Abstract—Internet of Things (IoTs) is an emerging trend that has enabled an upgrade in the design of wearable healthcare monitoring systems through the (integrated) edge, fog, and cloud computing paradigm. Energy efficiency is one of the most important design metrics in such IoT-healthcare systems especially, for the edge and fog nodes. Due to the sensing noise and inherent redundancy in the input data, even the most safety-critical biomedical applications can sometimes afford a slight degradation in the output quality. Hence, such inherent error tolerance in the bio-signals can be exploited to achieve high energy savings through the emerging trends like, the Approximate Computing which is applicable at both software and hardware levels. In this paper, we propose to leverage the approximate computing in digital Compressed Sensing (CS), through low-power approximate adders (LPAA) in an accurate Bernoulli sensing based CS acquisition (BCS). We demonstrate that approximations can indeed be safely employed in IoT-healthcare without affecting the detection of critical events in the biomedical signals. Towards this, we explored the trade-off between energy efficiency and output quality using the state-of-the-art l_p norm RLS reconstruction algorithm. The proposed framework is validated with the MIT-BIH Arrhythmia database. Our results demonstrated approximately 59% energy savings as compared to the accurate design.

I. INTRODUCTION

Internet of Things (IoT) is a megatrend in future technologies of the healthcare spectrum [1] where their economic worth is expected to be projected at $1.9 trillion by 2020 [2]. Such anticipated advancement has paved the way for novel system architectures in wireless body area network (WBAN), which aim to improve the currently deployed cloud computing paradigm [3]. Usually, the body sensors upload unprecedented amount of diverse physiological data (e.g., EEG, ECG, EMG, etc.) to centralized cloud servers for big data analytics. However, the cloud infrastructure poses a central bottleneck for such huge volume of data due to the high bandwidth requirement and unreliable Internet connection (especially, in under-developed countries). It is expedient to reallocate the distributed computing with computational offloading to more powerful layers, such as heterogeneous fogs [4]. However, it requires data transmission over a gateway, where low power wireless connection and slightly large bandwidth allocation are the major issues [5]. This demand can be reduced by using state-of-the-art compression algorithms [6] [7] [8] [9] at edge devices, but they are sometimes computationally intensive. The near-sensor devices are either battery operated or they rely on energy-harvesting. These limited energy resources tend to reduce their processing capability. Recently, many ultra-low power processors [10] [11], hybrid [12] or non-volatile memories [13] and system-on-chips (SoCs) with integrated radio transceivers [14] have been developed. However, they contribute to quite meager energy efficiency gains on edge devices for big data analytics. Thus, providing low bandwidth within a few milliwatts computing power envelope is an open research challenge. Fig. 1 provides a sketch of the distributed processing in IoT based WBAN along with its associated challenges at each layer.

A. State-of-the-Art and Open Research Problems

The bio-signals, usually, contain redundant information and can be compressed using Nyquist based lossy compression techniques such as embedded zero tree wavelet transform (EZW) [6] and the set partitioning in hierarchical trees (SPIHT) [7]. These methods involve storage, sorting and complex matrix-vector multiplications which subsequently drain the battery. In the recent past, Compressed Sensing (CS) has emerged as their low power substitute. It exploits the sparsity of the bio-signals and directly acquires the data at a rate proportional to the number of measurements, using sensing matrices. The sensing matrix can be generated through different techniques, like quantized Gaussian random, pseudo-random sensing [8], binary antipodal CS...
Approximate computing is a promising approach for energy savings, especially, in conjunction with other state-of-the-art energy efficient techniques [10] - [14]. It exploits the inherent error resilience of healthcare applications and relaxes the equivalence margin between specification and implementation [16]. In correspondence with the ‘digital CS’ model [9], the approximate computing in the basic computational phases of digital CS (9). The approximate computing in digital CS is discussed for IoT based WBAN is discussed below.

A. Data Acquisition

The quality of the input data can be reduced by acquiring the bio-signals at a low sample rate under a low power budget [16]. Since most bio-signals are sparse, CS can also be used to reduce the volume of data [12].

B. Data Processing

Through inexact arithmetic units (e.g., adder, multiplier, divider, etc.) and stage skipping, the energy efficiency of certain computations can be improved. For instance, the accurate additions or multiplications in linear transformation, redundancy removal (with mean) and sparse recovery can be replaced with their approximate counterparts. In recursive recovery algorithms, certain loops can also be skipped with a slight accuracy loss [17].

C. Data Storage

For ultra-low power designs, it is also possible to reduce the storage sizes (memories) or the number of memory accesses. Bortolotti et al. [12] proposed an ultra-low power bio-signal processor through approximate memory units in CS.
D. Data Transmission

The approximate computing has been misleadingly used in certain compression algorithms as optimized lossy transmission. However, the approximate arithmetic units can be embedded in the compression algorithms. It will help in saving the computation energy but the transmission energy will remain unaffected due to same number of total computational bits as in an accurate design.

In this paper, we exploited the near-sensor approximate computing in BCS∗ (approxCS) at the hardware level for ultra-low power acquisition and thereby, explored processing and transmission phases as well. Approximate computing is application specific so, the performance of approxCS is evaluated for Arrhythmia detection, using the most commonly used MIT-BIH Arrhythmia database [19].

III. Motivational Case Study: Error Margin Analysis of Compressed Sensing

To validate the applicability of approximate computing, we first explored the error margin in BCS∗ with additive white Gaussian noise (AWGN) and an outperforming 1st RLS algorithm [20]. As shown in Fig. 6, the noise is added to the input ECG signal. The performance is evaluated for Arrhythmia diagnosis (patient record: 100m) using four well-adopted performance metrics: Signal to Noise Ratio (SNR) and Percentage Root Difference (PRD) for measuring the distortion in the signal, and Positive Predictive Rate (PPR) and Detection Error Rate (DER) for quantifying Arrhythmia detection. Fig. 5 shows that an increase in AWGN noise causes high PRD and DER and low SNR and PRD (undesirable) and thus, high chance of missing the critical events. Moreover, there exists significant error tolerance (20%-30%) and thus, huge potential for approximations.

In this paper, we used seven advanced state-of-the-art 1-bit LPAA [18] with ripple carry chain for multiple bits. Figure 4 refers to their gate-level designs and truth tables. The existing low-latency adders [21] [22] experience carry chain breaking and may lead to undesirable errors. Our approxCS methodology is orthogonal to the use of any type of approximate adder.

IV. Proposed Methodology

An overview of the proposed methodology for designing approxCS is presented in Fig. 7. It consists of the following four key steps:

1) Error Margin Analysis: Since, approximate computing is itself an error inducing practice so, the first step is to identify the error margin in the healthcare application. This can be achieved by assuming an input signal corrupted with AWGN and then, analyzing its impact in comparison to a noise-free algorithm (see Fig. 6). The addition of noise in the compressed stream can be crucial and can lead to incorrect identification of R-peaks. However, if a comparatively low degradation in the output quality (e.g., SNR) is found and the number of mispredicted critical events are found to be below a certain threshold as prescribed by the diagnostics expert, then the approximate computing is applicable.

2) Hardware Error Resilience Analysis: There are two possible hardware approximation knobs that can be exploited for improving the energy efficiency. First, the Fixed-point Quantization is carried out by transforming the floating-point operations to fixed point and reducing the word sizes. Later, approximate hardware units are used for approxCS modeling.

3) Design Space Exploration: An exploration heuristic is employed that selects a subset of energy-efficient design points like approximate number of bits and type of LPAA while considering the quality constraint and the available energy budget.

4) Training for Performance Improvement: The reconstruction algorithm is then trained with a dictionary learning (DL) algorithm [20] for better reconstruction quality and the design points are re-evaluated in the approxCS model.

V. Approximate Computing Based Compressed Sensing Framework

The basic CS model includes data compression and reconstruction. The signal is first compressed in the data acquisition phase before transmitting it over a Gaussian (or any) channel. The channel induces AWGN in the system and its effect can be compensated with a reconstruction algorithm at the receiver end. In the following section, an energy efficient approxCS algorithm, while considering a noisy environment, has been developed and it mainly targets the ECG signals. The approxCS only contributes towards computation energy savings, but the wireless transmission energy and cost does not vary. This is due to the fact that the size of the received signal and the number of transmission bits remains the same as in an accurate model.

A. Signal Acquisition

Generally, in CS signal acquisition, the sparse input signal \( x \) of length \( N \) is acquired through its real-time linear transformation with a sensing matrix \( \Phi \) of size \( N \times M \) (such that \( M << N \)) to obtain a compressed measurement vector \( y \) of length \( M \). Mathematically, this relation can be written as:

\[
y = \Phi x + w
\]

where \( w \) represents the AWGN channel noise. To circumvent the on-board generation of the sensing matrices, the concept of sparse multiplier is exploited in linear transformation. A sorted vector \( z \), specifying the locations of ‘r’ ones in each row of the sensing matrix, is used for successive approximate additions of the corresponding ECG signal values. As this process does not summon a sorting algorithm and matrix multiplications so, it is assumed to be less time consuming and thus, more feasible for embedded systems. The approximate additions, for each element in \( y \), can be written as:

\[
y_{k,p} = y_{k-1,p} + \sum_{q} x(z_q)
\]

where \(0 \leq q < r\) for \(p = 0\) and \(r \leq q < 2r\) for \(p \neq 0\).

### B. Signal Recovery

In the bio-signals, there exists a temporal correlation between samples which can be exploited for reducing the approximation noise. Due to this correlation, their first order difference is usually sparser than the signal itself. Consequently, the method which improves sparsity on the first order difference can yield improved performance as compared to the algorithms which promote sparsity on the signal itself. In [20], Pant et al. proposed a sequential version \(l_p^{2d}\) Recursive Least Squares (RLS) algorithm’ of the basic conjugate-gradient algorithm, which yields an improved reconstruction performance (higher SNR at low compression rates), as compared to other state-of-the-art algorithms [23] [24]. The \(l_p^{2d}\) RLS algorithm recovers the sparse signal \(x^*\) by minimizing the \(l_p^{2d}\) second order difference pseudo-norm, \(\|2dx\|_p^r\), and solving the following \(p\)-RLS problem.

\[
\min_x f(x) = \frac{1}{2}\|\Phi x - y\|_2^2 + \lambda \|2dx\|_p^r\]

where \(\lambda\) is the regularization parameter and \(\epsilon\) is the approximation parameter which renders the function \(\|2dx\|_p^r\) smooth.

In this paper, the signal recovery has accurate implementation for the evaluation of approxCS.

### VI. RESULTS AND DISCUSSIONS

#### A. Experimental Tool Flow

For simulations and design tools, we use an Intel Core i7-6700T Quad-Core server operating at 3.06 GHz with 32 GB of RAM. Fig. 8 presents our integrated tool flow. According to this setup, the accuracy of approxCS framework is first evaluated for Arrhythmia detection in MATLAB and then, its corresponding behavioral Verilog code is developed. After confirming the correct behavior of the hardware in Verilog, Value Change Dump (VCD) file is generated and fed into the Synopsys Primetime tool to generate latency and power reports using a 65nm technology library.

#### B. System Design Configurations

The basic CS model is usually very compute-intensive due to arlange vectors or matrices. It takes on average about 22-24 hours for 10 MATLAB simulations in case of Arrhythmia detection (1 minute recording of patient record 100m). To expedite the execution of this algorithm, the least possible configurations for
the sensing matrix, measurement vector and other parameters are first explored through extensive testing of the accurate CS acquisition with reliable reconstruction. With this viewpoint, the *sensing matrix*, with different configurations, have recently been used in [24], [20], and [9]. The measurement of compressed signal is obtained by linearly transforming the input ECG signal, having 256 measurements, with this measurement matrix (using sparse multiplier concept). Furthermore, the parameters, in the *recovery algorithm* [20], are initialized as: $\epsilon_1 = 1$, $\lambda_1 = 1$, $T = 50$, $E_t^{-15}$, $L_1 = 15$, $r = 4$ and $\delta = 10^{-5}$. The DL algorithm [20] is used with the same parameters except $T = 5$. Fig. 9 presents our four experimental configurations with AWGN channel noise of zero mean and variance $4 \times 10^{-3}$ [20].

**C. Selection of Dataset for Arrhythmia Detection**

For the validation of the proposed methodology for Arrhythmia diagnosis, the approxCS is realized with the MIT-BIH Arrhythmia database [19]. This dataset contains 48 patient records with modified limb lead II (MLII) as the principal lead. Each recording is sampled at 360 Hz with a 11 bit resolution.

In this paper, the performance of approxCS is quantified for substantiating R-peak detection in ‘Tachycardia and Bradycardia’ using four performance metrics (mentioned in Fig. 5).

**D. Performance Evaluation**

The accurate $l_0^{2d}$ RLS reconstruction algorithm [20] uses normalized ECG signals and hence, the corresponding CS acquisition is based on floating point computations. However, FPGAs and ASICs support fixed point computations only. As, the fixed point quantization results into truncation of some bits so, CS compression algorithm is first analyzed by varying the fractional bits. However, the decimal bits are set as per the requirement of each computation and kept constant. It is observed that the reconstruction performance with 33 and 43 fractional bits in CS compression and reconstruction, respectively, seems to be the best optimal solution with transmission energy savings and without quality degradation. In this paper, different percentages of total bits have been used for employing approximate computing.

**E. Design Space Exploration and Parametric Analysis**

Approximating the CS results into noisy R-peaks. However, the approximation noise grows from the baseline of the ECG signal (see Fig. 10) so, the correct R-peaks are never missed (FN = 0). The effect of approximate computing on CS acquisition, alongwith accurate $l_0^{2d}$ RLS reconstruction dependent and independent of DL, is illustrated in Figs. 12 and 13. The summary of these results is provided below:

1) The 80% approximation noise is too much for the reconstruction algorithm (very high PRD and low SNR) and thus, the ECG signal is not recoverable.

**Fig. 10. Effect of Approximation Noise on Arrhythmia Detection (patient record: 100m): The green and red circles indicate TP and FP R-peaks respectively.**

**Fig. 11. Energy Consumption of Accurate and Approximate BCS* (Entities and Testbench)**
Fig. 12. Performance Evaluation of ‘Approximate BCS’ with \( l_p \)-2d RLS Reconstruction for Arrhythmia Detection (1 min recording of patient record 100m). Red bars show unrecoverable signals.

Fig. 13. Performance Evaluation of ‘Approximate BCS’ with DL based \( l_p \)-2d RLS Reconstruction for Arrhythmia Detection (10% and 90% training and test data from full length recording of patient record 100m). Red bars show unrecoverable signals.

2) Upto 40% approximation, all LPAA exhibits low degradation in signal quality (SNR) but LPAA 7 has the lowest energy consumption (see Fig. 11).

3) LPAA 4 exhibits comparatively better reconstruction with even 60% approximation but some R-peaks are noisy. So, this knob can only be considered at the cost of slight accuracy loss in Arrhythmia detection.

4) With 60% approximation noise, LPAA 6 has very low PPR, i.e., very high probability of noisy R-peaks.

5) According to Fig. 11 an increase in the number of approximate bits causes more energy savings. With tolerable approximation error, LPAA 7 has the minimum energy consumption (see Fig. 11). It saves approximately 59% energy with very low probability of incorrectly detected R-peaks.

6) 1-40% approximation does not strongly affect the signal quality and such approximation design can be opted for energy efficiency in BCS* and Arrhythmia diagnosis.

7) In general, the DL algorithm enhances the reconstruction quality. In Fig. 13 an improved SNR and PPR and low DER and PRD can be clearly observed with LPAA 7.

8) The DL algorithm is used on the receiving end so, the computation energy savings remain the same at the near-sensing node.

VII. CONCLUSION

In this paper, we exploited the inherent sensing noise resilience of the bio-signals by applying the approximate computing in an accurate BCS* acquisition for improving the energy efficiency of near-sensing node. In particular, we identified multiple application-aware approximation knobs using state-of-the-art seven low-power approximate adders. For illustration, we demonstrated the trade-off between energy efficiency and the output quality of Arrhythmia detection and thereby, obtained approximately 59% energy savings. In real-world applications, it is not necessary to utilize all computational resources of near-sensing node for Compressed Sensing but the energy consumption can be reduced by employing approximate computing and designing an energy efficient healthcare device depending on the error tolerance of the considered healthcare application.
