\psi) \) | 0 | 1/8 |
| \( P(0, 1|\psi) \) | 1/4 | 1/8 |
| \( P(1, 0|\psi) \) | 1/4 | 1/8 |
| \( P(1, 1|\psi) \) | 1/2 | 5/8 |

Table 4: The conditional probabilities of each outcome for two parallel or anti-parallel pairs of spins sent by Alice, when Bob and Charlie have a shared entangled state.
4.2 Shared reference frame as a resource

In this case, due to the arbitrariness of the direction of \( \mathbf{m} \) and rotational invariance, the projectors of Bob can be \( P_+ := |z_+\rangle\langle z_+| \) and \( P_- := |z_-\rangle\langle z_-| \), and those of Charlie can be \( P_+ = |n_+\rangle\langle n_+| \) and \( P_- = |n_-\rangle\langle n_-| \), where \( \mathbf{n} \) has been set to a definite direction \( \mathbf{n} \) to allow for general one-qubit projective measurements. To prove the inclusiveness of all measurements, it is enough to prove that none of the probabilities \( P(\pm, \pm|\mathbf{m}, \mathbf{m}) \) or \( P(\pm, \pm|\mathbf{m}, \mathbf{m}^\perp) \) can be zero for all choices of \( \mathbf{m} \). But this is an obvious fact, once we note the factorized form of the above probabilities, i.e. \( P(\pm, \pm|\mathbf{m}, \mathbf{m}) = |\langle z|\mathbf{m}\rangle|^2 |\langle n|\mathbf{m}\rangle|^2 \), etc.

Once again we have provided a task where shared entangled state is a more effective resource than a shared reference frame.

5 Discussion

We have considered two different quantum information tasks and have shown that for these specific tasks, the shared entangled state is not only a compensate for shared reference frame, but also is more efficient. The three tasks are estimation of the angle between two spins and discrimination between two two-qubit states, where Alice is a remote sender of the states and Bob and Charlie are two remote
observers to whom each particle of these two states are sent.

It is interesting to find other quantum information tasks for which shared entangled states is superior to shared reference frame. For these tasks and for the cases where establishing and maintaining a common reference frame has practical problems, it may be possible to redesign the protocol by adding entangled states with even increasing the efficiency of the protocol. A future line of research is to find in a systematic way, those quantum information tasks for which shared entangled states can supersede shared reference frames.
