(Dated: January 20, 2022)

We study the motion of a self-attractive Bose-Einstein condensate with pseudo-spin 1/2 driven by a synthetic Rabi (Zeeman-like) field. This field triggers the pseudo-spin dynamics resulting in a density redistribution between its components and, as a consequence, in changes of the overall density distribution. In the presence of an additional external potential, the latter produces a net force acting on the condensate and activates its displacement. As an example, here we consider the case of a one-dimensional condensate in a random potential.

## I. INTRODUCTION

The dynamics of self-interacting quantum matter in a random potential is a topic of a great significance [1–3]. Adding a spin degree of freedom and spin-orbit coupling (SOC) considerably extends the variety of patterns featured by these settings. The resulting coupled spin and mass density motion is one of the most interesting manifestations of the underlying SOC [4], where the particle spin is directly coupled to its momentum, and the spin evolution naturally drives changes in the particle position, both for solid-state [5–7] and cold atom realizations alike [8, 9]. The same mechanism may determine the motion of matter-wave solitons [10].

Taking a self-attractive two-component Bose-Einstein condensate (BEC), which constitutes a pseudo-spin 1/2system, as an example, we show here that such a mutual dependence of pseudo-spin and position can occur even without SOC provided that the BEC symmetry with respect to the spin rotations is lifted by particle-particle interactions. This effect occurs in generic situation when the inter- and intra-species couplings are not equal, resulting in the non SU(2)-symmetric nonlinearity, as it is often the case for mean field interaction in binary BECs. Then, the pseudospin-dependent force driving the BEC may appear as a joint result of the Rabi (Zeeman) coupling acting on the atomic hyperfine states, and, thus, affecting the BEC shape, and an external random potential into which the BEC is loaded.

## II. MODEL AND MAIN PARAMETERS

We consider a quasi one-dimensional condensate in the presence of a synthetic Rabi (Zeeman) field applied along the *x*-direction and of a spin-diagonal random potential U(x). The two-component pseudospinor wave function,  $\psi(\mathbf{x}) \equiv [\psi_1(\mathbf{x}), \psi_2(\mathbf{x})]^{\mathrm{T}}$  (T stands for transpose,  $\mathbf{x} \equiv$ 

(x,t)) obeys two Gross-Pitaevskii equations  $(\nu,\nu'=1,2)$ 

$$i\partial_t \psi_{\nu}(\mathbf{x}) = \left[ -\frac{1}{2} \partial_{xx} + U(x) \right] \psi_{\nu}(\mathbf{x}) -$$

$$\left( g |\psi_{\nu}(\mathbf{x})|^2 + \tilde{g} |\psi_{\nu'}(\mathbf{x})|^2 \right) \psi_{\nu}(\mathbf{x}) + \frac{\Delta}{2} \psi_{\nu'}(\mathbf{x}),$$
(1)

where  $\Delta$  is the Zeeman splitting and  $g, \tilde{g} > 0$  are the interatomic interaction constants. Units are chosen such that  $\hbar = M = N = 1$ , where M is the particle mass, and N is the norm. In the absence of the random potential, this model has been studied extensively in nonlinear optics of dual-core fibers (albeit in the time domain), where  $\tilde{g} = 0$ , with  $\Delta$  corresponding to the coupling between the fibers [11, 12] and in Rabi-coupled BECs [13–16], where both g and  $\tilde{g}$  present. An implementation with small random variations of  $\Delta(t)$  has been considered in Ref. [17].

Here we describe the system evolution by means of the density matrix  $\rho(\mathbf{x}) \equiv \psi(\mathbf{x})\psi^{\dagger}(\mathbf{x})$  and obtain observables by corresponding tracing. We characterize the condensate motion by the center of mass position X(t):

$$X(t) = \operatorname{tr} \int_{-\infty}^{\infty} x \boldsymbol{\rho}(\mathbf{x}) dx, \qquad (2)$$

and the spin components  $\sigma_i(t)$  (here i = x, y, z) as:

$$\sigma_i(t) = \operatorname{tr} \int_{-\infty}^{\infty} \hat{\sigma}_i \boldsymbol{\rho}(\mathbf{x}) dx, \qquad (3)$$

where  $\hat{\sigma}_i$  are the Pauli matrices. For a general description of the spin state we introduce its squared length:  $P(t) = \sum_i \sigma_i^2(t)$ . When the two spinor components are linearly dependent, P(t) = 1, the spin state is pure and it is located on the Bloch sphere.

The characteristic size of relatively high-density domains of the BEC is given by the normalized participation ratio  $\zeta(t)$ :

$$\zeta(t) \equiv \frac{1}{3} \left[ \int_{-\infty}^{\infty} |\psi(\mathbf{x})|^4 \, dx \right]^{-1}.$$
 (4)

FIG. 1. Width of the free space  $(U(x) \equiv 0)$  BEC for  $\Delta = 0.01$  (a), 0.02 (b), and 0.05 (c). Here and below we use for numerical simulations g = 0.5.

The prefactor 1/3 is chosen for consistency with the BEC width  $w(t) = [N_1(t)w_1^2(t) + N_2(t)w_2^2(t)]^{1/2}$ . The latter characterizes its total spread, with:

$$w_{\nu}^{2}(t) \equiv \int_{-\infty}^{\infty} \frac{x^{2} \left|\psi_{\nu}^{2}(\mathbf{x})\right|}{N_{\nu}(t)} dx, \qquad (5)$$
$$N_{\nu}(t) \equiv \int_{-\infty}^{\infty} \left|\psi_{\nu}^{2}(\mathbf{x})\right| dx.$$

Here  $w_{\nu}(t)$  is the component width, and  $N_{\nu}(t)$  is the corresponding fraction of atoms with  $N_1(t) + N_2(t) = 1$ .

## **III. SOLITON EVOLUTION**

## A. Free space spin rotation and broadening

Here we present the analysis, which can be obtained also by summarizing the results known in the general theory of Rabi solitons in different systems, by expressing them in terms of the pseudo-spin 1/2 BEC. To focus on the most fundamental effects, we consider first a realization maximally different from the SU(2) symmetric Manakov-like case [18], assuming  $\tilde{g} = 0$  (the role of this cross-coupling will be discussed later on). The Zeeman field couples the spinor components and leads to evolution of  $\sigma_i(t)$  defined by Eq. (3). This spin rotation causes a population redistribution between components of the BEC spinor and, therefore, modifies its self-interaction energy. As a result, the Zeeman coupling and self-interaction energies become mutually re-

FIG. 2. Evolution of the spin components along z- (a) and x- (b) axes, and of  $P(t) = \sum_i \sigma_i^2(t)$  (c), for a free space BEC at  $\Delta = 0.01, 0.02, 0.05$ .

lated and shape of the soliton changes accordingly. In order to better understand this process and for the qualitative analysis, we begin with the free motion where  $U(x) \equiv 0$ .

Since the effect of the Zeeman field depends on the initial spin configuration, for definiteness and simplicity, here we consider an initial state with  $\sigma_z(0) = 1$ . At  $\Delta = 0$ , a stationary solution of Eq. (1) is

$$\psi_1(\mathbf{x}) = e^{-i\mu t} \frac{\operatorname{sech}(x/w_0)}{\sqrt{2w_0}}, \quad \psi_2(\mathbf{x}) = 0,$$
 (6)

where  $w_0 = 2/g$  determines the energy scale [19], fixing the value of the chemical potential to  $\mu = -g^2/8$ . We indicate the relevant timescale as  $T_{\mu} \equiv 1/|\mu|$ , similar to the expansion time of a noninteracting wavepacket of the  $w_0$  width.

At nonzero  $\Delta$ , the energy scale  $\Delta$  comes into play, along with the corresponding spin rotation time  $T_{\Delta} = 2\pi/\Delta$ . Then, the competition between the Zeeman field and nonlinearity determines three possible regimes, namely for  $\Delta$  smaller, larger, or of the order of the crossover value  $\Delta_{\rm cr} \equiv |\mu|$ . Typical evolution patterns of the BEC parameters for the three regimes are shown respectively in Figs. 1, 2, and 3, and will be discussed in the following.

1. Weak Zeeman field,  $\Delta \ll |\mu|, T_{\Delta} \gg T_{\mu}$ . This regime is characterized by clearly different dynamics of the two spinor components (see Fig. 1(a)), small amplitude spin rotations,  $|\sigma_x(t)|, |\sigma_y(t)| \ll 1$  (Fig. 2), and a relatively small broadening of the wavepacket on the  $T_{\Delta}$  time. The latter is due to the fact that weak Zee-

FIG. 3. (a) Participation ratio of free space BEC defined by Eq. (4) for  $\Delta = 0.01, 0.02$ , and 0.05. The broadening of the soliton with the reorientation of the spin is evident for  $\Delta$ close to the crossover value  $\Delta_{cr} = |\mu|$ . (b) Density plot of the condensate in (t, x) space, for  $\Delta = 0.02$ .

man fields only produce a small population of the second component,  $N_2(t) \ll 1$ , so that – though this component spreads rapidly (with speed of the order of g, essentially due to the momentum-position uncertainty) – it only produces a moderate increase of the total width w (recall that the initial state  $\psi_1(x)$  is stationary). Regarding the behavior of the spin components shown in Fig. 2, iterative solution of Eq. (1) corroborated by numerical results shows that at the initial stage,  $t \ll T_{\mu}$ ,  $\sigma_x(t)$  behaves as  $2\Delta t^2 \mu/3$  and the minimum value of  $\sigma_x(t)$  is of the order of  $\Delta/\mu$ , while the maximum value of  $1 - \sigma_z(t)$  is of the order of  $(\Delta/\mu)^2 \ll \max(|\sigma_x(t)|)$ .

2. Crossover regime,  $\Delta \sim |\mu|, T_{\Delta} \sim T_{\mu}$ . The Zeeman field becomes sufficiently strong to rotate the spin by producing a sizable population  $N_2(t)$ . Consequently, the broadening of this component decreases due to the self-attraction. In this case, the wavepacket broadening during a spin rotation period  $T_{\Delta}$  is of the order of  $w_0$ , and spin components which can trigger a substantial population exchange due to sufficient Zeeman energy changes, namely  $\sigma_z(t) < 0$  and  $\sigma_x(t) \approx -1$ , can be achieved. Here, both components feature similar broadening with time while the dynamics of all relevant quantities is rather irregular. Numerical results show that although at  $t > T_{\Delta}$ the initial soliton shape is already destroyed, its spin state remains almost pure (see Fig. 2) with  $P(t) \approx 1$ . Therefore,  $\psi_1(\mathbf{x})$  and  $\psi_2(\mathbf{x})$  still remain approximately linearly dependent and the densities  $|\psi_1(\mathbf{x})|^2$  and  $|\psi_2(\mathbf{x})|^2$  have similar profiles.

3. Strong magnetic field,  $\Delta \gg |\mu|$ ,  $T_{\Delta} \ll T_{\mu}$ . In this case the two spin components show regular oscillations, with  $\sigma_z(t) \approx \cos(\Delta t)$ . The soliton width increases almost linearly, each component being characterized by alternating periodic kicks (see Fig. 1(c)). These kicks are due to the fact that each component spreads rapidly when its population  $N_{\nu}(t)$  is minimal (see the discussion in the previous point 1), and then, when  $N_{\nu}(t) \approx 1$ ,

the spread rate decreases significantly due to the selfattraction. The analysis of the energy conservation yields that at a quarter of the Zeeman period,  $t = T_{\Delta}/4$ , where  $|N_2(t) - N_1(t)| \ll 1$ , one obtains  $\sigma_x(\pi/2\Delta) \approx 2\mu/3\Delta$ , corresponding to the Zeeman energy required for this rotation (cf. Fig. 2(b)).

# B. Displacement driven by spin reorientation and disorder

A smooth disorder, like in the Lifshitz model [20], is produced at a long interval L by a distribution of  $\mathcal{N} \gg 1$ "impurities" with uncorrelated random positions  $x_j$  and mean linear density  $\bar{n} = \mathcal{N}/L$  as

$$U(x) = U_0 \sum_{j=1}^{j=\mathcal{N}} s_j u(x - x_j).$$
 (7)

Here  $s_j = \pm 1$  is a random function of j with mean values  $\langle s_j \rangle = 0$ , so that  $\langle U(x) \rangle = 0$ . Here we model the impurities as  $u(y) = \exp(-y^2/\xi^2)$ , where  $\xi$  is the corresponding width (the results discussed in the following do not depend qualitatively on this specific choice). The motion of the BEC center of mass X(t) (see Eq. (2)) is described by the Ehrenfest theorem [21] as:

$$\frac{d^2 X(t)}{dt^2} = F[\psi] \equiv -\text{tr} \int_{-\infty}^{\infty} \rho(\mathbf{x}) U'(x) dx, \qquad (8)$$

where  $F[\boldsymbol{\psi}]$  is the state-dependent force. For random U(x), we choose as initial condition a stationary solution of Eq. (1)  $\boldsymbol{\psi}^{[d]}(\mathbf{x}_0) = [\boldsymbol{\psi}_1^{[d]}(\mathbf{x}_0), 0]^{\mathrm{T}}$  with  $F[\boldsymbol{\psi}^{[d]}(\mathbf{x}_0)] = 0$ , where  $\mathbf{x}_0 \equiv (x, 0)$ , corresponding to  $\sigma_z(0) = 1$  as in the discussion of the free space case.

The disorder introduces a new energy-dependent timescale of elastic momentum relaxation related to particle backscattering in a random potential. For a wavepacket, this timescale, being associated with the packet width in the momentum space, determines the time of free broadening of the packet till the localization effect will become essential. In the Born scattering approximation this timescale is  $\tau_d \equiv g/U_0^2 \bar{n}\xi^2$ , and the corresponding expansion length becomes  $\ell = q\tau_d$ [22, 23]. We assume that the potential is weak such that  $\ell \gg 1/g$ , that is the initial width corresponding to  $\psi_1^{[d]}(\mathbf{x}_0)$  [see Eq. (4)],  $\zeta(0) \approx w_0$ , is due to the selfinteraction rather than due to the conventional Anderson localization. In the following we shall consider relatively weak self-interactions,  $g\xi \lesssim 1$ , to study wavepackets extended over several correlation lengths of U(x), where the effect of disorder is expected to be essential. Notice that in this regime the potential is not able to localize the condensate near a single minimum of U(x), that is  $\xi^2 \langle U^2 \rangle^{1/2} \ll 1$ , where  $\langle U^2 \rangle = U_0^2 \bar{n} \xi \sqrt{\pi}$ . Also, we assume that  $\min(\Delta, |\mu|)\tau_d \gtrsim 1$  hence the disorder does not influence strongly the short-term expansion.

In the following we will develop a simple scaling theory, describing this process qualitatively and then compare it with numerical results. For broad states as considered here, the force  $f_j$  imposed on the condensate by a single impurity located at the point  $x_i$  is given by:

$$f_j = \sqrt{\pi} U_0 s_j \xi \, \partial_x |\psi(\mathbf{x})|^2 \big|_{x=x_j} \,. \tag{9}$$

Disorder averaging,  $\langle F^2[\psi] \rangle \equiv \langle (\sum_j f_j)^2 \rangle$ , for the entire BEC yields [20] (see Appendix for details):

$$\langle F^2[\boldsymbol{\psi}] \rangle = \pi U_0^2 \xi^2 \bar{n} \int_{-\infty}^{\infty} \left( \partial_x |\boldsymbol{\psi}(\mathbf{x})|^2 \right)^2 dx.$$
 (10)

Equation (10) cannot be directly applied to the system considered here since the specific initial equilibrium condition  $F[\psi^{[d]}(\mathbf{x}_0)] = 0$  is not a subject of direct disorderaveraging. Then, we proceed as follows. At the initial stage of expansion  $(t \ll T_{\Delta})$  of this strongly asymmetric set of the components we have:

$$\psi_1^{[d]}(\mathbf{x}) = \psi_1^{[d]}(\mathbf{x}_0) + \delta \psi_1^{[d]}(\mathbf{x}), \quad \psi_2^{[d]}(\mathbf{x}) = \delta \psi_2^{[d]}(\mathbf{x}), \quad (11)$$

and the corresponding net force  $\delta F$  acting on the condensate due to the  $\delta \psi_1^{[d]}(\mathbf{x})$ -term, is expressed as

$$\delta F = -2\operatorname{Re} \int_{-\infty}^{\infty} \psi_1^{[d]}(\mathbf{x}_0) \delta \psi_1^{[d]}(\mathbf{x}) U'(x) dx.$$
(12)

For a qualitative analysis, we can use a model of expansion of  $\psi_1^{[d]}(\mathbf{x})$  by assuming that the change in its shape is solely due to change in the width  $\delta w$ . With the same approach to the averaging of  $\delta F$ , we obtain (details are presented in the Appendix)

$$\langle (\delta F)^2 \rangle = \frac{7\pi^2}{90} \frac{(\delta w)^2}{w_0^2} \langle F^2[\psi] \rangle.$$
 (13)

Here  $\langle F^2[\psi] \rangle = \pi U_0^2 \xi^2 \bar{n} g^3/30$  is the result of Eq. (10) for the state in Eq. (6). It is applicable for a weak disorder considered here, where equilibrium shape  $\psi_1^{[d]}$  is close to  $\psi_1(\mathbf{x})$  in Eq. (6). Thus, the broadening of the wavepacket caused by switching on the Zeeman field results in covering a different random potential and triggers its motion.

Now the three regimes of the spin evolution and broadening due to the Zeeman field  $\Delta\sigma_x/2$  leading to qualitatively similar regimes of its motion in the random field, can be identified. The main feature of the driven motion is that the force  $\delta F$  needs a certain time to develop and then, it drives displacement of the condensate, X(t) - X(0). For  $\Delta \ll |\mu|$ , we have  $|F[\psi_2^{[d]}(\mathbf{x})]| \ll |F[\psi_1^{[d]}(\mathbf{x})]|$ , the driven variations in the density are weak and the position shows only small irregular oscillations. At  $\Delta \gtrsim |\mu|$  (crossover and strong Zeeman couplings) the contributions of  $F[\psi_2^{[d]}(\mathbf{x})]$  and  $F[\psi_1^{[d]}(\mathbf{x})]$  are of the same order of magnitude, scaling as  $(U_0^2\xi^2\bar{n}g^3)^{1/2}$ . Therefore,

FIG. 4. Density plot of the condensate in a random potential for  $\Delta = 0.02$ . The initial values of the center-of-mass position and of the condensate width are  $X(0) \simeq 0.19$  and  $\zeta(0) \simeq 3.25$ , respectively. Note that for t < 100 ( $t < \tau_d$ ) this plot is very similar to that in Fig. 3(b).

in the crossover regime, the displacement during one Zeeman period can be estimated from Eq. (8) as  $\langle F^2 \rangle^{1/2} T_{\Delta}^2$ , that is:

$$\sqrt{\langle X^2(T_\Delta)\rangle} \sim U_0 \xi \sqrt{\bar{n}} g^{-5/2}.$$
 (14)

The condition for a large displacement during  $T_{\Delta}$  triggering a long-distance propagation of the condensate corresponds to  $\sqrt{\langle X^2(T_{\Delta}) \rangle} \sim w_0$ , that is  $U_0 \xi \sqrt{\bar{n}} g^{-3/2} \gtrsim$ 1. The subsequent motion is a manifestation of the spin-position coupling due to the non-Manakov selfinteraction in the BEC that can appear without SOC.

For numerical calculations, in the following we fix  $\xi = 1$ ,  $\bar{n} = 10/\xi$ , and  $U_0 = 0.01$ . With this choice, the ground state of the condensate extends over several disorder correlation length, that is  $2/g \gg \xi$  (we recall that  $g \equiv 0.5$ ). Figure 4 shows a typical evolution of the total density and demonstrates the net displacement and the change in the shape of the condensate, including its possible splitting among two potential minima. The spin evolution as presented in Fig. 5 shows that the purity of the spin state P(t) is rapidly destroyed by the random potential due to the fact that  $\psi_1^{[d]}(\mathbf{x})$  and  $\psi_2^{[d]}(\mathbf{x})$  are linearly independent.

The evolution of the force acting on the wavepacket, its size, and position are presented in Fig. 6. This figure show that in a weak Zeeman field the condensate displacement is much smaller than its width, the forces are weak, and the change in the width is small. Thus, the condensate shows only small irregular oscillations near X(0), as expected. Figure 6(b) clearly demonstrates that also in the presence of disorder broadening of the soliton depends on the Zeeman field. The forces presented in Fig. 6(a) have a clear correlation with the quantities shown in Figs. 6(b) and 6(c). Indeed, the force is large when  $\zeta$  is small and  $d^2X/dt^2$  is large at large F. In addition, a comparison with the multipeak density profile in Fig. 4, confirms that the force is determined by  $\zeta(t)$ in Eq. (4) rather than by total spread  $w(t) > \zeta(t)$  in Eq. (5). Although the random motion considerably depends on the realization of U(x), this dependence is only quantitative, and the entire qualitative analysis remains valid independent of the given realization.

FIG. 5. Evolution of the spin components along x- (a) and x- (b) axes, and of P(t) (c), for  $\Delta = 0.01, 0.02$ , and 0.05 (solid, dotted, and dashed lines, respectively).

## IV. CONCLUSIONS

We have demonstrated that the motion of the centerof-mass of a self-attractive spinor Bose-Einstein condensate can be caused by the joint effect of the spin precession in a Rabi-like Zeeman field and the presence of an external potential considered here in a random form as an example. The broadening of the condensate caused by the spin rotation leads to a net force acting on it and triggers its motion. Thus, the spin evolution can drive changes in the condensate position even in the absence of spin-orbit coupling. These results hint at possible interesting extensions of the present study, including the theory of multidimensional and multisoliton settings.

Having discussed a realization with  $\tilde{g} = 0$  and singlecomponent initial conditions, we proceed with a brief analysis of other possible scenarios. We begin with the same initial condition and different  $\tilde{g}$ , as presented in Fig. 7, demonstrating that with the increase in  $\tilde{g}$ , the driving effect of the Zeeman field decreases, and vanishes for the SU(2) symmetry [25–27], where  $\tilde{g} = g$ . In this limit, the spin rotation does not require energy to modify the self-interaction since the condensate rotates without change in its shape as  $\psi^{[d]}(\mathbf{x}) =$  $\psi_1^{[d]}(\mathbf{x}_0) \left(\cos(\Delta t/2), \sin(\Delta t/2)\right)^{\mathrm{T}}$ , and no net force  $\delta F$  appears as a result. As far as the role of the initial conditions is concerned, we notice that there is an infinite number of states  $\boldsymbol{\psi}^{[d]}(\mathbf{x}_0) = \left[\psi_1^{[d]}(\mathbf{x}_0), \psi_2^{[d]}(\mathbf{x}_0)\right]^{\mathrm{T}}$  satisfying the stationarity condition  $F[\psi^{[d]}(\mathbf{x}_0)] = 0$ . When a Zeeman field is applied along the x-axis, a precession around this axis begins, which in turn modifies the density distribution, then leading to a nonzero force and causing further dynamics. For linearly independent  $\psi_1^{[d]}(\mathbf{x}_0)$  and  $\psi_2^{[d]}(\mathbf{x}_0)$ , the spin rotation leads to a change in the selfinteraction energy, and in general a net force appears for the SU(2) coupling, as well. This guarantees that the triggering of the motion of initially stationary BEC by a Zeeman field as discussed in the present paper is in fact a general feature of self-interacting pseudo-spin 1/2condensates.

#### Appendix A: Disorder averaging

Here we describe the disorder-averaging calculation of the force acting on the condensate in a random field. For definiteness, we will omit the time dependence and consider only relevant coordinate-dependences using the same notations as in the main text.

We consider a random potential produced by distribution of "impurities" with "white-noise" uncorrelated random positions  $x_j$  and mean linear density  $\bar{n}$  of the form

$$U(x) = U_0 \sum_j s_j u(x - x_j), \qquad (A1)$$

where  $s_j = \pm 1$  is a random function of j with mean value  $\langle s_j \rangle = 0$ , so that  $\langle U(x) \rangle = 0$ , and Gaussian shape of  $u(x - x_j) = \exp(-(x - x_j)^2/\xi^2)$ , where  $\xi$  is the corresponding width. We begin with the effect of a single impurity located at the point  $x_j$  on the condensate energy and applied force for broad states of our interest, see Fig. A.1. The "single-impurity" interaction energy  $v_j$  and force  $f_j$  are given by:

$$v_j = U_0 s_j \int_{-\infty}^{\infty} u(x - x_j) |\psi(x)|^2 dx, \qquad (A2)$$

$$f_j = -U_0 s_j \int_{-\infty}^{\infty} |\psi(x)|^2 u'(x - x_j) dx.$$
 (A3)

For the chosen Gaussian impurity shape we obtain

$$v_j = \sqrt{\pi} U_0 s_j \xi |\psi(x_j)|^2.$$
 (A4)

For the force we expand the density in the vicinity of the  $x_j$  point as  $|\psi(x)|^2 = |\psi(x_j)|^2 + (d|\psi(x)|^2/dx)|_{x=x_j} (x-x_j)$  and obtain

$$f_j = \sqrt{\pi} U_0 s_j \xi \left. \frac{d}{dx} |\psi(x)|^2 \right|_{x=x_j}.$$
 (A5)

To produce the disorder averaging for the uncorrelated distribution of impurities,  $\langle F^2[\psi] \rangle \equiv \langle (\sum_j f_j)^2 \rangle$  and  $\langle V^2[\psi] \rangle \equiv \langle (\sum_j v_j)^2 \rangle$ , for the entire condensate, we use the technique presented in detail in Ref. [20]. With this approach the sum over impurities for a function  $\chi(x)$ ,  $p_{\chi} \equiv \sum_j \chi(x_j)$  is presented as an integral, in our case in the form:

$$\langle p_{\chi}^2 \rangle = \bar{n} \int \delta(x - x') \chi(x) \chi(x') dx dx'.$$
 (A6)

Thus, we arrive at the transformation:

$$\langle p_{\chi}^2 \rangle = \bar{n} \int \chi^2(x) dx,$$
 (A7)

and obtain for the energy and the force:

$$\langle V^2[\boldsymbol{\psi}] \rangle = \pi U_0^2 \xi^2 \bar{n} \int_{-\infty}^{\infty} |\boldsymbol{\psi}(x)|^4 dx$$

$$= \frac{\pi}{3} U_0^2 \xi^2 \bar{n} \frac{1}{\zeta},$$
(A8)

$$\langle F^2[\boldsymbol{\psi}] \rangle = \pi U_0^2 \xi^2 \bar{n} \int_{-\infty}^{\infty} \left( \frac{d}{dx} |\boldsymbol{\psi}(x)|^2 \right)^2 dx, \quad (A9)$$

where the participation ratio  $\zeta$  is defined by Eq. (4) of the main text. For the wavefunction in Eq. (6) of the main text:

$$\psi_1(x) = \frac{\operatorname{sech}(x/w_0)}{\sqrt{2w_0}}, \quad \psi_2(x) = 0,$$
 (A10)

these equations yield:

$$\langle V^2[\boldsymbol{\psi}] \rangle = \frac{\pi}{6} U_0^2 \xi^2 \bar{n} g, \qquad (A11)$$

$$\langle F^2[\psi] \rangle = \frac{\pi}{30} U_0^2 \xi^2 \bar{n} g^3.$$
 (A12)

Note that these relations can readily be understood by using the basic fluctuations theory for non-correlated ensembles. For this purpose we recall that the relevant spatial scale of the BEC density distribution is  $\zeta$ . Then, for a qualitative scaling analysis, the fluctuations in  $V[\psi]$  and  $F[\psi]$  can be presented in terms of the difference in the number of impurities with  $s_j = 1$  and  $s_j = -1$  at this spatial scale. The fluctuation of the square of this difference, relevant for  $\langle V^2[\psi] \rangle$  and  $\langle F^2[\psi] \rangle$ , is of the order  $\bar{n}\zeta$ , which yields  $\langle V^2[\psi] \rangle \sim U_0^2 \xi^2 \bar{n}/\zeta$  and  $\langle F^2[\psi] \rangle \sim U_0^2 \xi^2 \bar{n}/\zeta^3$ , in agreement with Eqs. (A11) and (A12).

The above disorder-averaging procedure of the force is not directly applicable near the equilibrium since at t = 0a special condition  $F[\psi^{[d]}(x)] = 0$  is satisfied. Thus, we have to consider variation of the force  $\delta F$  due to the variations of the BEC wavefunction in the form:

$$\delta F = -2\text{Re} \int_{-\infty}^{\infty} \psi_1^{[d]}(x_0) \delta \psi_1^{[d]}(x) U'(x) dx.$$
 (A13)

Due to a change in the width  $\delta w$  this variation for wavefunction in Eq. (6) of the main text becomes:

$$\delta \psi_1^{[d]}(x) = \delta w \frac{x \sinh(x/w_0)}{\sqrt{2w_0^{5/2} \cosh^2(x/w_0)}},$$
 (A14)

FIG. A.1. Schematic plot of the BEC density  $|\psi(x)|^2$  and impurity potential. Positions of impurities are marked with filled circles.

and we arrive at Eq. (13) of the main text:

$$\langle (\delta F)^2 \rangle = \frac{7\pi^2}{90} \frac{(\delta w)^2}{w_0^2} \langle F^2[\psi] \rangle, \qquad (A15)$$

with  $\langle F^2[\psi] \rangle$  from Eq. (A12).
