(Dated: November 21, 2018)

Within a framework based on the tools of the theory of open quantum systems, we study non-Markovianity trends in a disordered spin chain. Towards this aim, we investigate the decay profile of bipartite entanglement shared between an ancilla-qubit and a system-qubit, which is locally connected with a disordered transverse field Heisenberg chain, acting as an effective environment for it. Subsequently, the evolution of the system-part can be described using a dynamical map acting on it. The non-Markovian nature of the dynamical map is imprinted in the form of a non-monotonic decay of the initial entanglement. We show that a connection between environmental interruption and disorder strength can be established by monitoring the frequency of the entanglement revival, which effectively accounts for the backflow of information from the environment to the system.

I. INTRODUCTION

Investigations of quantum properties associated with disordered systems have gained much attention in last few decades [1–9]. This is primarily due to the fact that disorder is unavoidable in real materials and nowadays can also be engineered in a well controlled setting in laboratories [10–12]. Moreover, presence of disorder gives rise to many interesting phenomena which are in sharp contrast to the behavior observed in their homogeneous counterparts. The list includes order-from-disorder [4–6], enhancement of quantum correlation length [4], disorder-induced localization [1, 7–9], strong violation of area-law [3] etc. In general, to have a physical meaning of the quantities associated with the disordered quantum systems, configuration average over a large set of disordered realizations is performed. This increases the computational complexity of the analysis to many times and restricts most of the observations related to these systems to the ground state properties only. However, probing the system by studying the dynamics of qubits can unveil many interesting properties of the quantum many-body system [13, 14]. In particular, the study of time dynamics of the disordered quantum systems using the framework of open quantum system is an interesting way to look at the properties of these systems, which is basically the central theme of investigation of the present work.

In the realm of the theory of open quantum systems, the Markovian dynamics of a system signifies a situation where the system interacts very weakly with its surroundings [15]. As a result, there is almost loss of information from the system to the environment. However, in reality, it is often observed that the actual dynamics of an open quantum system deviates significantly than this idealized scenario and it is more practical to consider non-Markovian evolution, where there are instances at which the memory effect causes revivals of the quantum properties of the system, which is commonly known as backflow of information from the environment to the system [16]. Despite the fact that the concept of non-Markovianity is well established in the classical case [17], its quantum generalization still remains subtle and ambiguous. In recent years, significant attempts have been made to define non-Markovianity in a precise manner and to provide computable measures. The most customary one is the characterization of non-Markovianity based on the non-monotonic time evolution of some quantum information measures, viz. quantum entanglement [18], quantum mutual information [19], quantum Fisher information [20], quantum interferometric power [21], quantum coherence [22] etc.

The memory effects associated with the non-Markovian dynamics can be attributed as a reminder to the system about its past. In other words, during the course of evolution, the environment stores the information about the initial conditions of the system for a while and later information flows back from the environment which reminds the system about its past. This opens up a potential possibility to establish a connection between the non-Markovian dynamics to the localization of many-body wavefunctions [7–9]. The localization process of a many-body wavefunction is considered to be the case opposite to the thermalization process [23, 24], where the system has no memory of its initial conditions. A many-body system is thermal when the memories of its initial conditions erase completely: after a sufficiently long time, the system reaches at the same equilibrium state, irrespective of its initial state [25–25]. On the other hand, persistent of information about the initial state, prevail the system to thermalize completely and localization of wavefunction occurs.

In this work, we propose a framework to study the trends of non-Markovianity in a disordered quantum system and aim to establish a connection between the environmental interruption and disorder strength. In particular, we divide the whole many-body quantum state into two parts, system-part and environment-part and study the effects of environmental influences on the dynamics of the system-qubits. Subsequently, an interpretation of the localization of the many-body wavefunctions observed in the considered disordered model is presented in terms of the memory effects associ-
ated with the non-Markovian dynamics. As a prototypical model, we consider Heisenberg chain with the disordered transverse field \([8, 9, 26–31]\). The chosen model has been extensively studied in recent years and it is known that it exhibits an eigenstate thermalization (ETH) to many-body localization (MBL) transition at the critical value of the disorder strength \(h_c \approx 3.5\) \([31]\). Dividing the total \(N\)-qubit system in single-qubit ‘system’ \((S)\) and \((N-1)\)-qubit ‘environment’ \((E)\), we characterize the dynamical map acting on the single-qubit system-part by obtaining the decay profile of initial bipartite entanglement shared between the system-qubit and an ancilla-qubit \((A)\). We note that for all values of the disorder strength, initial entanglement decays non-monotonously, which signatures non-Markovian nature of the dynamical map \([16]\). Interestingly, it is observed that the decay pattern of the initial entanglement has a strong dependence on the disorder strength. The profiles of bipartite entanglement obtained for high disorder values are more non-monotonous than that obtained for the low disorder strength. In other words, the frequency of backflow of information from the environment to the system in the MBL phase is many times higher than that of the ETH phase. This feature of decay of bipartite entanglement provides a qualitative picture of complete localization of the \(N\)-qubit wavefunctions in the highly disordered region. More the frequency of interruption caused by the environment, lesser is the scope for the subsystems to thermalize. Subsequently, a quantitative estimation of the same is proposed by tracking down the sign alternation (from negative to positive) in the decay rate of bipartite entanglement. In the following sections, after briefly introducing the model, we discuss the methodology undertaken and elaborate on our main findings.

II. MODEL AND METHODOLOGY

In general, for a real dissipative system, where the system usually interacts with an infinitely large environment, the degrees of freedom of the environment-part remain inaccessible. Hence, it is not always an easy task to characterize its influences on the dynamics of the system-qubits. However, in case of a system and environment both consisting of finite number of sites, the characterization of system dynamics becomes straightforward, yet the perspective of understanding the system exploiting the theory of open quantum systems opens up. This brings the possibility of providing new insightful properties related to the system dynamics.

In this work, we consider a one-dimensional Heisenberg model with a random field along the \(z\)-direction. The Hamiltonian is given by

\[
H = \sum_{i=1}^{N-1} J S_i^z S_{i+1}^z + \sum_{i=1}^{N} h_i S_i^z,
\]

where \(h_i\) are independent random variables at each site \(i\), each with a probability distribution that is uniform in \([-h, h]\), \(J\) is the coupling constant and \(S^i = \sigma^i/2\), with \(i \in \{x, y, z\}\).

In order to study the quantum properties of the above disordered model using the tools of theory of open quantum systems, we first divide the total \(N\)-qubit system in two-parts, system-part \((S)\) and the environment-part \((E)\). In particular, the ‘system of interest’ consists of a single qubit at one of the edges of the chain. The rest of the \((N-1)\)-qubits form the ‘environment’ (see Figure 1). The total Hamiltonian \(H\) can be decomposed as

\[
H = H_S + H_E + H_I,
\]

where \(H_S = h_1 S_1^z\) is the single-particle Hamiltonian, \(H_I = J S_1^z S_2^z\) and \(H_E\) has same mathematical form as the Hamiltonian expressed in Eq. (1) but with the number of particles \(N-1\).

For a open quantum system, the evolutions are generally represented by dynamical map, \(\Lambda_t\), given by \([16]\)

\[
\rho_S(t) = \Lambda_t(\rho_S(0)) = \text{Tr}_E(U_{SE \rho_{SE}} U_{SE}^\dagger),
\]

where \(U_{SE}\) is a unitary acting on system-environment state \(\rho_{SE}\). In our case, in order to investigate the role of quantum interactions in the localization of \(N\)-qubit wavefunctions, we carried out a two-steps analysis. Firstly, we consider the initial system state, \(\rho_S(0)\), is evolving under a dynamical map, \(\Lambda_t\), obtained using Eq. (3) for certain choices of the initial environment state \(\rho_E(0)\) and the unitary \(U_{SE} = e^{-iHt}\) acting on system-environment state, where \(\hat{H}\) is expressed in Eq. (1). We then characterize the properties of the dynamical map \(\Lambda_t\) by studying its effects on the dynamics of the quantum entanglement, shared between the system and an ancilla qubit. We describe the procedure in details in the forthcoming section.

III. CHARACTERIZATION OF THE DYNAMICAL MAP \(\Lambda_t\)

To characterize the properties of the dynamical map, \(\Lambda_t\), acting on the system-qubits in detail, we start with a system qubit \((S)\) which is maximally entangled with an ancilla qubit \((A)\) and the system-ancilla state has following mathematical form in the computational basis \(|\psi\rangle_S A = |\frac{1}{\sqrt{2}}(00) + |11\rangle\rangle\). In addition to this, we consider initially, the environment is in the state \(\rho_E(0) = |00\ldots0\rangle |00\ldots0\rangle_{N-1}\) \([32]\). Therefore, the initial system-environment joint state can be expressed as, \(\rho_{SE} = I_S \otimes |00\ldots0\rangle |00\ldots0\rangle\), where \(I_S\) is the identity matrix acting on system’s Hilbert space. If we now study the evolution of the initially maximally entangled system-ancilla
bipartite state, $\rho_{SA}(0) = |\psi\rangle\langle\psi|_{SA}$, the evolved state $\rho_{SA}(t)$ can be written as

$$\rho_{SA}(t) = (\Lambda_t \otimes I)\rho_{SA}(0).$$  \hfill (4)$$

Once the bipartite state corresponding to the system and ancilla is evaluated, we can monitor the decay of initial system-ancilla entanglement with time.

![Plot of decay of bipartite entanglement quantified using concurrence $E_{SA}(t)$, of the initially maximally entangled system-ancilla state, $|\psi\rangle_{SA}$, with $t$, for various disorder strength $h$ and $N = 10$. We also put $J = 1$. For each disorder strength, $h$, here we consider only a single disorder realization. The ordinate is in ebits and the abscissa is dimensionless.](image1)

**FIG. 2.** (Color online.) Plot of decay of bipartite entanglement quantified using concurrence $E_{SA}(t)$, of the initially maximally entangled system-ancilla state, $|\psi\rangle_{SA}$, with $t$, for various disorder strength $h$ and $N = 10$. We also put $J = 1$. For each disorder strength, $h$, here we consider only a single disorder realization. The ordinate is in ebits and the abscissa is dimensionless.

Figure 2 depicts the variation of entanglement $E_{SA}(t)$ with time $t$, for the time-evolved state given in Eq. (4), for various strength of the random field and for a single disorder realization. From the figure, one can clearly observe that at high values of the disorder strength ((c)-(d)), only a small amount of decay of the bipartite entanglement ($E_{SA}(t) > 0.9$) are observed. On the other hand, when the weak disorder limit is considered ((a)-(b)), the amount of initial entanglement shared between the system and the ancilla gets affected significantly. We also perform the averaging over $10^3$ numbers of disorder realizations and the quenched averaged decay profile of bipartite entanglement $E_{SA}^{avg}(0)$ is plotted in Figure 3. In Figure 3, we note that averaging over many disorder realizations makes the plots smoother. For clean system with increasing field strength the dynamics of $E_{SA}(t)$ remains highly oscillatory with irregular oscillations. Thus the suppression of irregular high amplitude oscillatory behavior in $E_{SA}(t)$ in Figure 2 is due to presence of strong disorder.

![Quenched averaged decay profile of bipartite entanglement, $E_{SA}^{avg}(t)$, for various disorder strengths, $h$, obtained after performing an averaging over $10^3$ number of disorder realizations with $N = 10$. The dimension of the axes are same as that in Figure 2.](image2)

**FIG. 3.** (Color online.) Variation of quenched averaged frequency of oscillation $E_{SA}^{avg}$ with the disorder strength $h$, obtained after performing averaging over $10^3$ number of disorder realizations and time period, $t_{max} = 100$.

Interestingly, from Figure 2 we observe that at high value of disorder strength ($h \gtrsim 6.0$), when the model remains in the MBL phase, the decay of bipartite entanglement shared between the system and the ancilla qubit is highly non-monotonous in the sense that revival of entanglement is more frequent. This implies the frequency of information backflow from the system to the environment is large. As the strength of the disorder
is decreased, a very distinct behavior of the decay pattern can be noticed. At the very low value of the disorder strength \( h \approx 0.5 \), the environmental interruption on the dynamics of system-qubit becomes minimal, which causes bipartite entanglement decay almost monotonously for most of the regions in the \( t \)-axis. In other words, the backflow of information from the environment to the system occurs only at few instances. The number of revivals accounts for the instances of reminder from the environment to the system about its past. This, in turn, is expected to play an instrumental in preventing a quantum system from thermalizing. On the other hand, a near-monotonic decay of bipartite entanglement asserts a minimalistic interruption by environment, which may give a scope to the subsystems to thermalize. In order to quantify the effect of environmental perturbation, we introduce the following measure, reads as

\[
N(h) = \frac{\mathcal{F}}{t_{\text{max}}},
\]

where \( \mathcal{F} \) counts the number of instances at which the derivative of bipartite entanglement changes from negative to positive during a given total time period \( t_{\text{max}} \). We note that those are the instances where backflow of information occurs. Hence, counting the number of oscillations of such backflow per unit time interval provides us a quantitative picture of the frequency of backflow of the information. As an example, in Figure 2, the plot for \( h = 0.5 \) shows there are three occasions between \( t = 0 \to 20 \), where the bipartite entanglement revive. Hence, in this case, we have \( \mathcal{F} = 3 \) and the quantity \( N(h = 0.5) \) takes the value \( 3/20 = 0.15 \). On the other hand, if we consider highly localized regions, say \( h = 10 \), the quantity \( N(h = 10.0) \) takes the value close to unity 0.98. This suggests, the memory effect associated with the non-Markovianity is more in the entanglement dynamics of the subsystem consisting of the system-qubit and the ancilla under the influence of a strongly disordered environment in comparison to the weakly ones.

We compute the value of \( N \) averaged over \( 10^3 \) number of disorder realizations and for time interval \( t \in [0, 100] \) and obtained the behavior of \( N_{\text{avg}}(h) \) with respect to the change of disorder strength \( h \) in Figure 4. This provides us a quantitative picture of the environmental disruption with the change of disorder strength: Higher the value of the disorder strength, more frequent is the interruption caused by the environment, which may eventually compel the \( N \)-qubit wavefunctions to remain localized.

IV. DISCUSSIONS

In this work, using the tools of the theory of open quantum systems, we studied non-Markovianity trends in the disordered transverse field Heisenberg model. From the perspective of the single qubit system-part, the evolution is realized via action of a dynamical map acting on it. Subsequently, we characterized the nature of the dynamical map by looking at the decay profile of bipartite entanglement shared between the system and the ancilla qubit. The non-monotonous decay profile of the initial entanglement reveals non-Markovian nature of the dynamics, which essentially signals presence of memory effects from the environment to the system. We then established a relation between the environmental interruption to that of the disorder strength: strongly many-body localized states of the environment interfere more in the entanglement dynamics of system and ancilla qubit as compared to the extended states in weak disorder. Our findings provide an interesting route for understanding localization in terms of the memory effects associated with the non-Markovian dynamics of the qubits.

[32] Note that the behavior of the bipartite entanglement reported, has no significant dependence on the choices of the environmental state. As an example, instead of the state $|00\ldots0\rangle_{N-1}$ if we choose the following environmental state $|++\cdots+\rangle_{N-1}$, the qualitative behavior will remain same.
