Abstract

In computer communications, discrete data are channel coded to add robustness to noise and then modulated into continuous signals for transmission and reception. In a hard detection setting, received signals are demodulated into discrete data that are provided to a decoder for inference of the transmitted code-word. If additional soft detection information on the quality of the received signal is provided to the decoder, it is known that its use can improve decoding accuracy. Incorporating that information, however, typically comes at the expense of increased algorithmic complexity of the decoder.

Here we introduce and analyse a mechanism by which soft detection information can be used within Guessing Random Additive Noise Decoding (GRAND) framework in such a way that decoding accuracy is increased, but computational complexity is decreased. The principle envisions an enhanced code-book-independent quantization of soft detection information where demodulated symbols are indicated to be confidently reliable or are labeled as being unreliable. We introduce two algorithms that incorporate this symbol reliability information, one of which identifies a Maximum Likelihood (ML) decoding and the other either reports an ML decoding or an error. We prove that both are capacity-achieving when used with random code-books, and determine both error exponents and asymptotic complexity. These decoding algorithms are suitable for use with any block-code and have complexities that can only reduce as code-book rates increase. With respect to their hard detection counterparts, they are capable of achieving higher rates with lower error probabilities, and have reduced algorithmic complexity.

As a worked example, we consider a channel, which we call the Soft Binary Symmetric Channel (S-BSC), where it is possible to directly compare the decoding performance with and without knowledge of the symbol reliability information. We determine capacity, error exponents and complexity, all of which illustrate that substantial gains can be obtained from use of the symbol reliability information considered in this article.

Index Terms

Channel noise; Soft detection; Symbol reliability; Maximum likelihood decoding; Capacity; Error exponents; Algorithmic complexity.

I. INTRODUCTION

Essentially all computer communications involve taking discrete data, channel coding them to add robustness to noise, and then modulating those digital data into continuous signals suitable for transmission and reception. For example, Phase Shift Keying (PSK) is a form of modulation that is used in almost all wireless communications systems. PSK encodes groups of binary data into one of a finite set of phases of a continuous carrier signal for transmission, reception and ultimately demodulation back into discrete data. In Binary PSK each modulated symbol encodes a bit, while in Quadrature PSK (QPSK) each symbol encodes two bits, and in 8PSK each symbol encodes three bits. To avail of better channel conditions in practice, not only is the code-book rate increased, but a modulation with a larger the number of bits per modulated symbol is also employed.

Illustrations of QPSK and 8PSK are provided in Fig. 1. In QPSK, each pair of bits to be transmitted is modulated into two phases of a continuous wave, marked by their real and imaginary components, while in 8PSK each triple of bits is mapped to three phases. Between transmission and reception, noise can result in a perturbation such that the receiver observes a distorted version of the input. With transmitted symbols indicated by the red dots, assuming all symbols are equally likely to be transmitted and they are disturbed by independent additive Gaussian channel noise, the probability density of a received signal being observed is indicated by the heat maps in Fig. 1(a). Hard detection demodulation maps each received signal to the nearest potentially-transmitted symbol. For QPSK and 8PSK, hard decoding corresponds to dividing the received space into quadrants and octants, respectively, and mapping any received signal that falls in that region to the symbol contained within it. One metric of confidence that a hard decoded symbol corresponds to the transmitted one is the Minimum Likelihood Ratio (LR) that a received signal was observed given the hard detection symbol was transmitted as compared with each other possibly transmitted symbol. The resulting LR surface is depicted in Fig. 1(b), where, by this measure, one is confident in a hard decoded symbol if the received signal is distant from the boundary between hard-decoding regions.

Hard detection decoders infer transmitted code-words based solely on that demodulated output, while soft detection decoders attempt to make further use of the received signal to better inform their decoding. Incorporating soft detection information

These results were presented in part at ITA 2019, and in part at the 2019 International Symposium on Information Theory, Paris, France.

In this article lower case letters correspond to realizations of upper-case random variables or their normalized limits, apart from for noise where \( z \) is used as \( n \) denotes the code block-length. Logs are taken base \( |\mathbb{A}| \) throughout, and we assume that \( 0 \in \mathbb{A} \) corresponds to no noise.
results in improved accuracy, but typically at the cost of increased computational complexity in the decoding process, as discussed further in Sec. IV Related Work. In the present paper, we identify a means of availing of soft detection information within the recently introduced hard-detection Guessing Random Additive Noise Decoding (GRAND) framework \cite{1, 2} that results in increased accuracy of decoding with, crucially, reduced computational complexity.

Instead of solely reporting the hard detection output, we envisage a further code-book independent quantization of the received signal into a symbol reliability indicator that separates reliably received symbols from unreliable ones. The principle behind the approach is illustrated in Fig. 1(c) where a thresholding of the LR results in a masked region such that if a signal is received within that region, the hard detection demodulated symbol is flagged as being unreliable. The probability density of receiving a signal conditional on being in the masked region is shown in Fig. 1(d). Thus the uncertainty region serves as a mask that labels received symbols whose values are questionable, enabling the decoder to focus on them. This quantized soft detection symbol reliability information is similar in spirit to how soft information is generated for use within Chase decoding \cite{3, 4}. The key distinction, however, is that Chase decoding is code-book centric and uses the resulting symbol reliability information to, in effect, consider alternate code-books, resulting in significant additional algorithmic complexity. As the GRAND approach is is code-book independent and noise-centric, we establish that we can incorporate the symbol reliability information in a way that results in reduced complexity.

Our mathematical abstraction of this soft detection symbol reliability model assumes that symbols received from the channel have been accurately indicated to be error free or to have possibly been subjected to independent additive random noise. In practice, this corresponds to a situation where soft information such as instantaneous Signal to Interference plus Noise Ratios (SINR) has been thresholded, as described above, so as to provide false negatives with a sufficient small likelihood that poor masking does not dominate the block error probability. In effect, this symbol reliability information is a codebook-independent quantization of soft information \cite{5}. Here we determine the gain in capacity, reduction in block error rate, and decrease in complexity that can be obtained by leveraging this soft detection symbol reliability information within the GRAND approach. The desirable features of GRAND stem from its focus on the noise rather than on the code-book as transmissions that are subject to light noise are quickly decoded, irrespective of the code-book construction or its rate, and these properties are preserved as we incorporate the symbol reliability information.

II. GUESSING RANDOM ADDITIVE NOISE DECODING

Consider a hard-detection channel with inputs, \(X^n\), and outputs, \(Y^n\), consisting of blocks of \(n\) symbols from a finite alphabet \(\mathbb{A} = \{0, \ldots, |\mathbb{A}| - 1\}\). Assume that channel input is altered by random noise, \(N^n\), that is independent of the channel input and
also takes values in $\mathbb{A}^n$. Assume that the function, $\oplus$, describing the channel’s action,

$$Y^n = X^n \oplus N^n,$$

is invertible so that knowing the output and input the noise can be recovered:

$$N^n = Y^n \ominus X^n.$$  \hspace{1cm} (2)

In this hard detection setting, for each transmission the receiver is solely provided with the discrete channel output $Y^n$.

Assuming code-words are selected uniformly at random, to implement Maximum-Likelihood (ML) decoding, the sender and receiver first share a code-book $C_n = \{c_1^n, \ldots, c_{M_n}\}$ consisting of $M_n$ elements of $\mathbb{A}^n$. For a given channel output $y^n$, denote the conditional probability of the received sequence given the transmitted code-word was $c^{n,i}$ by $P_{Y^n|C}(y^n|c^{n,i}) = P(Y^n = y^n \oplus c^{n,i})$ for $i \in \{1, \ldots, M_n\}$. The ML decoding is then an element of the code-book that has the highest conditional likelihood of transmission given what was received:

$$c^{n,*} \in \arg \max \{ P_{Y^n|C}(y^n|c^{n,i}) : c^{n,i} \in C_n \}. \hspace{1cm} (3)$$

For hard detection, the principle underlying the algorithms in [1], [2] is to focus on identifying the noise that was experienced in the channel rather than directly trying to identify the transmitted code-word. The receiver achieves this by first rank-ordering noise sequences from most likely to least likely, breaking ties arbitrarily. In that order, the decoder sequentially queries whether the sequence that remains when the putative noise is removed from the received signal is an element of the code-book. The first instance where the answer is in the affirmative is the decoded element. To see that this algorithm, GRAND, corresponds to ML decoding for channels described in equations (1) and (2) irrespective of how the code-book is constructed, note that owing to the definition of $c^{n,*}$ in equation (3),

$$P_{Y^n|C}(y^n|c^{n,*}) = P(N^n = y^n \ominus c^{n,*}) \geq P(N^n = y^n \ominus c^{n,i})$$

for all $c^{n,i} \in C_n$.

and so by sequentially subtracting noise sequences from the received sequence in order from the most likely to least likely and querying if it is in the code-book, the first identified element is a ML decoding. GRAND can be thought of as a guessing race where the querying process is halted either with success on identifying the true noise, and hence the transmitted code-word, or with an error on identifying a non-transmitted element of the code-book [2]. The second algorithm considered in [2], GRANDAB (GRAND with ABandonment), follows the same procedure as GRAND, but abandons noise guessing and declares an error if more than $|A|^{n(H+\delta)}$ queries have been made, where $H$ is the Shannon entropy rate of the noise and $\delta > 0$ is arbitrary. If more than $|A|^{n(H+\delta)}$ queries are needed to identify a ML decoding, then the noise has been sufficiently unusual that, in query number terms, it is beyond the Shannon typical set. As a result, the block-error rate cost of abandoning is asymptotically negligible and, moreover, the conditional likelihood that a ML decoding is in error increases as the number of queries made before identification of a code-book element increases so that one is abandoning the identification of what would be less certain decodings anyway.

In the hard detection setting, in [2] it is proven that GRAND and GRANDAB are capacity-achieving when used with random code-books. Owing to the abandonment, however, GRANDAB has an a priori upper-bound on its complexity in terms of the number of queries made before it completes by returning a proposed decoding or declaring an error.

### III. SOFT GUESSING RANDOM ADDITIVE NOISE DECODING

The contribution of the current article is to identify how to incorporate soft detection symbol reliability information into the GRAND approach, and the determination of the gains in performance that come from it. We assume that, as well as being in receipt of a channel output, $Y^n$, the receiver is provided with a vector of soft detection symbol reliability information, $S^n$ taking values in $\{0,1\}^n$ where a 0 truthfully indicates a symbol has not been subject to noise while a 1 indicates it may have been. This model is similar in spirit to the well-known Gilbert-Elliott model [6], [7], although our results will hold for channel state process $\{S^n\}$ that have more involved correlation structures than Markovian. The core idea is that the vector $S^n$ be used as a mask that separates symbols that require guessing from those that do not. Using symbol reliability information in this way results in increased capacity, reduced block error probability, and decreased complexity.

The adaptation of this noise guessing principle to the soft detection setting results in a ML decoder, SGRAND that proceeds as follows:

- Given channel output $y^n$ and soft detection information $s^n$, initialize $i = 1$, set the non-noise-impacted symbol locations of guessed noise sequence $z^n$ to 0 and set the masked potentially noise-impacted locations $z^n$ to be the most likely noise sequence of length $l^n = \sum s^i$.
- While $x^n = y^n \ominus z^n \notin C_n$, increase $i$ by 1 and change the masked potentially noise-impacted symbols $z^n$ to be the next most likely noise sequence of length $l^n$.
- The $x^n$ that results from this while loop is the decoded element.

Based on the same logic as given for the hard decoding algorithm, this procedure identifies a ML decoding in this setting, but, depending on $s^n$, it will have performed fewer queries and the output element is more likely to be the transmitted one, owing
to the targeted nature of the querying. While SGRAND always returns an element of the code-book that is a ML decoding, the version with abandonment, SGRANDAB, either provides a ML decoding or returns an error. Several distinct abandonment thresholds, which can be used in combination, that result in reduced complexity without impacting capacity are possible. We comment on two other possibilities in Section VII and prove results for one representative rule:

- With \( L^* = \sum S^\alpha \) being the random number of potentially noise-impacted symbols, assuming it exists, let \( \lim_n E(L^*/n) = \mu L^* > 0 \) be the long run average proportion of potentially noise-impacted symbols. SGRANDAB proceeds as SGRAND, but abandons and declares an error without providing an element of the code-book if more than \( |A|n^{\mu^2H+\delta} \) queries are made, where \( H \) is the Shannon entropy of the noise for a potentially noise-impacted symbol, and \( \delta > 0 \) is arbitrary.

This is similar to the GRANDAB abandonment rule, but where enough queries are made to cover the typical set of the average number of potentially noise-impacted symbols.

In the remainder of the paper we establish that SGRAND and SGRANDAB are capacity achieving when used with random code-books and uniform sources. In addition, we provide error exponents for random code-books as a function of code-book rate and determine algorithmic complexity in terms of the number of noise-guessing queries made until an element of the code-book is found. We present a worked example of the schemes for a Soft Binary Symmetric Channel, which is the simplest circumstance where soft and hard detection channels can be directly compared.

IV. RELATED WORK

While quantification of symbol reliability is separate from the decoding process, it serves as an input to it. Availing of symbol reliability information to inform more accurate decoding has been considered since early on in the history of decoding of block codes with, for example, Wagner codes and their multiple-error extensions by Silverman and Balser [8], [9], which were later expanded and generalized to different types of soft information [10], [11], and notably in soft information Chase decoding [3], which we shall revisit later.

The more general use of soft input decoding, where the soft information is real valued, was studied for block and lattice codes in [12]. An extensive overview of the history and subsequent developments in decoding of block codes with soft information until the end of the 1980s can be found in [13]. The field has remained an active one, with many developments for block codes [14], [15], [16], [17], [18], [19], [20], including some providing maximum-likelihood decoding [21]. Incorporation of soft information in decoding convolutional codes has seen a development that broadly parallels those found for algebraic block codes [22], [23], [24], [25].

Further developments to incorporating soft information in decoding stemmed from the work of Guruswami and Sudan [27] on efficient algebraic means of performing list decoding on Reed-Solomon codes. In particular, in the early 2000s, the Kötter-Vardy approach to soft decoding of algebraic codes [28], which relied on the concept of list decoding, provided a new approach and resulted in considerable follow-on work [29], [30], [31], [32].

The aspects of earlier work that make explicit use of the structure of the code are not relevant to the code-book-independent, noise-centric approach considered here. In SGRAND, each candidate decoded word is merely queried as to whether it is in the codebook. While that verification step may entail algebraic computation, say by checking parity check bits, the code-book remains unchanged and is essentially external to the process of guessing code-book membership.

The germane aspects of the inclusion of soft information in prior work instead relates to its conversion to symbol reliability information. Chase decoding, for instance, first applies a thresholding to categorize bits as reliable or unreliable. Its decoding then entails exhaustively flipping the least reliable bits, or symbols in the case of non-binary codes, leading to test patterns. Each of these test patterns is then applied to the code, and for each of these patterns a hard decision decoder, say an algebraic, distance-based, decoder is applied. In effect each test vector leads to a different realization of the code-book, with a different syndrome or error locator polynomial, from which decoding derives [33]. In its original form, Chase decoding incurs the complexity of performing hard decoding multiplied by a factor that is exponential in the number of unreliable bits. Improvements to this approach make use of the stochastic nature of errors to enhance performance [34], [35], [36], [37], [38], [4], but with improvement of the order of halving, on average, the number of operations. A thorough overview of Chase decoding for BCH and Reed-Solomon codes, and of the recent developments in incorporating soft information in decoding, is provided in [4].

As is used in Chase decoding, we threshold to segregate bits or symbols into reliable and unreliable, but for each test pattern of unreliable symbols we do not seek to perform decoding, only to verify codebook pertinence after subtraction of late test pattern from the received signal. Moreover, since SGRAND explores the unreliable symbol sequences in order of decreasing likelihood, it stops at the first occasion where a valid codeword is found, giving the ML decoding for the unreliability masking thresholding that was used. We remark that as, SGRAND uses the thresholded soft information in a different manner than in Chase decoding, in general the threshold design will itself differ.

For the mathematical analysis of SGRAND and SGRANDAB, we leverage results for Massey’s guesswork [39]. For an ever increasing generality of sources from i.i.d. to Markovian and beyond, it has been established that moments of guesswork scale in terms of their Rényi entropy rates [40], [41], [42]. In [43] Arikan leveraged those results to determine large deviation bounds for conditional probability rank, with the full Large Deviation Principle (LDP) for guesswork proven in [44]. Here
we leverage the LDP for subordinated guesswork [45], which was established for an entirely different purpose, to analyse a wiretap model. Developing results from that starting point allows us to identify error exponents and determine asymptotic algorithmic complexity of the decoders.

We comment that the Related Work discussion in [2] is also relevant to the present article. In particular, the background regarding guesswork [46], [47] and its relation [40] to sequential decoding [48], [49], [50], and the complexity of achieving the cut-off rate [48], [51], [52], [53], [54], [55], [56], [40], [57], [58], [59], as well as the explanation of the distinction between the abandonment criterion of GRANDAB and state sequence estimation (RSSE) and cognate approaches that limit the search cut-off rate [48], [51], [52], [53], [54], [55], [56], [40], [57], [58], [59], as well as the explanation of the distinction between guesswork [46], [47] and its relation [40] to sequential decoding [48], [49], [50], and the complexity of achieving the algorithmic complexity of the decoders.

V. ANALYSIS

As in [2], for the analysis of SGRAND and SGRANDAB we exploit the fact that the algorithm is a race between sequential queries either identifying the noise in the channel, which results in a correct decoding, or accidentally encountering a non-transmitted element of the code-book, which results in an error. The difference here is that the decoder is faster and more precise because only it only asks questions of the sub-string that has been potentially impacted by noise. While the mathematical analysis is more involved, the results obtained are, possibly surprisingly, as clean as in the hard detection setting.

To analyze the algorithm, we recall notions of guesswork [39], [40]. Given the receiver is told that \( n \) symbols have been potentially impacted by noise, it creates a list of noise sequences, \( G : \mathcal{A}^n \rightarrow \{1, \ldots, |\mathcal{A}|^n\} \), ordered from most likely to least likely, with ties broken arbitrarily:

\[
G(z^{n,i}) \leq G(z^{n,j}) \iff P(N^n = z^{n,i}) \geq P(N^n = z^{n,j}).
\]

(4)

For example, if the channel were binary, \( \mathcal{A} = \{0,1\} \), and noise was Bernoulli for some \( p < 0.5 \), then the guesswork order is the string of all zeros, followed by each of the strings with a single one in any order, followed by each of the strings with two ones in any order, and so forth. For independent and identically distributed noise on more general alphabets, it has recently been established that the family of measures that share the same guesswork order are described by a simple exponential family [68].

**Assumption 1** (Noise distribution). When noise occurs, it is independent and identically distributed as \( N_1 \) where \( P(N_1 = i) = p_{N|S}(i|1) = P(N = i|S = 1) \) for \( i \in \mathcal{A} \).

Under assumption 1 if one must guess the entire noise string of length \( n \), Arikan [40] first established how the non-negative moments of guesswork, \( E(G(N^n)\alpha) \) for \( \alpha > 0 \), scale in \( n \) in terms of Rényi entropies. Building on those and subsequent results that treated negative moments, [42] for \( \alpha > -1 \) and [44] for \( \alpha \leq -1 \), and more general noise sources, it was established that the logarithm of guesswork satisfies a LDP [44]. The LDP provides estimates on the distribution of the number of queries required to correctly identify a noise-string and was used as the basis to analyze one half of the decoding race in the hard detection setting [1], [2].

**Proposition 1** (Guesswork Moments and Large Deviation Principle [40], [42], [44]). Under assumption 7 if \( S^n = 1^n \) so that all received symbols are potentially impacted by noise and are distributed as \( N_1 \), the scaled Cumulant Generating Function (sCGF) of \( \{n^{-1} \log G(N^n)\} \) exists:

\[
\Lambda^N(\alpha) = \lim_{n \to \infty} \frac{1}{n} \log E(G(N^n)^\alpha | S^n = 1^n) = \lim_{n \to \infty} \frac{1}{n} \log E(G(N^n)^\alpha) = \begin{cases} 
\alpha H_{1/(1+\alpha)} & \text{if } \alpha > -1 \\
-H_{\min} & \text{if } \alpha \leq -1,
\end{cases}
\]

(5)

where \( H_{\alpha} \) is the Rényi entropy of a single noise element, \( N_1 \), with parameter \( \alpha \)

\[
H_{\alpha} = \frac{1}{1-\alpha} \log \left( \sum_{i \in \mathcal{A}} p_{N|S}(i|1)^\alpha \right), \quad H_1 = H = - \sum_{i \in \mathcal{A}} p_{N|S}(i|1) \log p_{N|S}(i|1), \quad \text{and } H_{\min} = -\max_{i \in \mathcal{A}} \log p_{N|S}(i|1)
\]

Moreover, given \( S^n = 1^n \), the process \( \{n^{-1} \log G(N^n)\} \) satisfies a LDP (e.g. [69]) with convex rate-function

\[
I^N(\alpha) = \sup_{\alpha \in \mathbb{R}} (\alpha \alpha - \Lambda^N(\alpha)),
\]

(6)

where \( I^N(0) = H_{\min} \) and \( I^N(H) = 0 \).

Setting \( \alpha = 1 \) in equation 5, as Arikan originally did in his investigation of sequential decoding, establishes that the expected guesswork grows exponentially in \( n \) with growth rate \( H_{1/2} \), the Rényi entropy of the noise with parameter 1/2, which is greater than the Shannon entropy, \( H \). That the zero of the rate-function in equation 6 occurs at the Shannon entropy of the noise ensures, however, that the majority of the probability is accumulated by making queries up to and including the Shannon typical set. The apparent discrepancy in these two facts occurs because the guesswork distribution has a long tail that dominates its average. As that tail has little probability, however, it does not impact the rates that are achievable with
GRAND, and its negative impact on complexity can be ameliorated by abandoning guessing after a set number of queries, as is exploited in the design of GRANDAB.

In the soft detection symbol reliability setting, for a transmitted block of length \( n \), it is not necessary to guess a noise-string of length \( n \). Instead, one must guess a random number of symbols corresponding to those that are potentially noise-impacted. To that end, we have the following assumption on the number of potentially noise-impacted symbols per transmission.

**Assumption 2** (Number of potentially noise-impacted symbols). With \( L^n = \sum_{i=1}^n S^n_i \) being the number of potentially noise-impacted symbols in a block of length \( n \), the proportion of them, \( \{L^n / n\} \), satisfies a LDP with a strictly convex rate-function \( I^L : \mathbb{R} \mapsto [0, \infty] \) such that \( I^L(l) = \infty \) if \( l \notin [0, 1] \) and \( I^L(\mu^L) = 0 \), where \( \lim_{n \to \infty} E(L^n / n) = \mu^L > 0 \). Define the sCGF for \( \alpha \in \mathbb{R} \) to be

\[
\Lambda^L(\alpha) = \lim_{n \to \infty} \frac{1}{n} \log E (|A|^{\alpha L^n}) = \sup_{l \in [0,1]} (\alpha x - I^L(l)),
\]

which exists in the extended reals due to Varadhan’s Lemma (e.g. [69][Theorem 4.3.1]).

Roughly speaking, Assumption[2] which is true for a broad class of process \( \{S^n\} \) including i.i.d., Markov and general mixing, e.g. [69], says that the probability that the number of symbols that are potentially noise-impacted is \( nl \) decays exponentially in \( n \) with a rate, \( I^L(l) \), that is positive unless \( l \) is the mean \( \mu^L \), i.e. \( P(L^n \approx nl) \approx |A|^{-nl^L(l)} \).

With some abuse of notation for Shannon entropy, under Assumptions[1] and [2], the soft decoding channel’s capacity is upper bounded by

\[
C^{\text{Soft}} \leq \limsup_{n \to \infty} \frac{1}{n} \sup I(X^n, (Y^n, S^n)) \leq 1 - \lim_{n \to \infty} \frac{1}{n} H\left(N_1^{L^n} \right) = 1 - \lim_{n \to \infty} \frac{E(L^n)}{n} H(N_1),
\]

where \( h(p_{N|S}(\cdot |1)) = -\sum_{i \in A} p_{N|S}(i|1) \log p_{N|S}(i|1) \) is the Shannon entropy of \( p_{N|S}(\cdot |1) \), we have upper-bounded the entropy of the input by its maximum, 1, and we have used the fact that the channel is invertible (i.e. equation (2)). Through the construction of SGRAND and GRANDAB, we will show that \( C^{\text{Soft}} \) is attainable.

Under Assumptions[1] and [2] in a distinct context and for a distinct purpose, it was established in [45] that with a random number of characters to be guessed one has the following LDP.

**Proposition 2** (LDP for guessing subordinated noise [45]). Under assumptions[2] and [2] the joint subordinated guesswork and length process \( \{(1/n \log G(N_1^{L^n}), L^n / n)\} \) satisfies a LDP with the jointly convex rate-function

\[
I^{N,L}(g,l) = I^N\left(\frac{g}{2}\right) + I^L(l),
\]

where \( I^N \) is the guesswork rate-function defined in equation (6) and \( I^L \) is the length rate-function defined in Assumption2. Note that \( I^{N,L}(H, \mu^L) = 0 \), where \( H \) is Shannon entropy of a noise-impacted symbol and \( \mu^L \) is the average number of potentially noise-impacted symbols.

The subordinated guesswork process \( \{1/n \log G(N_1^{L^n})\} \) alone satisfies a LDP with the convex rate function

\[
I^{N,L}(g) = \inf_{l \in [0,1]} \left( I^N\left(\frac{g}{2}\right) + I^L(l) \right),
\]

where \( I^{N,L}(\mu^L) = I^{N,L}(H, \mu^L) = 0 \).

The sCGF for \( \{1/n \log G(N_1^{L^n})\} \), the Legendre-Fenchel transform of \( I^{N,L} \), is given by the composition of the sCGF for the length with the sCGF for the guesswork of non-subordinated noise

\[
\Lambda^{N,L}(\alpha) = \lim_{n \to \infty} \frac{1}{n} \log E \left( G\left(N_1^{L^n}\right)^\alpha \right) = \Lambda^L(N(\alpha)) = \sup_{g} (g\alpha - I^{N,L}(g)) \text{ for } \alpha \in \mathbb{R}.
\]

In particular, the average number of queries to required to identify subordinated noise is given by

\[
\Lambda^{N,L}(1) = \lim_{n \to \infty} \frac{1}{n} \log E \left( G\left(N_1^{L^n}\right) \right) = \Lambda^L(H_{1/2}),
\]

where \( H_{1/2} \) is the Rényi entropy of the noise with parameter 1/2.

Roughly speaking, the joint LDP indicates that for large \( n \)

\[
P\left(\frac{1}{n} \log G\left(N_1^{L^n}\right), \frac{L^n}{n} \approx (g,l)\right) \approx |A|^{-nl^{N,L}(g,l)},
\]

and \( I^{N,L}(g,l) \) in equation (8) can be interpreted as follows: if the number of potentially noise-impacted symbols is \( L^n \approx nl \), which is exponentially unlikely with rate \( I^L(l) \), then having the logarithm of the subordinated guesswork be \( \log G\left(N_1^{L^n}\right) \approx ng \) has essentially the same likelihood as \( \log G\left(N_1^{L^n}\right) \approx ng \), which has rate \( I^N(g/l) \) as a total deviation of \( g \) must be accrued over
a smaller proportion of potentially noise-impacted symbols. The unconditioned LDP follows from the large deviations mantra that rare events occur in the most likely way, so that the rate-function $I_n$ is determined from the proportion of potentially noise-impacted symbols that gives the smallest decay rate for the probability.

Results on the subordinated guesswork process \( \{1/n \log G(N_1^{L_n}) \} \) governed by the rate-function in equation \( 9 \) are sufficient to enable us to prove a Channel Coding Theorem for the soft detection channel. Finer-grained results on error exponents that depend on the proportion of symbols that were noise-impacted, however, follow from the LDP for the joint subordinated guesswork and length process \( \{(1/n \log G(N_1^{L_n}), L_n / n) \} \) governed by the rate-function given in equation \( 8 \).

We note that \( \Lambda^L \) is a convex function whose derivative at the origin is \( \mu^L \), the mean number of potentially noise-impacted symbols, so that \( \Lambda^L(H_{1/2}) \geq \mu^L H_{1/2} \). Hence, from equation \( 11 \), the average number of queries until the true channel-noise is identified grows exponentially in \( n \) at a potentially larger rate than the guesswork required for the average proportion of potentially noise-impacted symbols. Despite that, the zero of the rate-function in equation \( 9 \) occurs at \( \mu^L H \), so that the majority of the likelihood of identifying the true subordinated noise occurs by the Shannon entropy of the typical set of average number of potentially noise-impacted symbols. Thus, while stochastic fluctuations in the number of potentially noise-impacted symbols has relevance to complexity and error exponents, that variability has no impact on capacity. Akin to GRANDAB, without loss of capacity, the negative impact on complexity can be ameliorated by abandoning guessing after a suitably large number of queries.

To characterize the number of queries made until a non-transmitted element of the code-book is identified, which is the second part of the guesswork decoding race, we assume that the code-book is random. For uniformly distributed code-books, the location of each of these elements in the guessing order of a received transmission is itself uniform in \( \{1, \ldots, |A_n^L| \} \). As a result, the distribution of the number of queries until any non-transmitted element of the code-book is hit upon is distributed as the minimum of \( M_n \) such uniform random variables. We can, therefore, directly use the following result from \( 11, 22 \).

**Proposition 3** (LDP for Guessing a Non-transmitted Code-word \( 11, 22 \)). Assume that \( M_n = \{ |A|^R \} \) for some \( R > 0 \), and that \( U_n^{1, \ldots, U_n^{M_n}} \) are independent random variables, each uniformly distributed in \( \{1, \ldots, |A|^R \} \). Defining \( U^n = \min U_n^{1, \ldots, U_n^{M_n}}, \{1/n \log U^n \} \) satisfies a LDP with the lower semi-continuous rate-function

\[
I^U(u) = \begin{cases} \frac{1}{1-R} - u & \text{if } u \in [0,1-R] \\ +\infty & \text{otherwise} \end{cases}
\]  

and

\[
\lim_{n \to \infty} \frac{1}{n} \log E(U^n) = 1 - R.
\]

A graphical representation of the rate-functions that determine the asymptotic likelihoods of outcomes of this guessing race can be found in Figure 2. When all symbols are subject to noise, as in \( 11, 22 \), the channel is within capacity so long as the zero of the rate-function for guessing noise, which occurs at the Shannon entropy rate of the noise \( H \), is smaller than the zero of the rate-function for identifying a non-transmitted code-word, which occurs at \( 1 - R \) where \( R \) is the normalized code-book rate. As in all likelihood the correct decoding is identified after fewer queries than an incorrect element of the code-book would be identified, the algorithm experiences concentration onto correct decodings, which leads to the proof of the classical hard detection Channel Coding Theorem \((R < 1 - H)\) in \( 11, 22 \). In the present paper, the zero of the rate function for the subordinated noise-guessing occurs at \( \mu^L H \), the average number of potentially noise-impacted symbols times the Shannon entropy of the noise. So long as \( \mu^L H \) is smaller than \( 1 - R \), noise-guessing concentrates on identifying correct decodings before erroneous ones, leading to the Soft Detection Symbol Reliability Channel Coding Theorem, proved below, where any \( R < 1 - \mu^L H \) is achievable.

While we determine overall error exponents, the additional information of the proportion of potentially noise-impacted symbols is available to the receiver and so it is reasonable to consider error exponents subject to its knowledge. In particular, define

\[
\varepsilon^L(R,l) = -\lim_{\delta \to 0} \lim_{n \to \infty} \frac{1}{n} \log P \left( \frac{L_n}{n} \in (l - \delta, l + \delta), U^n \leq G \left( N_1^{L_n} \right) \right)
\]

to be the probability exponent that the proportion of potentially noise-impacted symbols is \( l \), and that there is an error, as the number of queries required to identify a non-transmitted code-word is smaller than the number of queries required to identify the true noise. We characterize these error exponents in terms of the code-book rate \( R \) and the rate-function \( I_n \) given in equation \( 8 \).

**Theorem 1** (Soft Detection Symbol Reliability Channel Coding Theorem). Assuming the code-book rate is less than the capacity, \( R < 1 - \mu^L H \), under Assumptions \( 7 \) and \( 2 \) and those of Proposition \( 3 \) with \( I^L \) defined in equation \( 12 \), \( I^{NL} \) defined in equation \( 8 \), and \( I^{NL} \) in equation \( 9 \), we have the following results for GRANDAB and GRANDAB.
If, in addition, $g^*$ exists such that
\[
\frac{d}{dg} I^N(g) \big|_{g=g^*} = 1, \tag{15}
\]
which is analogous to one minus Gallager’s critical rate, then the joint error exponent, defined in equation (13), subject to a given proportion of potentially noise-impacted symbols satisfies
\[
e^L(R, I) = \begin{cases} 
I^L(I) + 1 - R - lH_{1/2} & \text{if } R \in (0, 1 - l g^*) \\
I^L(I) + l lN \left( \frac{1 - R}{l} \right) & \text{if } R \in [1 - l g^*, 1 - l H]
I^L(I) & \text{if } R \in (1 - l H, 1].
\end{cases} \tag{16}
\]
Recalling $H_{1/2}$ is the Rényi entropy of the noise with parameter $1/2$, the unconditioned SGRAND error rate simplifies to
\[
\epsilon(R) = \inf_{I \in [0,1]} e^L(R, I) = - \lim_{n \to \infty} \frac{1}{n} \log P \left( U^n \leq G \left( N^L_1 \right) \right) = \begin{cases} 
1 - R - \Lambda^L \left( H_{1/2} \right) & \text{if } R \in (0, 1 - l g^*) \\
I^N \left( 1 - R \right) & \text{if } R \in [1 - l g^*, 1 - l H]
0 & \text{if } R \in (1 - l H, 1].
\end{cases} \tag{17}
\]
With $\delta > 0$, abandoning guessing if $|A|^{n \left( \mu^L H + \delta \right)}$ queries have been made without identifying an element of the code-book, the SGRANDAB error rate is also negative,
\[
\lim_{n \to \infty} \frac{1}{n} \log P \left( \left\{ U^n \leq G \left( N^L_1 \right) \right\} \cup \left\{ G \left( N^L_1 \right) \geq |A|^{n \left( \mu^L H + \delta \right)} \right\} \right) = - \min \left( \left\{ \inf_{u \in [\mu^L H, 1 - R]} \left( I^U(u) + I^N \left( u \right) \right), I^N \left( \mu^L H + \delta \right) \right\} \right) < 0. \tag{18}
\]
If, in addition, \( g^* \) defined in equation (15) exists then the expression simplifies to
\[
\varepsilon^\text{AB}(R) = \min \left( \varepsilon(R), P^N_t(H + \delta) \right) < 0
\]  
(19)
where \( \varepsilon(R) \) is the ML decoding error rate in equation (17).

Proof. As \( \{U^n\} \) is independent of \( \{(G(N^L_t), L^n)\} \), we have that \( \{(n^{-1} \log U^n, n^{-1} \log G(N^L_t), L^n/n)\} \) satisfies an LDP with rate-function \( I^U(u) + P^N_t(g,l) \). Noting the equivalence of the following two events,
\[
\left\{ U^n \leq G \left( N^L_t \right) \right\} = \left\{ \frac{1}{n} \log \left( U^n / G \left( N^L_t \right) \right) \leq 0 \right\}
\]
by the contraction principle (e.g. [69] (Theorem 4.2.1)) with the continuous function \( f(u,g,l) = (u-g,l) \), the process
\[
\left\{ \left( \frac{1}{n} \log \left( U^n / G \left( N^L_t \right) \right), \frac{L^n}{n} \right) \right\}
\]
satisfies a LDP with rate-function \( \inf_{u \in [0,1-R]} \{(I^U(u) + P^N_t(u-x,l))\} \).

Consider \( \varepsilon^L(R,l) \) defined in equation (16), where the limits exist as the rate-functions are convex and so continuous on the interior of where they are finite,
\[
\varepsilon^L(R,l) = - \lim \sup_{\delta \to 0} \frac{1}{n} \log P \left( \frac{1}{n} \log \left( U^n / G \left( N^L_t \right) \right) \right) \leq 0, \frac{L^n}{n} \in (l-d,l+d)
\]

\[
\inf_{u \in [0,1-R]} \inf_{g \in [0,1]} \left\{ I^U(u) + P^N_t(u-x,l) \right\} = \inf_{u \in [0,1-R]} \left\{ I^U(u) + \inf_{g \geq u} P^N_t \left( \frac{g}{l} \right) \right\} + I^L(l).
\]

This final expression essentially encapsulates that the error exponent is the exponent for the likelihood that the proportion of potentially noise-impacted symbols is \( l \), plus the smallest exponent (corresponding to the most likely event) for the minimum of the scaled uniforms being at \( u \), while the scaled sub-ordinated guesswork occurs at any value \( g \) at least as large as \( u \).

For \( u \in [0,1-R] \), \( I^U(u) = 1 - R - u \) is linearly decreasing, while \( P^N(u/l) \) is convex in \( g \) with minimum, zero, at \( g = lH \).

Thus if \( R \geq 1 - lH \), setting \( u = 1 - R \) and \( g = lH \), \( \varepsilon^L(R,l) = I^L(l) \). If, alternatively, \( R < 1 - lH \), then as both \( I^U(u) \) and \( P^N(u/l) \), as a function of \( g \), are strictly decreasing on \( (0,lH) \), we have
\[
\inf_{u \in [0,1-R]} \left\{ I^U(u) + \inf_{g \geq u} P^N_t \left( \frac{g}{l} \right) \right\} = \inf_{u \in [lH,1-lH]} \left\{ 1 - R - u + P^N_t \left( \frac{u}{l} \right) \right\}.
\]

which is strictly positive as \( I^U(u) \) is strictly decreasing to 0 on \( (lH,1-R) \) while \( P^N(u/l) \) is strictly increasing in \( u \) on the same range. Assuming \( g^* \) defined in equation (15), exists, as \( I^U(u) \) is decreasing at rate 1 and
\[
\frac{d}{dg} P^N_t \left( \frac{g}{l} \right) \bigg|_{g = g^*} = 1,
\]
then if \( lg^* \leq 1 - R \), i.e. if \( R \leq 1 - lg^* \),
\[
\inf_{u \in [lH,1-R]} \left\{ 1 - R - u + P^N_t \left( \frac{u}{l} \right) \right\} = 1 - R - lg^* + P^N_t \left( \frac{lg^*}{l} \right) = 1 - R - lg^* + P^N_t \left( g^* \right) = 1 - R - lH_{1/2},
\]
as \( P^N_t \left( g^* \right) = g^* - H_{1/2} \).

If, instead, \( lg^* \geq 1 - R \), then the infimum occurs at \( u = 1 - R \) and
\[
\inf_{u \in [lH,1-R]} \left\{ 1 - R - u + P^N_t \left( \frac{u}{l} \right) \right\} = lH_{1/2} \left( \frac{1 - R}{l} \right) \text{ if } R \in [1 - lg^*, 1 - lH].
\]

Thus the expression in (16) follows.

The unconditional error exponent, \( \varepsilon(R) \) in equation (17), is obtained from that in (16) by the contraction principle, projecting out \( L^n/n \), giving \( \varepsilon(R) = \inf_{l \in [0,1]} \varepsilon^L(R,l) \). If \( R \geq 1 - \mu^2H \), then \( \varepsilon(R) = \varepsilon^L(R,\mu^2) = 0 \). If \( R \in [1 - lg^*, 1 - lH] \), then
\[
\varepsilon(R) = \inf_l \left\{ I^L(l) + P^N_t \left( \frac{1 - R}{l} \right) \right\} = I^N_t(1-R).
\]
Finally, if \( R \in (0,1-l) \), then
\[
\varepsilon(R) = \inf_l \left\{ I^L(l) + 1 - R - lH_{1/2} \right\} = (1 - R) - \inf_l \left\{ lH_{1/2} - I^L(l) \right\} = 1 - R - N^L_t(H_{1/2}).
\]

inverting the Legendre-Fenchel transform in the last step.
To determine the error exponent of SGRANDAB, by the Principle of the Largest Term \( [69, \text{Lemma 1.2.15}] \) it suffices to consider only the smallest of the two exponential rates in equation \([15]\). The first term is the error rate for GRAND. Second term is the exponent of the probability of error due to abandonment of guessing. For it, note that

\[
P \left( G(N^L_n) \geq |A|^n(\mu^L H + \delta) \right) = P \left( \frac{1}{n} \log G(N^L_n) \geq \mu^L H + \delta \right)
\]

and the result follows from the LDP as \( P_{N^L}(x) \) is convex and increasing for \( x > \mu^L H \).

The error exponent for the ML decoding with soft detection symbol reliability information via SGRAND, \( \epsilon^L(R,l) \) in \([16]\), has the following interpretation: the exponent for the likelihood that the proportion of potentially noise-impacted symbols, \( L^w/n \), is approximately \( l \), is \( I^L(l) \). With this occurring, the error-exponent is the same as in a channel where only a proportion \( l \) of the transmitted symbols are subject to noise, e.g. \([2]\). The unconditional equivalent, \( \epsilon(R) \) in equation \([17]\) identifies the most likely proportion of noise-impacted symbols that are likely to give rise to an error for a given code-book rate. For SGRANDAB, an error occurs either if the identified ML decoding is in error or if abandonment occurs. Whichever of these two events is more likely, dominates in the limit.

Combining Propositions \([2]\) and \([3]\) in a distinct way enables us to determine the asymptotic complexity of the SGRAND and SGRANDAB in terms of the number of queries until an decoding, correct or incorrect, is identified:

\[
D^u := \min \left( G \left( N^L_n \right), U^U \right).
\]

That is, the algorithm terminates at either identification of the noise that was in the channel or when a non-transmitted element of the code-book is unintentionally identified, whichever occurs first. On the scale of large deviations, if the code-book is within capacity, \( R < 1 - \mu^L H \), then it will become apparent that the sole impact of the code-book is to curtail excessive guessing when unusual noise occurs. The number of guesses SGRANDAB makes until terminating is

\[
D^u_{AB} := \min \left( G \left( N^L_n \right), U^U, |A|^n(\mu^L H + \delta) \right),
\]

The final term corresponds to the abandonment threshold that curtails guessing shortly after querying the Shannon typical set for an average number of potentially noise impacted symbols.

**Theorem 2** (Complexity of SGRAND and SGRANDAB). If \( R < 1 - \mu^L H \), under Assumptions \([2]\) and \([3]\) and those of Proposition \([3]\) the rescaled complexity of SGRAND, \( \{1/n \log D^u\} \), satisfies the LDP with a convex convex rate-function

\[
I^D(d) = \begin{cases} 
    I^N(d) & \text{if } d \in [0,1-R] \\
    +\infty & \text{if } d > 1-R
\end{cases}
\]

and the expected number of guesses until a ML decoding is found by SGRAND satisfies

\[
\lim_{n \to \infty} \frac{1}{n} \log E(D^u) = \min \left( \Lambda^L(H_{1/2}), 1-R \right).
\]

With \( \delta > 0 \), the complexity of SGRANDAB, \( \{1/n \log D^u_{AB}\} \), satisfies a LDP with a convex function

\[
I^{D,AB}(d) = \begin{cases} 
    I^N(d) & \text{if } d \in [0,\min(1-R,\mu^L H)] \\
    +\infty & \text{if } d > \min(1-R,\mu^L H)
\end{cases}
\]

and the expected number of guesses until SGRANDAB terminates, \( \{D^u_{AB}\} \), satisfies

\[
\lim_{n \to \infty} \frac{1}{n} \log E(D^u_{AB}) = \min \left( A^L(H_{1/2}), 1-R, \mu^L H + \delta \right).
\]

**Proof.** Consider the process \( \{n^{-1} \log D^u\} \), following \([2]\)[Proposition 2], as \( f(g,u) = \min(g,u) \) is a continuous function, by the contraction principle it satisfies a LDP with rate-function \( I^D(d) = \inf \{I^N(g) + I^U(u) : \min(g,u) = d\} \). If \( d > 1-R \), \( I^D(d) = \infty \) as \( I^U(d) = \infty \) for \( d > 1-R \). Alternatively, if \( d \leq 1-R \),

\[
I^D(d) = \min \left( I^N(d) + \inf_{x \geq d} I^U(x), \inf_{x \geq d} I^N(x) + I^U(d) \right) = \min \left( I^N(d), \inf_{x \geq d} I^N(x) + I^U(d) \right)
\]

as \( I^U(x) \) is decreasing for \( x \in [0,1-R] \). If \( R < 1 - \mu^L H \), then we make the following geometric considerations

\[
I^N(0) = \inf_{l} \left\{ I^L(l) + I^N(0) \right\} = \inf_{l} \left\{ I^L(l) + lH_{\min} \right\} \leq \mu^L H_{\min},
\]

where in the last inequality we have set \( l = \mu^L \). As min-entropy is less than Shannon entropy \( \mu^L H_{\min} < \mu^L H < 1-R \) and as \( I^N \) is convex, \( I^N(d) \leq I^U(d) \) for all \( d \in [0,H] \) while \( I^N(d) \) is increasing on \([H,1-R]\) and so \( I^D(d) = I^N(d) \) for \( d \in [0,1-R] \).
Fig. 3. Channel capacity comparison with and without soft detection information. In the soft detection model, transmitted symbols are potentially noise-impacted independently with probability \( q \) and, on being noise impacted, are binary symmetric independently with probability \( p \) leading to a channel capacity of \( 1 - q h_2(p) \). The channel without soft detection information is a binary symmetric channel with probability \( pq \), giving a capacity of \( 1 - h_2(qp) \). The left hand side plots the difference between soft detection and hard detection channel capacities, which is maximized when \( q = 1/2 \) and \( p = 1 \) whereupon the soft channel has capacity 1 and the hard has 0. The right hand side plots the ratio of the soft detection to hard detection capacities, establishing that a proportional gain of several orders of magnitude is possible depending on parameters.

To obtain the scaling result for \( E(D^n) \) we invert the transformation from the rate function \( I^D \) to its Legendre-Fenchel transform, the sCGF of the process \( \{ n^{-1} \log D^n \} \) via Varadhan’s Theorem [69][Theorem 4.3.1]. In particular, note that, regardless of whether \( I^D \) is convex or not,

\[
\lim_{n \to \infty} \frac{1}{n} \log E(D^n) = \lim_{n \to \infty} \frac{1}{n} \log E \left( |A|^{\log D^n} \right) = \sup_{d \in \mathbb{R}} \{ d - I^D(d) \} = \min \left( \Lambda_L(H_{1/2}), 1 - R \right).
\]

For the complexity of SGRANDAB, the final component of the minimum satisfies an LDP with a rate function

\[
\begin{cases} 
0 & \text{if } d = \mu + \delta \\
+\infty & \text{if } d \neq \mu + \delta
\end{cases}
\]

and, again, as minimum is continuous by the contraction principle the LDP with a rate-function given in equation (23) and the scaling of \( E(D^\mu_{AB}) \) follows from similar considerations.

Theorem 2 effectively says that in SGRAND the algorithm terminates with the likelihood of identifying the true noise in the channel, and so a correct decoding, so long as the number of queries made before identifying an element of the code-book is less than \(|A|^{n(1-R-\varepsilon)}\) for some \( \varepsilon > 0 \). If more queries are made than that, the ML decoding will be erroneous. The average number of queries SGRAND makes scales as the average number of queries to identify the true noise or the number of queries until an erroneous identification, whichever is smaller. In this realization of SGRANDAB, querying is abandoned for noise sequences beyond the typical set of the average number of potentially noise impacted symbols, curtailing complexity, but at no capacity cost.

VI. THE SOFT BINARY SYMMETRIC CHANNEL

We consider a setting in which it is possible to directly compare channels with and without knowledge of the soft detection symbol reliability information vector \( S^n \), the Soft Binary Symmetric Channel (S-BSC). We compare differences in capacity and complexity, which is a feature of the noise-guessing approach, as well as error exponents, which is a property of ML decoding no matter whether it is identified by the noise-guessing methodology or by brute force.
of noise impacted symbols, the hard detection capacity. Depending on the parameterization, the soft detection capacity can be several orders of magnitude larger than $S$ where $h$ capacity is necessarily higher. A plot of the difference in capacity between the soft and hard detection channels, $C_{\text{dec}}$ decoding channel capacity is maximized when $q = 1/2$ and $p = 1$ whereupon the exponent for the hard detection channel is 1 and for the soft detection channel it is 0. The right hand side plots the ratios of these two exponents, where the exponent for the hard detection channel can be orders of magnitude larger than for the soft detection channel.

For the S-BSC, we assume that each transmitted symbol is impacted independently by noise with probability $p_S(1) = q \in [0, 1]$. Code-book and noise symbols take values in a binary alphabet $A = \{0, 1\}$, $\oplus$ is addition in $\mathbb{F}_2$, and thus 0 represents the no-noise character. Given a symbol has been potentially noise-impacted, we have that the conditional probability that the corresponding bit has been flipped is $p_{N|S}(1|1) = p \in [0, 1], p_{N|S}(0|1) = 1 - p$ and $p_{N|S}(0|0) = 1$. From equation (7), the soft decoding channel’s capacity is

$$C_{\text{Soft}}(q, p) = 1 - q h_2(p),$$

where $h_2(p) = -(1 - p) \log_2(1 - p) - p \log_2(p)$ is the binary Shannon entropy. The corresponding hard detection channel where $S^o$ is not observed is a Binary Symmetric Channel with probability $P(N = 1) = p(N = 1|S = 1)P(S = 1) = pq$ and so the hard decoding channel capacity is

$$C_{\text{Hard}}(q, p) = 1 - h_2(qp).$$

As $h_2$ is concave, $C_{\text{Soft}}(q, p) \geq C_{\text{Hard}}(q, p)$ for all $q$ and $p$, and so the capacity of the channel with soft detection information is necessarily higher. A plot of the difference in capacity between the soft and hard detection channels, $C_{\text{Soft}}(q, p) - C_{\text{Hard}}(q, p) = h_2(qp) - q h_2(p)$, can be found on the left hand side of Fig. 3. This difference is maximized when $q = 1/2$ and $p = 1$ as the soft detection channel has no uncertainty, with some bits being unaffected by noise and others necessarily being flipped, while the hard detection channel has bit flip probability $qp = 1/2$ and so zero capacity. Although not obvious in that representation, the difference is asymmetric in $p$, which is more apparent when the ratio of capacities $C_{\text{Soft}}(q, p)/C_{\text{Hard}}(q, p)$ is plotted on the right hand side. Depending on the parameterization, the soft detection capacity can be several orders of magnitude larger than the hard detection capacity.

As the symbol reliability information is constructed of i.i.d. elements, the rate function governing the LDP for the proportion of noise impacted symbols, $\{L^n/n\}$ in Assumption 2, is the Kullback-Leibler divergence,

$$I^L(l) = -(1 - l) \log_2 \left( \frac{1 - l}{1 - q} \right) - l \log_2 \left( \frac{l}{q} \right),$$

which has the corresponding sCGF

$$\Lambda^L(\alpha) = \log_2 \left( 1 - q + q 2^\alpha \right).$$

(24)
For error probabilities we employ the conditional probability of a noise impact, \( p \), as the block length increases. For two selections of hard detection channel bit flip probability, representative plots can be found as a function of the code-book rate \( R \). It can be seen in the figure that even though the probability that a bit is potentially noise-impacted, \( q \), decreases the conditional probability of a noise impact, \( p \), increases, the combined effect is to increase the error exponent. Thus, the provision of symbol reliability information significantly reduces the likelihood of that the ML decoding is in error.

Armed with the sCGFs for the proportion of potentially noise impacted bits and for the rescaled logarithm of the guesswork of potentially noise impacted bits, the asymptotic error exponent given in (17) is readily computable numerically. Recall that, as a function of the code-book rate \( R \), this is the exponent in the decay rate in the likelihood than an ML decoding is in error

\[
\Lambda^N(\alpha) = \begin{cases} 
- \log_2 \max(p, 1-p) & \text{if } \alpha \leq -1 \\
- p \log_2(p) - (1-p) \log_2(1-p) & \text{if } \alpha = 1 \\
(1+\alpha) \log_2 \left( p^{1/(1+\alpha)} + (1-p)^{1/(1+\alpha)} \right) & \text{if } \alpha \in (-1, 1) \cup (1, \infty).
\end{cases}
\]

From equation (25), the sCGF for the subordinated guesswork of true noise is \( \Lambda^N_q(\alpha) = \Lambda^L(\Lambda^N(\alpha)) \), where \( \Lambda^L \) and \( \Lambda^N \) are given by equations (24) and (25) respectively. The exponent of the average complexity required to identify the true noise in the soft detection channel is given by

\[
\lim_{n \to \infty} \frac{1}{n} \log_2 E \left( G \left( N_{\alpha}^n \right) \right) = \Lambda^N_q(1) = \Lambda^L(\Lambda^N(1)) = \log_2 \left( 1 - q + q^2 \log_2 \left( \frac{q}{p} \right)^{1/2} + (1-p)^{1/2} \right),
\]

while for the hard detection channel it is

\[
\lim_{n \to \infty} \frac{1}{n} \log_2 E(G(N^p)) = 2 \log_2 \left( \frac{q}{p} \right)^{1/2} + (1-p)^{1/2}.
\]

Plots in Fig. 4 show the difference in the guessing complexity exponents for true noise of the hard detection channel less soft detection channel as a function of \( q \) and \( p \), as well as their ratios. As with the channel capacity, these are maximized when \( q = 1/2 \) and \( p = 1 \), and, in general, the complexity exponent with only hard detection information is substantially larger than that with soft detection information. This indicates that significant reduction in complexity is available through the incorporation of symbol reliability information into the decoding algorithm.

Armed with the sCGFs for the proportion of potentially noise impacted bits and for the rescaled logarithm of the guesswork of potentially noise impacted bits, the asymptotic error exponent given in (17) is readily computable numerically. Recall that, as a function of the code-book rate \( R \), this is the exponent in the decay rate in the likelihood than an ML decoding is in error as the block length increases. For two selections of hard detection channel bit flip probability, representative plots can be found in Fig. 3. It can be seen in the figure that even though the probability that a bit is potentially noise-impacted, \( q \), decreases the conditional probability of a noise impact, \( p \), increases, the combined effect is to increase the error exponent. Thus, the provision of symbol reliability information significantly reduces the likelihood of that the ML decoding is in error.

While prefactors are not captured in that asymptotic analysis in Theorems 1 and 2 they allow the following approximations. For error probabilities we employ

\[
\text{ML prob. of error} \approx 2^{-n \epsilon(R)} \text{ for } R < 1 - q h_2(p),
\]
For a selection of probabilities of noise impacting a transmitted symbol, $q$, and conditional probabilities of a bit-flip given noise, $p$, chosen such that $pq$ is constant and hence the soft and hard detection channels are comparable. The left hand column shows results for $n = 100$, $pq = 10^{-2}$ and a target block error of $10^{-2}$. In the upper plot, the horizontal dashed line is the target error and approximate block error probabilities are shown as a function of code-book rate, $R$, for a selection of $(q,p)$ pairs. When $q = 1$, corresponding to the left-most line, these are results for the ML decoding of a hard detection channel. The lower plot shows the approximate complexity in terms of the number of guesses per-bit that is made on average prior to identification of an element of the code-book, which decreases as soft detection information is provided to the receiver even though the conditional probability of a bit-flip given noise possibly occurred is increasing. The dashed black line gives the approximate complexity for the brute force approach, with circles indicating complexity crossing points. Diamonds indicate the rate above which the target block error rate would be exceeded. The right hand column shows corresponding results, but for $n = 1000$, $pq = 10^{-4}$ and a target block error of $10^{-3}$. Note that the horizontal axes of the top two panels are curtailed at different places.

which holds true regardless of whether it is identified by SGRAND or brute force, where the expression for $\varepsilon(R)$ can be found in equation (17). For SGRAND decoding, our measure of complexity is the average number of guesses per bit per decoding:

$$\text{ML ave. no. guesses / bit} \approx \frac{2^{\min(1-R, L^*(H_1;Z))}}{n}$$

For comparison, we define the complexity of the brute force computation of the ML decoding in equation (3) to be the number of conditional probabilities that must be computed per bit before rank ordering and determining the most likely code-book element:

$$\text{No. conditional prob. computations / bit} = \frac{2^{\sigma R}}{n}.$$ 

Thus we are equating the work performed in one noise guess, which amounts to checking if a string is an element of the code-book, with the computation of one conditional probability.

For two values of block size, $n = 100$ and $n = 1000$, and $(q,p)$ pairs such that $pq$ is constant and so comparable with the hard detection channel, Figure 6 plots the approximate error probabilities and complexity as a function of code-book rate. The upper panels show the error probabilities with a target block error rate indicated by the dashed horizontal line. The provision of soft detection symbol reliability information greatly improves the block error probability, even though in this comparison the conditional probability of a bit flip given soft detection information increases as the soft detection probability decreases.

The lower two panels show the approximate complexity. The dashed line gives the approximate complexity for the brute force approach of computing a conditional probability for every element of the code-book, which grows exponentially in the code-book rate. By contrast, the complexity of the SGRAND approach is initially flat, corresponding to the average number
of guesses until the true noise is identified. As the code-book rate increases, eventually the SGRAND complexity drops as encountering an erroneous element of the code-book clips the long guessing tail of true noise. The diamonds indicate the rate above which the target block error rate would be violated. The provision of soft detection information can be seen to dramatically improve the algorithm’s complexity.

VII. DISCUSSION

We have introduced SGRAND and SGRANDAB, by identifying how to expand the remit of two noise-centric capacity achieving decoding algorithms, GRAND and GRANDAB, to a situation where soft detection symbol reliability information is available. By using the symbol reliability information to mask symbols that are reliable and guessing noise only on unreliable symbols, these algorithms can realise higher rates, with lower error probabilities, and less complexity.

All of the GRAND algorithms are suitable for use with any code-book so long as an efficient method exists to test a string’s of symbols membership of the code-book. For linear codes, testing code-book membership requires only a matrix multiplication over a finite field. For Polar Codes [70], which are linear, even more efficient mechanisms are available. A random code-book, as employed in our normal proofs of capacity and complexity, can be stored in an $A$-ary tree, so that testing code-book membership amounts to a tree search, which can be performed efficiently. Thus all these schemes are universally applicable in the sense that their execution only depends on the structure of the noise rather than how the code-book was constructed. Moreover, guesswork orders are known to be robust to mismatch [71], and so decoding precision should not be sensitive to precision in the channel noise model.

While we presented results for one SGRANDAB abandonment rule that reduces average algorithmic complexity without sacrificing channel capacity, others are possible and, indeed, can be used in combination. Here we mention two more. The first is a natural extension to the rule of abandoning guessing when coverage of the typical set for the average number of potentially noise impacted symbols. In the soft detection model, the specific number of potentially noise-impacted symbols, $L_n$, for each received transmission, $Y^n$, is known to the algorithm and if querying is abandoned after $|A|L_n(H+\delta)$ guesses, which is enough to cover the typical set for that length. Analysis of the impact of this rule on error exponents and complexity follows the same line of argument as presented in the paper, though the resulting expressions are less elegant. A distinct alternative is to not guess at all if too many symbols are reported to be potentially noise impacted; i.e. if $L_n > n(\mu_L+\delta)$. It is straightforward to show this rule does not impact capacity, but an analysis of complexity, which would now be conditional on $L_n \leq n(\mu_L+\delta)$, would not follow readily from the large deviation arguments presented here. The analysis in this paper for codes of fixed length could, however, be readily extended to decoding with soft information for variable length codes [72], [73] and rateless codes.

While we consider soft information at the level of symbol reliability, all of the GRAND algorithms can themselves provide, in addition to a decoding, soft information through the number of noise queries that were performed before a code-book element was identified. A lower number of guesses corresponds to a higher likelihood of correct decoding. Such soft information can be of use, for example, for component codes in a concatenated code or Turbo code [74], [75], [76], [77]. Thus one may envisage using the information on decoding reliability of SGRAND and SGRANDAB in a manner akin to the reliability information provided by the Soft-Output Viterbi Algorithm [74], [75], [76], [77], by the operation of Turbo decoding [77], [80], [81], [82], [83], [84], by the syndrome information used in Ordered Statistics Decoding (OSD) [85], [86], [87], or other soft-input, soft-output schemes [88], [89], [73], [90]. In general, we can envisage in future work systems that meld equalization and decoding as in [91], [92] or soft information originating from other decoding processes, [93], [94], [95], [96], [97].
