Abstract

Recent applications that arise in machine learning have surged significant interest in solving min-max saddle point games. This problem has been extensively studied in the convex-concave regime for which a global equilibrium solution can be computed efficiently. In this paper, we study the problem in the non-convex regime and show that an $\varepsilon$–first order stationary point of the game can be computed when one of the player’s objective can be optimized to global optimality efficiently. In particular, we first consider the case where the objective of one of the players satisfies the Polyak-Łojasiewicz (PL) condition. For such a game, we show that a simple multi-step gradient descent-ascent algorithm finds an $\varepsilon$–first order stationary point of the problem in $\tilde{O}(\varepsilon^{-2})$ iterations. Then we show that our framework can also be applied to the case where the objective of the “max-player” is concave. In this case, we propose a multi-step gradient descent-ascent algorithm that finds an $\varepsilon$–first order stationary point of the game in $\tilde{O}(\varepsilon^{-3.5})$ iterations, which is the best known rate in the literature. We applied our algorithm to a fair classification problem of Fashion-MNIST dataset and observed that the proposed algorithm results in smoother training and better generalization.

1 Introduction

Recent years have witnessed a wide range of machine learning and robust optimization applications being formulated as a min-max saddle point game; see [45, 11, 10, 44, 18, 47] and the references therein. Examples of problems that are formulated under this framework include generative adversarial networks (GANs) [45], reinforcement learning [11], adversarial learning [47], learning exponential families [10], fair statistical inference [16, 50, 46, 33], generative adversarial imitation learning [6, 24], distributed non-convex optimization [31] and many others. These applications

require solving an optimization problem of the form

\[
\min_{\theta \in \Theta} \max_{\alpha \in A} f(\theta, \alpha).
\]  

(1)

This optimization problem can be viewed as a zero-sum game between two players. The goal of the first player is to minimize \( f(\theta, \alpha) \) by tuning \( \theta \), while the other player’s objective is to maximize \( f(\theta, \alpha) \) by tuning \( \alpha \). Gradient-based methods, especially gradient descent-ascent (GDA), are widely used in practice to solve these problems. GDA alternates between a gradient ascent steps on \( \alpha \) and a gradient descent steps on \( \theta \). Despite its popularity, this algorithm fails to converge even for simple bilinear zero-sum games \([36, 34, 13, 2, 28]\). This failure was fixed by adding negative momentum or by using primal-dual methods proposed by \([20, 19, 8, 12, 14, 29]\).

When the objective \( f \) is convex in \( \theta \) and concave in \( \alpha \), the corresponding variational inequality becomes monotone. This setting has been extensively studied and different algorithms have been developed for finding a Nash equilibrium \([40, 19, 39, 26, 35, 21, 23, 38]\). While the convex-concave setting has been extensively studied in the literature, recent machine learning applications urge the necessity of moving beyond this classical setting. For example, in a typical GAN problem formulation, two neural networks (generator and discriminator) compete in a non-convex zero-sum game framework \([22]\).

For general non-convex non-concave games, \([25, \text{Proposition 10}]\) provides an example for which local Nash equilibrium does not exist. Similarly, one can show that even second-order Nash equilibrium may not exist for non-convex games, see Section 2 for more details. Therefore, a well-justified objective is to find first order Nash equilibria of such games \([12]\); see definitions and discussion in Section 2. The first order Nash equilibrium can be viewed as a direct extension of the concept of first order stationarity in optimization to the above min-max game. While \( \varepsilon \)-first order stationarity in the context of optimization can be found efficiently in \( \mathcal{O}(\varepsilon^{-2}) \) iterations with gradient descent algorithm \([11]\), the question of whether it is possible to design a gradient-based algorithm that can find an \( \varepsilon \)-first order Nash equilibrium for general non-convex saddle point games remains open.

Several recent results provided a partial answer to the problem of finding first-order stationary points of a non-convex min-max game. For instance, \([45]\) proposed a stochastic gradient descent algorithm for the case when \( f(\cdot, \cdot) \) is strongly concave in \( \alpha \) and show convergence of the algorithm to an \( \varepsilon \)-first-order Nash equilibrium with \( \tilde{\mathcal{O}}(\varepsilon^{-2}) \) gradient evaluations. More recently, \([31, 32]\) considered the case where \( f \) is concave in \( \alpha \). They developed a descent-ascent algorithm with iteration complexity \( \tilde{\mathcal{O}}(\varepsilon^{-4}) \). In this non-convex concave setting, \([44]\) proposed a stochastic sub-gradient descent method with worst-case complexity \( \tilde{\mathcal{O}}(\varepsilon^{-6}) \). Under the same concavity assumption on \( f \), in this paper, we propose an alternative multi-step framework that finds an \( \varepsilon \)-first order Nash equilibrium/stationary with \( \tilde{\mathcal{O}}(\varepsilon^{-3.5}) \) gradient evaluations, which is superior to the existing iteration complexities. Below is a table that summarizes the results in the non-convex concave setting.
Table 1: Algorithms for solving Min-Max games in the non-convex concave setting.

In an effort to solve the more general non-convex non-concave setting, [30] developed a framework that converges to $\varepsilon$-first order stationarity/Nash equilibrium under the assumption that there exists a solution to the Minty variational inequality at each iteration. Although among the first algorithms with have theoretical convergence guarantees in the non-convex non-concave setting, the conditions required are strong and difficult to check. To the best of our knowledge, there is no practical problem for which the Minty variational inequality condition has been proven. With the motivation of exploring the non-convex non-concave setting, we propose a simple multi-step gradient descent ascent algorithm for the case where the objective of one of the players satisfies the Polyak-Łojasiewicz (PL) condition. We show the worst-case complexity of $O(\varepsilon^{-2})$ for our algorithm. This rate is optimal in terms of dependence on $\varepsilon$ up to logarithmic factors as discussed in Section 3. Compared to Minty variational inequality condition used in [30], the PL condition is very well studied in the literature and has been theoretically verified for objectives of optimization problems arising in many practical problems. For example, it has been proven to be true for objectives of over-parameterized deep networks [15], learning LQR models [17], phase retrieval [48], and many other simple problems discussed in [27]. In the context of min-max games, it has also been proven useful in generative adversarial imitation learning with LQR dynamics [6], as discussed in Section 3.

The rest of this paper is organized as follows. In Section 2, we define the concepts of First-order Nash equilibrium (FNE) and $\varepsilon$–FNE. In Section 3, we describe our algorithm designed for min-max games with the objective of one player satisfying the PL condition. Finally, in Section 4, we describe our method for solving games in which the function $f(\theta, \alpha)$ is concave in $\alpha$ (or convex in $\theta$).

2 Two-player Min-Max Games and First-Order Nash Equilibrium

Consider the two-player zero sum min-max game

$$\min_{\theta \in \Theta} \max_{\alpha \in \mathcal{A}} f(\theta, \alpha),$$

where $\Theta$ and $\mathcal{A}$ are both convex sets, and $f(\theta, \alpha)$ is a continuously differentiable function. We say $(\theta^*, \alpha^*) \in \Theta \times \mathcal{A}$ is a Nash equilibrium of the game if

$$f(\theta^*, \alpha) \leq f(\theta^*, \alpha^*) \leq f(\theta, \alpha^*) \quad \forall \theta \in \Theta, \; \forall \alpha \in \mathcal{A}. $$

$^*$This complexity corresponds to the number of times the inner maximization problem is solved. Thus it does not consider the complexity of solving the inner problem.
In convex-concave games, such a Nash equilibrium always exists [25] and several algorithms were proposed to find Nash equilibria [21, 23]. However, in the non-convex non-concave regime, computing these points is in general NP-Hard. In fact, even finding local Nash equilibria is NP-hard in the general non-convex non-concave regime. In addition, as shown by [25, Proposition 10], local Nash equilibria for general non-convex non-concave games may not exist. Thus, in this paper we aim for the less ambitious goal of finding first-order Nash equilibrium which is defined in the sequel.

**Definition 1 (FNE).** A point \((\theta^*, \alpha^*) \in \Theta \times A\) is a first order Nash equilibrium (FNE) of the game (2) if
\[
\langle \nabla_\theta f(\theta^*, \alpha^*), \theta - \theta^* \rangle \geq 0 \quad \forall \theta \in \Theta \quad \text{and} \quad \langle \nabla_\alpha f(\theta^*, \alpha^*), \alpha - \alpha^* \rangle \leq 0 \quad \forall \alpha \in A.
\]

Notice that this definition, which is also used in [42, 43], contains the first order necessary optimality conditions of the objective function of each player [5]. Thus they are necessary conditions for local Nash equilibrium. Moreover, in the absence of constraints, the above definition simplifies to \(\nabla_\theta f(\theta^*, \alpha^*) = 0\) and \(\nabla_\alpha f(\theta^*, \alpha^*) = 0\), which are the well-known unconstrained first-order optimality conditions. Based on this observation, it is tempting to think that the above first-order Nash equilibrium condition does not differentiate between the min-max type solutions of (2) and min-min solutions of the type \(\min_{\theta \in \Theta, \alpha \in A} f(\theta, \alpha)\). However, the direction of the second inequality in (3) would be different if we had considered the min-min problem instead of min-max problem. This different direction makes the problem of finding a FNE non-trivial. The following theorem guarantees the existence of first-order Nash equilibria under some mild assumptions.

**Theorem 2 (Restated from Proposition 2 in [42]).** Suppose the sets \(\Theta\) and \(A\) are non-empty, compact, and convex. Moreover, assume that the function \(f(\cdot, \cdot)\) is twice continuously differentiable. Then there exists a feasible point \((\bar{\theta}, \bar{\alpha})\) that is first-order Nash equilibrium.

The above theorem guarantees existence of FNE points even when (local) Nash equilibria may not exist. The next natural question is about the computability of such methods. Since in practice we use iterative methods for computation, we need to define the notion of approximate–FNE.

**Definition 3 (Approximate FNE).** A point \((\theta^*, \alpha^*)\) is said to be an \(\varepsilon\)-first-order Nash equilibrium (\(\varepsilon\)-FNE) of the game (2) if
\[
\mathcal{X}(\theta^*, \alpha^*) \leq \varepsilon \quad \text{and} \quad \mathcal{Y}(\theta^*, \alpha^*) \leq \varepsilon,
\]
where
\[
\mathcal{X}(\theta^*, \alpha^*) \triangleq -\min_{\theta} \langle \nabla_\theta f(\theta^*, \alpha^*), \theta - \theta^* \rangle \quad \text{s.t.} \quad \theta \in \Theta, \quad \|\theta - \theta^*\| \leq 1,
\]
and
\[
\mathcal{Y}(\theta^*, \alpha^*) \triangleq \max_{\alpha} \langle \nabla_\alpha f(\theta, \alpha), \alpha - \alpha^* \rangle \quad \text{s.t.} \quad \alpha \in A, \quad \|\alpha - \alpha^*\| \leq 1.
\]

In the absence of constraints, \(\varepsilon\)-FNE in Definition 3 reduces to \(\|\nabla_\theta f(\theta^*, \alpha^*)\| \leq \varepsilon\) and \(\|\nabla_\alpha f(\theta^*, \alpha^*)\| \leq \varepsilon\).

**Remark 4.** The \(\varepsilon\)-FNE definition above is based on the first order optimality measure of the objective of each player. Such first-order optimality measure has been used before in the context of optimization; see [9]. Such a condition guarantees that each player cannot improve their objective function using first order information. Similar to the optimization setting, one can define the
second-order Nash equilibrium as a point that each player cannot improve their objective further by using first and second order information of their objectives. However, the use of second order Nash equilibria is more subtle in the context of games. The following example shows that such a point may not exist. Consider the game

\[
\min_{-1 \leq \theta \leq 1} \max_{-2 \leq \alpha \leq 2} -\theta^2 + \alpha^2 + 4\theta\alpha.
\]

Then \((0, 0)\) is the only first-order Nash equilibrium and is not a second-order Nash equilibrium.

In this paper, our goal is to find an \(\varepsilon\)-FNE of the game \((2)\) using iterative methods. To proceed, we make the following standard assumptions about the smoothness of the objective function \(f\).

**Assumption 5.** The function \(f\) is continuously differentiable in both \(\theta\) and \(\alpha\) and there exists constants \(L_{11}, L_{22}\) and \(L_{12}\) such that for every \(\alpha, \alpha_1, \alpha_2 \in \mathcal{A}\), and \(\theta, \theta_1, \theta_2 \in \Theta\), we have

\[
\|\nabla_{\theta} f(\theta_1, \alpha) - \nabla_{\theta} f(\theta_2, \alpha)\| \leq L_{11} \|\theta_1 - \theta_2\|,
\]

\[
\|\nabla_{\alpha} f(\theta, \alpha_1) - \nabla_{\alpha} f(\theta, \alpha_2)\| \leq L_{22} \|\alpha_1 - \alpha_2\|,
\]

\[
\|\nabla_{\alpha} f(\theta_1, \alpha) - \nabla_{\alpha} f(\theta_2, \alpha)\| \leq L_{12} \|\theta_1 - \theta_2\|,
\]

\[
\|\nabla_{\theta} f(\theta, \alpha_1) - \nabla_{\theta} f(\theta, \alpha_2)\| \leq L_{12} \|\alpha_1 - \alpha_2\|.
\]

### 3 Non-Convex PL-Game

In this section, we consider the problem of developing an “efficient” algorithm for finding an \(\varepsilon\)-FNE of \((2)\) when the objective of one of the players satisfies Polyak-Łojasiewicz (PL) condition. To proceed, let us first formally define the Polyak-Łojasiewicz (PL) condition.

**Definition 6 (Polyak-Łojasiewicz Condition).** A differentiable function \(h(x)\) with the minimum value \(h^* = \min_x h(x)\) is said to be \(\mu\)-Polyak-Łojasiewicz (\(\mu\)-PL) if

\[
\frac{1}{2}\|\nabla h(x)\|^2 \geq \mu(h(x) - h^*), \forall x.
\]

The PL-condition has been established and utilized for analyzing many practical modern problems [27, 17, 15, 48, 6]. Moreover, it is well-known that a function can be non-convex and still satisfy the PL condition [27]. Based on the definition above, we define a class of min-max PL-games.

**Definition 7 (PL-Game).** We say that the min-max game \((2)\) is a PL-Game if the max player is unconstrained, i.e., \(\mathcal{A} = \mathbb{R}^n\), and there exists a constant \(\mu > 0\) such that the function \(h_\theta(\alpha) \triangleq -f(\theta, \alpha)\) is \(\mu\)-PL for any fixed value of \(\theta \in \Theta\).

A simple example of a practical PL-game is detailed next.

**Example 8 (Generative adversarial imitation learning of linear quadratic regulators).** Imitation learning is a paradigm that aims to learn from an expert’s demonstration of performing a task [6]. It is known that this learning process can be formulated as a min-max game [22]. In such a game the minimization is performed over all the policies and the goal is to minimize the discrepancy between the accumulated reward for expert’s policy and the proposed policy. On the other hand, the maximization is done over the parameters of the reward function and aims at maximizing this discrepancy over the parameters of the reward function. This approach is also referred to as generative adversarial imitation learning (GAIL) [27]. The problem of generative adversarial imitation learning for linear quadratic regulators [6] refers to solving this problem for the specific case where the underlying
dynamic and the reward function come from a linear quadratic regulator [17]. To be more specific, this problem can be formulated [6] as

$$\min_{K} \max_{\theta \in \Theta} m(K, \theta),$$

where $K$ represents the choice of the policy and $\theta$ represents the parameters of the dynamic and the reward functions. Under the discussed setting, $m$ is strongly concave in $\theta$ and PL in $K$ (see [6] for more details). Note that since $m$ is strongly concave in $\theta$ and PL in $K$, any FNE of the game would also be a Nash equilibrium point. Also note that the notion of FNE does not depend on the ordering of the min and max. Thus, to be consistent with our notion of PL-games, we can formulate the problem as

$$\min_{\theta \in \Theta} \max_{K} -m(K, \theta)$$

(7)

Thus, generative adversarial imitation learning of linear quadratic regulators is an example of finding a FNE for a min-max PL-game.

In what follows, we present a simple iterative method for computing an $\varepsilon$–FNE of PL games.

3.1 Multi-step gradient descent ascent for PL-games

In this section, we propose a multi-step gradient descent ascent algorithm that finds an $\varepsilon$–FNE point for PL-games. At each iteration, our method runs multiple projected gradient ascent steps to estimate the solution of the inner maximization problem. This solution is then used to estimate the gradient of the inner maximization value function, which directly provides a descent direction. In a nutshell, our proposed algorithm is a gradient descent-like algorithm on the inner maximization value function. To present the ideas of our multi-step algorithm, let us re-write (2) as

$$\min_{\theta \in \Theta} g(\theta),$$

(8)

where

$$g(\theta) \triangleq \max_{\alpha \in A} f(\theta, \alpha).$$

(9)

A famous classical result in optimization is Danskin’s theorem [4] which provides a sufficient condition under which the gradient of the value function $\max_{\alpha \in A} f(\theta, \alpha)$ can be directly evaluated using the gradient of the objective $f(\theta, \alpha^*)$ evaluated at the optimal solution $\alpha^*$. This result requires the optimizer $\alpha^*$ to be unique. Under our PL assumption on $f(\theta, \cdot)$, the inner maximization problem (9) may have multiple optimal solutions. Hence, Danskin’s theorem does not directly apply. However, as we will show in Lemma 22 in the supplementary, under the PL assumption, we still can show the following result

$$\nabla_{\theta} g(\theta) = \nabla_{\theta} f(\theta, \alpha^*) \quad \text{with} \quad \alpha^* \in \arg \max_{\alpha \in A} f(\theta, \alpha),$$

despite the non-uniqueness of the optimal solution.

Motivated by this result, we propose a Multi-step Gradient Descent Ascent algorithm that solves the inner maximization problem to “approximate” the gradient of the value function $g$. This gradient direction is then used to descent on $\theta$. More specifically, the inner loop (Step 4) in Algorithm 1 solves the maximization problem (9) for a given fixed value $\theta = \theta_t$. The computed solution of this optimization problem provides an approximation for the gradient of the function $g(\theta)$, see Lemma 23 in Appendix A. This gradient is then used in Step 7 to descent on $\theta$. 
Algorithm 1 Multi-step Gradient Descent Ascent

1: INPUT: $K$, $T$, $\eta_1 = 1/L_2^2$, $\eta_2 = 1/L$, $\alpha_0 \in \mathcal{A}$ and $\theta_0 \in \Theta$
2: for $t = 0, \ldots, T - 1$ do
3: Set $\alpha_0(\theta_t) = \alpha_t$
4: for $k = 0, \ldots, K - 1$ do
5: Set $\alpha_{k+1}(\theta_t) = \alpha_k(\theta_t) + \eta_1 \nabla_{\alpha} f(\theta_t, \alpha_k(\theta_t))$
6: end for
7: Set $\theta_{t+1} = \text{proj}_{\Theta}(\theta_t - \eta_2 \nabla_{\theta} f(\theta_t, \alpha_K(\theta_t)))$
8: end for
9: Return $(\theta_t, \alpha_K(\theta_t))$ for $t = 0, \ldots, T - 1$.

3.2 Convergence analysis of Multi-Step Gradient Descent Ascent Algorithm for PL games

Throughout this section, we make the following assumption.

Assumption 9. The constraint set $\Theta$ is convex and compact. Moreover, there exists a ball with radius $R$, denoted by $B_R$, such that $\Theta \subseteq B_R$.

We are now ready to state the main result of this section.

Theorem 10. Under Assumptions 5 and 9, for any given scalar $\varepsilon \in (0, 1)$, if we choose $K$ and $T$ large enough such that

$$T \geq N_T(\varepsilon) \triangleq O(\varepsilon^{-2}) \quad \text{and} \quad K \geq N_K(\varepsilon) \triangleq O(\log(\varepsilon^{-1})),$$

then there exists an iteration $t \in \{0, \ldots, T\}$ such that $(\theta_t, \alpha_{t+1})$ is an $\varepsilon$-FNE of (2).

Proof. The proof is relegated to Appendix A.2.

Corollary 11. Under Assumption 5 and Assumption 9, Algorithm 1 finds an $\varepsilon$-FNE of the game (2) with $O(\varepsilon^{-2})$ gradient evaluations of the objective with respect to $\theta$ and $O(\varepsilon^{-2} \log(\varepsilon^{-1}))$ gradient evaluations with respect to $\alpha$. If the two gradient oracles have the same complexity, the overall complexity of the method would be $O(\varepsilon^{-2} \log(\varepsilon^{-1}))$.

Remark 12. The iteration complexity order $O(\varepsilon^{-2} \log(\varepsilon^{-1}))$ in Theorem 10 is tight (up to logarithmic factors). This is due to the fact that for general non-convex smooth problems, finding an $\varepsilon$-stationary solution requires at least $\Omega(\varepsilon^{-2})$ gradient evaluations [7, 41]. Clearly, this lower bound is also valid for finding an $\varepsilon$-FNE of PL-games. This is because we can assume that the function $f(\theta, \alpha)$ does not depend on $\alpha$ (and thus PL in $\alpha$).

Remark 13. Theorem 10 shows that under the PL assumption, the pair $(\theta_t, \alpha_K(\theta_t))$ computed by Algorithm 1 is an $\varepsilon$-FNE of the game (2). Since $\alpha_K(\theta_t)$ is an approximate solution of the inner maximization problem, we get that $\theta_t$ is concurrently an $\varepsilon$-first order stationary solution of the optimization problem (8).

Remark 14. In [45, Theorem 4.2], a similar result was shown for the case when $f(\theta, \alpha)$ is strongly concave in $\alpha$. Hence, Theorem 10 can be viewed as an extension of [45, Theorem 4.2]. Similar to [45, Theorem 4.2], one can easily extend the result of Theorem 10 to the stochastic setting by replacing the gradients with stochastic gradients.
In the next section we consider the non-convex concave min-max saddle game. It is well-known that convexity/concavity does not imply the PL condition and PL condition does not imply convexity/concavity \cite{27}. Therefore, the problems we consider in the next section are neither restriction nor extension of our results on PL games.

4 Non-Convex Concave Games

In this section, we focus on "non-convex concave" games satisfying the following assumption:

\textbf{Assumption 15.} The objective function $f(\theta, \alpha)$ is concave in $\alpha$ for any fixed value of $\theta$. Moreover, the set $A$ is convex and compact, and there exists a ball with radius $R$ that contains the feasible set $A$.

One major difference of this case with the PL-games is that in this case the function $g(\theta) = \max_{\alpha \in A} f(\theta, \alpha)$ might not be differentiable. To see this, consider the example $g(\alpha) = \max_{0 \leq \alpha \leq 1} (2\alpha - 1)\theta$ which is concave in $\alpha$. However, the value function $g(\theta) = |\theta|$ is non-smooth. Using a small regularization term, we approximate the function $g(\cdot)$ by a differentiable function

$$g_\lambda(\theta) \triangleq \max_{\alpha \in A} f_\lambda(\theta, \alpha),$$ \hspace{1cm} (10)

where $f_\lambda(\theta, \alpha) \triangleq f(\theta, \alpha) - \frac{\lambda}{2}\|\alpha - \bar{\alpha}\|^2$. Here $\bar{\alpha} \in A$ is some given fixed point and $\lambda > 0$ is a regularization parameter that we will specify later. Since $f(\theta, \alpha)$ is concave in $\alpha$, $f_\lambda(\theta, \cdot)$ is $\lambda$-strongly concave. Thus, the function $g_\lambda(\cdot)$ becomes smooth with Lipschitz gradient; see Lemma \cite{24} in the supplementary. Using this property, we propose an algorithm that runs at each iteration multiple steps of Nesterov accelerated projected gradient ascent to estimate the solution of \cite{10}. This solution is then used to estimate the gradient of $g_\lambda(\theta)$ which directly provides a descent direction on $\theta$. Our algorithm computes an $\varepsilon$-FNE point for non-convex concave games with $O(\varepsilon^{-3.5})$ gradient evaluations. Then for sufficiently small regularization coefficient, we show that the computed point is an $\varepsilon$-FNE.

Notice that since $f_\lambda$ is Lipschitz smooth and based on the compactness assumption, we can define

$$g_\theta \triangleq \max_{\theta \in \Theta} \|\nabla g_\lambda(\theta)\|, \hspace{0.5cm} g_\alpha \triangleq \max_{\theta \in \Theta} \|\nabla_\alpha f_\lambda(\theta, \alpha^*(\theta))\|, \hspace{0.5cm} \text{and} \hspace{0.5cm} g_{\text{max}} = \max\{g_\theta, g_\alpha, 1\},$$ \hspace{1cm} (11)

where $\alpha^*(\theta) \triangleq \arg \max_{\alpha \in A} f_\lambda(\theta, \alpha)$. We are now ready to describe our proposed algorithm.

4.1 Algorithm Description

Our proposed method is outlined in Algorithm \cite{2}. This algorithm has two steps: step 2 and step 3. In step 2, $K$ steps of accelerated gradient ascent method is run over the variable $\alpha$ to find an approximate maximizer of the problem $\max_\alpha f_\lambda(\theta_t, \alpha)$. Then using approximate maximizer $\alpha_{t+1}$, we update $\theta$ variable using one step of first order methods in step 3.

8
Algorithm 2 Multi-Step Frank Wolfe/Projected Gradient Step Framework

Require: Constants $\bar{L} \triangleq \max\{L, L_{12}, g_{\max}\}$, $N \triangleq \lceil \sqrt{8L_{22}/\lambda} \rceil$, $K$, $T$, $\eta$, $\lambda$, $\theta_0 \in \Theta$, $\alpha_0 \in A$

1: for $t = 0, 1, 2, \ldots, T$ do
2: \hspace{1em} Set $\alpha_{t+1} = \text{APGA}(\alpha_t, \theta_t, \eta, N, K)$ by running $K$ steps of Accelerated Projected Gradient Ascent subroutine (Algorithm 3) with periodic restart at every $N$ iteration.
3: \hspace{1em} Compute $\theta_{t+1}$ using first-order information (Frank-Wolfe or projected gradient descent).
4: end for

In step 2, we run $K$ step of accelerated gradient ascent algorithm over the variable $\alpha$ with restart every $N$ iterations. The details of this subroutine can be found in subsection B.1 of the supplementary materials. In step 3 of Algorithm 2 we can either use projected gradient descent update rule

$$
\theta_{t+1} \triangleq \text{proj}_\Theta \left( \theta_t - \frac{1}{L_{11} + L_{12}^2/\lambda} \nabla f_{\lambda}(\theta_t, \alpha_{t+1}) \right),
$$

or Frank-Wolfe update rule described in subsection B.2 in the supplementary material. We show convergence of the algorithm to $\epsilon$–FNE in Theorems 16.

\textbf{Theorem 16.} Given a scalar $\epsilon \in (0, 1)$. Assume that Step 7 in Algorithm 2 sets either runs projected gradient descent or Frank-Wolfe iteration. Under Assumptions 15 and 5,

$$
\eta = \frac{1}{L_{22}}, \quad \lambda \triangleq \frac{\epsilon}{4R}, \quad T \geq N_T(\epsilon) \triangleq \mathcal{O}(\epsilon^{-3}), \quad \text{and} \quad K \geq N_K(\epsilon) \triangleq \mathcal{O}(\epsilon^{-1/2} \log(1/\epsilon)),
$$

then there exists $t \in \{0, \ldots, T\}$ such that $(\theta_t, \alpha_{t+1})$ is an $\epsilon$–FNE of problem (2).

\textit{Proof.} The proof is relegated to Appendix B.4. \qed

\textbf{Corollary 17.} Under Assumptions 6 and 15, Algorithm 2 finds an $\epsilon$-first-order stationary solution of the game (2) with $\mathcal{O}(\epsilon^{-3})$ gradient evaluations of the objective with respect $\theta$ and $\mathcal{O}(\epsilon^{-3.5} \log(1/\epsilon))$ gradient evaluations with respect to $\alpha$. If the two oracles have the same complexity, the overall complexity of the method would be $\mathcal{O}(\epsilon^{-3.5} \log(1/\epsilon))$.

5 \hspace{0.5em} Numerical Results

We evaluate the numerical performance of Algorithm 2 by performing an experiment on the Fashion MNIST dataset [49]. This dataset consists of $28 \times 28$ arrays of grayscale pixel images classified into 10 categories of clothing. It includes 60,000 training images and 10,000 testing images.

\textbf{Experimental Setup:} A recent work in [37] observed that training a logistic regression model to classify the images of the Fashion MNIST dataset can be biased against certain categories. To remove this bias, [37] proposed to minimize the maximum loss incurred by the different categories. We repeat the experiment when using a more complex Convolutional Neural Network (CNN) model for classification. Similar to [37], we limit our experiment to the three categories T-shirt/top, Coat,
and Shirts, that correspond to the lowest three testing accuracies achieved by the trained classifier. To minimize the maximum loss over these three categories, we train the classifier to minimize

\[
\min_{W} \max_{i=1}^{3} \{ \mathcal{L}_i(W) \}, \quad (12)
\]

where \( W \) represents the parameters of the CNN; and \( \mathcal{L}_1, \mathcal{L}_2, \) and \( \mathcal{L}_3 \) correspond to the loss incurred by samples in T-shirt/top, Coat, and Shirt categories. Problem (12) can be re-written as

\[
\min_{W} \max_{t_1, t_2, t_3} \sum_{i=1}^{3} t_i \mathcal{L}_i(W) \quad \text{s.t.} \quad t_i \geq 0 \quad \forall \ i = 1, 2, 3; \quad \sum_{i=1}^{3} t_i = 1.
\]

Clearly the inner maximization problem is concave. To empirically evaluate the regularization scheme proposed in Section 4, we implement two versions of Algorithm 2. The first version solves at each iteration the regularized strongly concave problem

\[
\max_{t_1, t_2, t_3} \sum_{i=1}^{3} t_i \mathcal{L}_i(W) - \lambda \sum_{i=1}^{3} t_i^2 \quad \text{s.t.} \quad t_i \geq 0 \quad \forall \ i = 1, 2, 3; \quad \sum_{i=1}^{3} t_i = 1, \quad (13)
\]

and use the optimum \( t \) to perform a gradient descent step on \( W \). The second version of Algorithm 2 solves at each iteration the concave inner maximization problem without the regularization term. Then uses the computed solution to perform a descent step on \( W \). Notice that in both cases, the optimization with respect to \( t \) variable can be done in almost closed-form update. Although regularization is required to have theoretical convergence guarantees, we compare the two versions of the algorithm on empirical data to determine whether these theoretical advantages appear in experimental results. We further compare these two algorithms with normal training that uses gradient descent to minimize the averages loss among the three categories. We run all algorithms for 5500 epochs and record the test accuracies of each category. To reduce the effect of random initialization, we run our methods with 50 different random initializations and record the average and standard deviation of the accuracies collected. For fair comparison, the same initialization is used for all methods in each run. The results are summarized in Tables 2. To test our framework in stochastic settings, we repeat the experiment running all algorithms for 12,000 iterations with Adam optimizer with a batch size of 600 images (200 from each category). The results of the second experiment are summarized in Table 3. The model architecture and parameters are detailed in Appendix C.

**Results:** Tables 2 and 3 show the average and standard deviation of the number of correctly classified samples. The average and standard deviation are taken over 50 runs. For each run 1000 testing samples are considered for each category. The results show that when using MinMax and MinMax with regularization, the accuracies across the different categories are more balanced compared to normal training. Moreover, the tables show that Algorithm 2 with regularization provides a slightly better worst-case performance compared to the unregularized approach. Note that the advantages are larger for the stochastic algorithm, i.e., Adam, in the regularized setting compared to unregularized one; see Table 3. Figure 1 depicts a sample trajectory of deterministic algorithm applied in both settings. This figures shows that regularization provides a smoother and slightly faster convergence compared to the unregularized approach.

A Proofs for results in Section 3

Before proceeding to the proofs of the main results, we need some intermediate lemmas and preliminary definitions.

**Definition 18.** A function $h(x)$ is said to satisfy the Quadratic Growth (QG) condition with constant $\gamma > 0$ if

$$h(x) - h^* \geq \frac{\gamma}{2} \text{dist}(x)^2,$$

where $h^*$ is the minimum value of the function, and $\text{dist}(x)$ is the distance of the point $x$ to the optimal solution set.

The following lemma shows that PL implies QG [27].

**Lemma 19** (Corollary of Theorem 2 in [27]). If function $f$ is PL with constant $\mu$, then $f$ satisfies the quadratic growth condition with constant $\gamma = 4\mu$.

The next Lemma shows the stability of $\arg \max_\alpha f(\theta, \alpha)$ with respect to $\theta$ under PL condition.

**Lemma 20.** Assume that $\{h_\theta(\alpha) = -f(\theta, \alpha) \mid \theta \}$ is a class of $\mu$-PL functions in $\alpha$. Define $A(\theta) = \arg \max_\alpha f(\theta, \alpha)$ and assume $A(\theta)$ is closed. Then for any $\theta_1$, $\theta_2$ and $\alpha_1 \in A(\theta_1)$, there exists an $\alpha_2 \in A(\theta_2)$ such that

$$\|\alpha_1 - \alpha_2\| \leq \frac{L_{12}}{2\mu} \|\theta_1 - \theta_2\| \quad (14)$$

**Proof.** Based on the Lipchitzness of the gradients, we have that $\|\nabla_\alpha f(\theta_2, \alpha_1)\| \leq L_12\|\theta_1 - \theta_2\|$. Then using the PL condition, we know that

$$g(\theta_2) + h_{\theta_2}(\alpha_1) \leq \frac{L_{12}^2}{2\mu} \|\theta_1 - \theta_2\|^2. \quad (15)$$

Now we use the result of Lemma 19 to show that there exists $\alpha_2 = \arg \min_{\alpha \in A(\theta_2)} \|\alpha - \alpha_1\|^2 \in A(\theta_2)$ such that

$$2\mu \|\alpha_1 - \alpha_2\|^2 \leq \frac{L_{12}^2}{2\mu} \|\theta_1 - \theta_2\|^2 \quad (16)$$

re-arranging the terms, we get the desired result that

$$\|\alpha_1 - \alpha_2\| \leq \frac{L_{12}}{2\mu} \|\theta_1 - \theta_2\|. \quad \square$$

Finally, the following lemma would be useful in the proof of Theorem 10.

**Lemma 21** (See Theorem 5 in [27]). Assume $h(x)$ is $\mu$-PL and $L$-smooth. Then, by applying gradient descent with step-size $1/L$ from point $x_0$ for $K$ iterations we get an $x_K$ such that

$$h(x) - h^* \leq \left(1 - \frac{\mu}{L}\right)^K (h(x_0) - h^*), \quad (17)$$

where $h^* = \min_x h(x)$.

We are now ready to prove the results in Section 3.
A.1 Danskin-type Lemma for PL Functions

Lemma 22. Under Assumption 3 and PL-game assumption,
\[ \nabla g(\theta) = \nabla f(\theta, \alpha^*), \quad \text{where} \quad \alpha^* \in \arg\max_{\alpha \in A} f(\theta, \alpha). \]

Moreover, \( g \) is \( L \)-Lipschitz smooth with \( L = L_{11} + \frac{L_{12}^2}{2\mu} \).

Proof. Let \( \alpha^* \in \arg\max_{\alpha \in A} f(\theta, \alpha) \). By Lemma 20 for any scalar \( \tau \) and direction \( d \), there exists \( \alpha^*(\tau) \in \arg\max_{\alpha} f(\theta + \tau d, \alpha) \) such that
\[ \|\alpha^*(\tau) - \alpha^*\| \leq \frac{L_{12}}{2\mu} \tau \|d\|. \]

Using Taylor expansion, we get
\[
g(\theta + \tau d) - g(\theta) = f(\theta + \tau d, \alpha^*(\tau)) - f(\theta, \alpha^*) = \tau \nabla f(\theta, \alpha^*)^T d + \underbrace{\nabla f(\theta, \alpha^*)^T (\alpha^*(\tau) - \alpha^*)}_{0} + O(\tau^2). \]

Thus, by definition of the directional derivative of \( g \), we obtain
\[
g'(\theta; d) = \lim_{\tau \to 0^+} \frac{g(\theta + \tau d) - g(\theta)}{\tau} = \nabla f(\theta, \alpha^*)^T d. \tag{18} \]

Note that this relationship holds for any \( d \). Thus, \( \nabla g(\theta) = \nabla f(\theta, \alpha^*) \) for any \( \alpha^* \in \arg\max_{\alpha \in A} f(\theta, \alpha) = A(\theta) \). Interestingly, the directional derivative does not depend on the choice of \( \alpha^* \). This means that \( \nabla f(\theta, \alpha_1) = \nabla f(\theta, \alpha_2) \) for any \( \alpha_1 \) and \( \alpha_2 \) in \( \arg\max_{\alpha \in A} f(\theta, \alpha) \).

We finally show that function \( g \) is Lipschitz smooth. Let \( \alpha_1^* \in A(\theta_1) \) and \( \alpha_2^* = \arg\min_{\alpha \in A(\theta_2)} \|\alpha - \alpha_1^*\|^2 \in A(\theta_2) \), then
\[
\|\nabla g(\theta_1) - \nabla g(\theta_2)\| = \|\nabla f(\theta_1, \alpha_1^*) - \nabla f(\theta_2, \alpha_2^*)\|
\leq \|\nabla f(\theta_1, \alpha_1^*) - \nabla f(\theta_2, \alpha_1^*) + \nabla f(\theta_2, \alpha_1^*) - \nabla f(\theta_2, \alpha_2^*)\|
\leq L_{11} \|\theta_1 - \theta_2\| + L_{12} \|\alpha_1^* - \alpha_2^*\|
\leq \left( L_{11} + \frac{L_{12}^2}{2\mu} \right) \|\theta_1 - \theta_2\|. \]

where the last inequality holds by Lemma 20.

\[ \]

A.2 Proof of Theorem 10

Using Lemma 22 and Assumption 9, we can define
\[ g_\theta \triangleq \max_{\theta \in \Theta} \|\nabla g(\theta)\| \quad \text{and} \quad g_{\max} \triangleq \max\{g_\theta, 1\}. \tag{19} \]

The next result shows that the inner loop in Algorithm 1 computes an approximate gradient of \( g(\cdot) \). In other words, \( \nabla f(\theta_t, \alpha_{t+1}) \approx \nabla g(\theta_t) \).

17
Lemma 23. Define }\kappa = \frac{L_{22}}{\mu} \geq 1 \text{ and } \rho = 1 - \frac{1}{\kappa} < 1 \text{ and assume } g(\theta_t) - f(\theta_t, \alpha_0(\theta_t)) < \Delta, \text{ then for any prescribed } \varepsilon \in (0, 1) \text{ if we choose } K \text{ large enough such that}

\begin{equation}
K \geq N_K(\varepsilon) \triangleq \frac{1}{\log 1/\rho} \left(4 \log(1/\varepsilon) + \log(2^{15/6} R^6 \Delta / L^2 \mu)\right), \tag{20}
\end{equation}

where } \bar{L} = \max\{L_{12}, L_{22}, L_{g_{\max}}, 1\} \text{ and } \bar{R} = \max\{R, 1\}, \text{ then the error } e_t \triangleq \nabla_\theta f(\theta_t, \alpha_K(\theta_t)) - \nabla g(\theta_t) \text{ has a norm}

\begin{align}
\|e_t\| &\leq \delta \triangleq \frac{L \varepsilon^2}{2^6 R(g_{\max} + LR)^2} \quad \text{and} \quad \|
abla_\alpha f(\theta_t, \alpha_K(\theta_t))\| \leq \varepsilon. \tag{21}
\end{align}

Proof. First of all, Lemma 21 implies that

\begin{equation}
g(\theta_t) - f(\theta_t, \alpha_K(\theta_t)) \leq \rho^K \Delta. \tag{22}
\end{equation}

Thus, using the QG result of Lemma 19, we know that there exists an } \alpha^* \in A(\theta_t) \text{ such that

\begin{equation}
\|\alpha_K(\theta_t) - \alpha^*\| \leq \rho^{K/2} \sqrt{\frac{\Delta}{2\mu}}. \tag{23}
\end{equation}

Thus,

\begin{align}
\|e_t\| &= \|\nabla_\theta f(\theta_t, \alpha_K(\theta_t)) - \nabla g(\theta)\| \leq L_{12}\|\alpha_K(\theta_t) - \alpha^*\| \\
&\leq L_{12}\rho^{K/2} \sqrt{\frac{\Delta}{2\mu}} \\
&\leq \frac{L \varepsilon^2}{2^6 R(g_{\max} + LR)^2}, \tag{24}
\end{align}

where the last inequality holds by our choice of } K \text{ which yields

\begin{equation}
\rho^K \leq \frac{2^6 L^2 \varepsilon^4 \mu}{2^{12} \Delta R^2 L^2 (2LR)^4} \leq \frac{2^6 L^2 \varepsilon^4 \mu}{2^{12} \Delta R^2 L^2 (\bar{L} + LR)^4} \leq \frac{2^6 L^2 \varepsilon^4 \mu}{2^{12} \Delta R^2 L^2 (g_{\max} + LR)^4} \leq \frac{2^6 L^2 \varepsilon^4 \mu}{2^{12} \Delta R^2 L^2 (g_{\max} + LR)^4}. \tag{25}
\end{equation}

Here the second inequality holds since } \bar{R} \geq 1, \text{ and the third inequality holds since } g_{\max} \leq \bar{L}. \text{ To prove the argument of the Lemma, note that

\begin{equation}
\|\nabla_\alpha f(\theta_t, \alpha_K(\theta_t)) - \nabla_\alpha f(\theta_t, \alpha^*)\| \leq L_{22}\|\alpha_K(\theta_t) - \alpha^*\| \leq L_{22}\rho^{K/2} \sqrt{\frac{\Delta}{2\mu}} \leq \varepsilon, \tag{25}
\end{equation}

where the last inequality holds by our choice of } K \text{ which yields

\begin{equation}
\rho^K \leq \left(\frac{\varepsilon^2 \mu}{L^2 \Delta}\right)^{4} \left(\frac{\varepsilon^2 L^2}{2^{15} L^4 R^4}\right) \leq \frac{\varepsilon^2 \mu}{L^2 \Delta}. \tag{25}
\end{equation}

Here the second inequality holds since } \varepsilon < 1, \bar{L}, \bar{R} \geq 1, \text{ and } L \leq \bar{L}.
The above lemma implies that Algorithm \(^{1}\) behaves similar to the simple vanilla gradient descent method applied to problem \(^{8}\).

Notice that the assumption \(g(\theta_t) - f(\theta_t, \alpha_0(\theta_t)) \leq \Delta, \ \forall t\) could be justified by Lemma \(^{20}\). More specifically, by Lemma \(^{20}\)

\[
\|\alpha_{t+1} - \alpha_t\| \leq \frac{L_{12}}{2\mu} \|\theta_{t+1} - \theta_t\|,
\]

where \(\alpha_{t+1} \triangleq \arg\max_\alpha f(\theta_{t+1}, \alpha)\) and \(\alpha_t \triangleq \arg\max_\alpha f(\theta_t, \alpha)\). Hence, the difference between consecutive optimal solutions computed by the inner loop of the algorithm, are upper bounded by the difference between corresponding \(\theta\)'s. Since \(\Theta\) is a compact set, we can find an upper bound \(\Delta\) such that \(g(\theta_t) - f(\theta_t, \alpha_0(\theta_t)) \leq \Delta\), for all \(t\). We are now ready to show Theorem \(^{10}\).

**Proof.** We start by defining

\[
\Delta_g = g(\theta_0) - g^*,
\]

where \(g^* \triangleq \min_\theta g(\theta)\) is the optimal value of \(g\). Note that by the compactness assumption of the set \(\Theta\), we have \(\Delta_g = g(\theta_0) - g^* < \infty\).

Based on the projection property, we know that

\[
\langle \theta_t - \frac{1}{L} \nabla_\theta f(\theta_t, \alpha) - \theta, \theta - \theta_t \rangle \leq 0 \quad \forall \ \theta \in \Theta.
\]

Therefore, by setting \(\theta = \theta_t\), we get

\[
\langle \nabla_\theta f(\theta_t, \alpha_{t+1}), \theta_{t+1} - \theta_t \rangle \leq -L \|\theta_t - \theta_{t+1}\|^2,
\]

which implies

\[
\langle \nabla_\theta f(\theta_t, \alpha^*(\theta_t)), \theta_{t+1} - \theta_t \rangle \leq -L \|\theta_t - \theta_{t+1}\|^2 + \langle \nabla_\theta f(\theta_t, \alpha^*(\theta_t)) - \nabla_\theta f(\theta_t, \alpha_{t+1}), \theta_{t+1} - \theta_t \rangle
\]

\[
= -L \|\theta_t - \theta_{t+1}\|^2 + \langle e_t, \theta_t - \theta_{t+1} \rangle
\]

where \(\alpha^*(\theta_t) \in \arg\max_{\alpha \in \mathcal{A}} f(\theta_t, \alpha)\) and \(e_t \triangleq \nabla_\theta f(\theta_t, \alpha_{t+1}) - \nabla_\theta f(\theta_t, \alpha^*(\theta_t))\). By Taylor expansion, we have

\[
g(\theta_{t+1}) \leq g(\theta_t) + \langle \nabla_\theta f(\theta_t, \alpha^*(\theta_t)), \theta_{t+1} - \theta_t \rangle + \frac{L}{2} \|\theta_{t+1} - \theta_t\|^2
\]

\[
\leq g(\theta_t) - \frac{L}{2} \|\theta_{t+1} - \theta_t\|^2 + \langle e_t, \theta_t - \theta_{t+1} \rangle.
\]

where the last inequality holds by \(^{26}\). Moreover, by the projection property, we know that

\[
\langle \nabla_\theta f(\theta_t, \alpha_{t+1}), \theta - \theta_{t+1} \rangle \geq L \langle \theta_t - \theta_{t+1}, \theta - \theta_{t+1} \rangle \quad \forall \ \theta \in \Theta,
\]

which implies

\[
\langle \nabla_\theta f(\theta_t, \alpha_{t+1}), \theta - \theta_t \rangle \geq \langle \nabla_\theta f(\theta_t, \alpha_{t+1}), \theta_{t+1} - \theta_t \rangle + L \langle \theta_t - \theta_{t+1}, \theta - \theta_{t+1} \rangle
\]

\[
\geq -(g_{\max} + 2LR + \|e_t\|) \|\theta_{t+1} - \theta_t\|
\]

\[
\geq -2(g_{\max} + LR) \|\theta_{t+1} - \theta_t\|.
\]

19
Here the second inequality holds by Cauchy-Schwartz, the definition of \(e_t\) and our assumption that \(\Theta \subseteq B_R\). Moreover, the last inequality holds by our choice of \(K\) in Lemma 23 which yields

\[
\|e_t\| = \|\nabla G(\theta_t, \alpha_K(\theta_t)) - \nabla g(\theta)\| \\
\leq L_{12}\|\alpha_K(\theta_t) - \alpha^*\| \\
\leq L_{12}\rho^{K/2}\sqrt{\frac{\Delta}{2\mu}} \\
\leq 1 \\
\leq g_{\text{max}}. 
\]

Hence,

\[-X_t \geq -2(g_{\text{max}} + LR)\|\theta_{t+1} - \theta_t\|,\]

or equivalently

\[
\|\theta_{t+1} - \theta_t\| \geq \frac{X_t}{2(g_{\text{max}} + LR)}. 
\]

Combined with (27), we get

\[
g(\theta_{t+1}) - g(\theta_t) \leq -L \frac{X_t^2}{8(g_{\text{max}} + LR)^2} + 2\|e_t\|R,
\]

where the inequality holds by using Cauchy Schwartz and our assumption that \(\Theta\) is in a ball of radius \(R\). Hence,

\[
\frac{1}{T} \sum_{t=0}^{T-1} X_t^2 \leq \frac{8\Delta g(g_{\text{max}} + LR)^2}{LT} + \frac{16\delta R(g_{\text{max}} + LR)^2}{L} \\
\leq \frac{\varepsilon^2}{2},
\]

where the last inequality holds by using Lemma 23 and choosing \(K\) and \(T\):

\[
T \geq N_T \triangleq \frac{32\Delta g(g_{\text{max}} + LR)^2}{L^2}, \quad K \geq N_K(\varepsilon) \triangleq \frac{1}{\log 1/\rho}(4\log(1/\varepsilon) + \log(2^{15}\tilde{L}^6\tilde{R}^6\Delta/L^2\mu)).
\]

Therefore, using Lemma 23 there exists at least one index \(\hat{t}\) for which

\[
X_{\hat{t}} \leq \varepsilon \quad \text{and} \quad \|\nabla f(\theta_{\hat{t}}, \alpha_{\hat{t}+1})\| \leq \varepsilon. 
\]

This completes the proof of the theorem.
B Algorithmic details and proofs for the results in Section 4

B.1 Accelerated Projected Gradient Ascent Subroutine Used in Algorithm 2

Algorithm 3 APGA: Accelerated Projected Gradient Ascent with Restart

Require: Constants $\alpha_t$, $\theta_t$, $\eta$, $K$, and $N$.

1: for $k = 0, \ldots, \lfloor K/N \rfloor$ do
2:  Set $\gamma_1 = 1$
3:  if $k = 0$ then $y_1 = \alpha_t$ else $y_1 = x_N$
4: for $i = 1, 2, \ldots, N$ do
5:  Set $x_i = \text{proj}_A(y_i + \eta \nabla_y f_\lambda(\theta_t, y_i))$
6:  Set $\gamma_i+1 = \frac{1 + \sqrt{1 + 4 \gamma_i^2}}{2}$
7:  $y_{i+1} = x_i + \left(\frac{\gamma_i - 1}{\gamma_i+1}\right)(x_i - x_{i-1})$
8: end for
9: end for
10: Return $x_N$

B.2 Frank–Wolfe update rule for Step 3 in Algorithm 2

In Step 3 of Algorithm 2 instead of projected gradient descent discussed in the main body, we can also run one step of Frank–Wolfe method. More precisely, we can set

$$\theta_{t+1} = \theta_t + \frac{X_t}{L} \hat{s}_t,$$

where

$$X_t \triangleq -\min_s \langle \nabla_\theta f_\lambda(\theta_t, \alpha_{t+1}), s \rangle \quad \text{s.t.} \quad \theta_t + s \in \Theta, \|s\| \leq 1,$$

and

$$\hat{s}_t \triangleq \arg \min_s \langle \nabla_\theta f_\lambda(\theta_t, \alpha_K(\theta_t)), s \rangle \quad \text{s.t.} \quad \theta_t + s \in \Theta, \|s\| \leq 1.$$

is the first order descent direction. In the unconstrained case, the descent direction is $\hat{s}_t = -\nabla_\theta f_\lambda(\theta_t, \alpha_{t+1})$, which becomes the same as the gradient descent step.

B.3 Smoothness of function $g_\lambda(\cdot)$

Lemma 24. Under Assumption 5 and Assumption 15, the function $g_\lambda$ is $L$-Lipschitz smooth with $L = L_{11} + \frac{L_{12}}{\lambda}$.
**Proof.** First notice that the differentiability of the function \( g_\lambda(\cdot) \) follows directly from Danskin’s Theorem \([4]\). It remains to show that \( g_\lambda \) is a Lipschitz smooth function. Let

\[
\alpha_1^* \triangleq \arg \max_{\alpha \in A} f_\lambda(\theta_1, \alpha) \quad \text{and} \quad \alpha_2^* \triangleq \arg \max_{\alpha \in A} f_\lambda(\theta_2, \alpha).
\]

Then by strong convexity of \(-f_\lambda(\theta, \cdot)\), we have

\[
f_\lambda(\theta_2, \alpha_2^*) \leq f_\lambda(\theta_2, \alpha_1^*) + \langle \nabla_\alpha f_\lambda(\theta_2, \alpha_1^*), \alpha_2^* - \alpha_1^* \rangle - \frac{\lambda}{2} \| \alpha_2^* - \alpha_1^* \|^2,
\]

and

\[
f_\lambda(\theta_2, \alpha_1^*) \leq f_\lambda(\theta_2, \alpha_2^*) + \langle \nabla_\alpha f_\lambda(\theta_2, \alpha_2^*), \alpha_1^* - \alpha_2^* \rangle - \frac{\lambda}{2} \| \alpha_1^* - \alpha_2^* \|^2.
\]

Adding the two inequalities, we get

\[
\langle \nabla_\alpha f_\lambda(\theta_2, \alpha_1^*), \alpha_2^* - \alpha_1^* \rangle \geq \lambda \| \alpha_2^* - \alpha_1^* \|^2.
\] (36)

Moreover, due to optimality of \( \alpha_1^* \), we have

\[
\langle \nabla_\alpha f_\lambda(\theta_1, \alpha_1^*), \alpha_2^* - \alpha_1^* \rangle \leq 0.
\] (37)

Combining (36) and (37) we obtain

\[
\lambda \| \alpha_2^* - \alpha_1^* \|^2 \leq \langle \nabla_\alpha f_\lambda(\theta_2, \alpha_1^*) - \nabla_\alpha f_\lambda(\theta_1, \alpha_1^*), \alpha_2^* - \alpha_1^* \rangle \\
\leq L_{12} \| \theta_1 - \theta_2 \| \| \alpha_2^* - \alpha_1^* \|,
\] (38)

where the last inequality holds by Cauchy-Schwartz and the Lipschitz assumption. We finally show that \( g_\lambda \) is Lipschitz smooth.

\[
\| \nabla g_\lambda(\theta_1) - \nabla g_\lambda(\theta_2) \| = \| \nabla \theta f_\lambda(\theta_1, \alpha_1^*) - \nabla \theta f_\lambda(\theta_2, \alpha_2^*) \| \\
= \| \nabla \theta f_\lambda(\theta_1, \alpha_1^*) - \nabla \theta f_\lambda(\theta_2, \alpha_1^*) + \nabla \theta f_\lambda(\theta_2, \alpha_1^*) - \nabla \theta f_\lambda(\theta_2, \alpha_2^*) \| \\
\leq L_{11} \| \theta_1 - \theta_2 \| + L_{12} \| \alpha_1^* - \alpha_2^* \| \\
\leq \left( L_{11} + \frac{L_{12}^2}{\lambda} \right) \| \theta_1 - \theta_2 \|,
\]

where the last inequality holds by (38). □

Algorithm 2 solves the inner maximization problem using accelerated projected gradient descent (outlined in Algorithm 3). The next lemma is known for accelerated projected gradient descent when applied to strongly convex functions.

**Lemma 25.** Assume \( h(x) \) is \( \lambda \)-strongly convex and \( L \)-smooth. Then, applying accelerated projected gradient descent algorithm \([3]\) with step-size \( 1/L \) and restart parameter \( N \triangleq \sqrt{8L/\lambda} - 1 \) for \( K \) iterations, we get \( x_K \) such that

\[
h(x_K) - h(x^*) \leq \left( \frac{1}{2} \right)^{K/N} (h(x_0) - h(x^*)),
\] (39)

where \( x^* \triangleq \arg \min_{x \in \mathcal{X}} h(x) \).
Proof. According to [3, Theorem 4.4], we have

\[ h(x_{iN}) - h(x^*) \leq \frac{2L}{(N+1)^2} \| x_{(i-1)N} - x^* \|^2 \]

\[ \leq \frac{4L}{\lambda(N+1)^2} (h(x_{(i-1)N}) - h(x^*)) \]

\[ \leq \frac{1}{2} (h(x_{(i-1)N}) - h(x^*)) , \]

where the second inequality holds by strong convexity of \( h \) and the optimality condition of \( x^* \), and the last inequality holds by our choice of \( N \). This yields,

\[ h(x_K) - h(x^*) \leq \left( \frac{1}{2} \right)^{K/N} (h(x_0) - h(x^*)) , \]

which completes our proof.

B.4 Proof of Theorem 16
We first show that the inner loop in Algorithm 2 computes an approximate gradient of \( g_\lambda (\cdot) \). In other words, \( \nabla_\theta f_\lambda (\theta_t, \alpha_t) \approx \nabla g_\lambda (\theta_t) \).

Lemma 26. Define \( \kappa = \frac{L_2^2}{\lambda^2} \geq 1 \) and assume \( g_\lambda (\theta_t) - f_\lambda (\theta_t, \alpha_0 (\theta_t)) < \Delta \), then for any prescribed \( \varepsilon \in (0,1) \) if we choose \( K \) large enough such that

\[ K \geq N_K (\varepsilon) \triangleq \frac{\sqrt{8\kappa}}{\log 2} (4 \log (1/\varepsilon) + \log (2^{17} \bar{L}^6 \bar{R}^6 \Delta/L^2 \lambda)) , \]

where \( \bar{L} = \max \{L_{12}, L_{22}, L, g_{\text{max}}, 1\} \) and \( \bar{R} = \max \{R, 1\} \), then the error \( e_t \triangleq \nabla_\theta f_\lambda (\theta_t, \alpha_K (\theta_t)) - \nabla g_\lambda (\theta) \) has a norm

\[ \| e_t \| \leq \delta \triangleq \frac{L^2 \varepsilon}{2^6 \bar{R} (g_{\text{max}} + \bar{L} R)^2} \]

and

\[ \frac{\varepsilon}{2} \geq \gamma_{t,K} \triangleq \max_s \langle \nabla_\alpha f_\lambda (\theta_t, \alpha_K (\theta_t)), s \rangle \]

s.t. \( \alpha_K (\theta_t) + s \in \mathcal{A}, \| s \| \leq 1 \). \]

Proof. Starting from Lemma 25 we have that

\[ g_\lambda (\theta_t) - f_\lambda (\theta_t, \alpha_K (\theta_t)) \leq \frac{1}{2 \sqrt{\kappa}} \Delta . \]

Let \( \alpha^*(\theta_t) \triangleq \arg \max_{\alpha \in \mathcal{A}} f_\lambda (\theta_t, \alpha) \). Then by strong convexity of \( -f(\theta_t, \cdot) \), we get

\[ \frac{\lambda}{2} \| \alpha_K (\theta_t) - \alpha^*(\theta_t) \|^2 \leq g_\lambda (\theta_t) - f_\lambda (\theta_t, \alpha_K (\theta_t)) \leq \frac{1}{2 \sqrt{\kappa}} \Delta . \]
Combined with the Lipschitz smoothness property of the objective, we obtain

\[
\|e_t\| = \|\nabla f_\lambda(\theta_t, \alpha_K(\theta_t)) - \nabla g_\lambda(\theta_t)\| \\
= \|\nabla f_\lambda(\theta_t, \alpha_K(\theta_t)) - \nabla f_\lambda(\theta_t, \alpha^*(\theta_t))\| \\
\leq L_{12}\|\alpha_K(\theta_t) - \alpha^*(\theta_t)\| \\
\leq \frac{L_{12}}{2K/2\sqrt{2\pi}} \sqrt{\frac{2\Delta}{\lambda}} \\
\leq \frac{L_{12}}{2\sqrt{2\pi}} \frac{2\Delta}{\lambda} \leq L_\varepsilon^2
\]

where the second inequality uses (46), and the third inequality uses the choice of \(K\) in (42) which yields

\[
\left(\frac{1}{2}\right)^K \leq \frac{L_2^2\varepsilon^4\lambda}{2^{13}\Delta^2 R^2L^2(2LR)^4} \leq \frac{2^2\varepsilon^4\lambda}{2^{13}\Delta^2 R^2L^2(L + LR)^4} \leq \frac{L_2^2\varepsilon^4\lambda}{2^{13}\Delta^2 R^2L^2(g_{\text{max}} + LR)^4}.
\]

Here the second inequality holds since \(\tilde{R} \geq 1\), and the third inequality holds since \(g_{\text{max}} \leq \tilde{L}\). To prove the second argument of the lemma, we also use the Lipschitz smoothness property of the objective to get

\[
\langle \nabla f_\lambda(\theta_t, \alpha_K(\theta_t)), s \rangle = \langle \nabla f_\lambda(\theta_t, \alpha_K(\theta_t)) - \nabla f_\lambda(\theta_t, \alpha^*(\theta_t)), s \rangle + \langle \nabla f_\lambda(\theta_t, \alpha^*(\theta_t)), s \rangle \\
\leq \|\nabla f_\lambda(\theta_t, \alpha_K(\theta_t)) - \nabla f_\lambda(\theta_t, \alpha^*(\theta_t))\| \|s\| + \langle \nabla f_\lambda(\theta_t, \alpha^*(\theta_t)), s \rangle \\
\leq (L_{22} + \lambda\|\alpha^*(\theta_t) - \alpha_K(\theta_t)\|) \|s\| + \langle \nabla f_\lambda(\theta_t, \alpha^*(\theta_t)), s \rangle \\
\leq 2L_{22}\|\alpha^*(\theta_t) - \alpha_K(\theta_t)\| \|s\| + \langle \nabla f_\lambda(\theta_t, \alpha^*(\theta_t)), s \rangle,
\]

where the second inequality holds by our Lipschitzness assumption and the last inequality holds by our assumption that \(L_{22}/\lambda \geq 1\). Moreover,

\[
\min_s -\langle \nabla f_\lambda(\theta_t, \alpha^*(\theta_t)), s \rangle = \min_{\alpha} -\langle \nabla f_\lambda(\theta_t, \alpha^*(\theta_t)), \alpha - \alpha_K(\theta_t) \rangle \\
\text{s.t.} \quad \alpha_K(\theta_t) + s \in \mathcal{A}, \|s\| \leq 1 \\
\leq -\langle \nabla f_\lambda(\theta_t, \alpha^*(\theta_t)), \alpha^*(\theta_t) - \alpha_K(\theta_t) \rangle \\
\leq -\max_\alpha \langle \nabla f_\lambda(\theta_t, \alpha^*(\theta_t)), \alpha - \alpha^*(\theta_t) \rangle \\
\text{s.t.} \quad \alpha \in \mathcal{A}, \|\alpha - \alpha_K(\theta_t)\| \leq 1
\]

\[
= -\langle \nabla f_\lambda(\theta_t, \alpha^*(\theta_t)), \alpha^*(\theta_t) - \alpha_K(\theta_t) \rangle
\]

where the last equality holds since \(\alpha^*(\theta_t)\) is optimal and \(\|\alpha^*(\theta_t) - \alpha_K(\theta_t)\| \leq 1\). Combining (48) and (49), we get

\[
\min_s -\langle \nabla f_\lambda(\theta_t, \alpha_K(\theta_t)), s \rangle \geq -\langle \nabla f_\lambda(\theta_t, \alpha^*(\theta_t)), s \rangle + 2L_{22}\|\alpha_K(\theta_t) - \alpha^*\|
\]

\[
= -\langle \nabla f_\lambda(\theta_t, \alpha^*(\theta_t)), \alpha^*(\theta_t) - \alpha_K(\theta_t) \rangle + 2L_{22}\|\alpha_K(\theta_t) - \alpha^*\|. \tag{50}
\]
Hence, using (11), we get
\[ Y_{t,K} \leq (2L_{22} + g_{\text{max}})\|\alpha_K(\theta_t) - \alpha^*\| \]
\[ \leq \frac{3L}{2K^{2/\sqrt{8k}}} \sqrt{\frac{2\Delta}{\lambda}} \]
\[ \leq \frac{\varepsilon}{2}, \tag{51} \]
where the second inequality uses (46), and the last inequality holds by our choice of \( K \) in (42) and since \( \varepsilon \in (0,1) \).

The above lemma implies that \( \|\nabla f_\lambda(\theta_t, \alpha_K(\theta_t)) - \nabla g_\lambda(\theta_t)\| \leq \delta \equiv \frac{L\varepsilon^2}{64R^3L^2} \). We now show that our assumption \( g(\theta_t) - f(\theta_t, \alpha_0(\theta_t)) \leq \Delta \) for all \( t \) in the above Lemma holds. Let
\[ \alpha_{t+1}^* \triangleq \arg\max_{\alpha \in A} f_\lambda(\theta_{t+1}, \alpha) \quad \text{and} \quad \alpha_t^* \triangleq \arg\max_{\alpha \in A} f_\lambda(\theta_t, \alpha). \]
Then by strong convexity of \( -f_\lambda(\cdot, \cdot) \), we have
\[ f_\lambda(\theta_{t+1}, \alpha_{t+1}^*) \leq f_\lambda(\theta_{t+1}, \alpha_t^*) + \langle \nabla_\alpha f_\lambda(\theta_{t+1}, \alpha_t^*), \alpha_{t+1}^* - \alpha_t^* \rangle - \frac{\lambda}{2} \|\alpha_{t+1}^* - \alpha_t^*\|^2, \]
and
\[ f_\lambda(\theta_t, \alpha_t^*) \leq f_\lambda(\theta_t, \alpha_t^*) + \langle \nabla_\alpha f_\lambda(\theta_{t+1}, \alpha_{t+1}^*), \alpha_t^* - \alpha_{t+1}^* \rangle - \frac{\lambda}{2} \|\alpha_{t+1}^* - \alpha_t^*\|^2. \]
Adding the two inequalities, we get
\[ \langle \nabla_\alpha f_\lambda(\theta_{t+1}, \alpha_t^*), \alpha_{t+1}^* - \alpha_t^* \rangle \geq \lambda \|\alpha_{t+1}^* - \alpha_t^*\|^2. \tag{52} \]
Moreover, due to optimality of \( \alpha_t^* \), we have
\[ \langle \nabla_\alpha f_\lambda(\theta_t, \alpha_t^*), \alpha_{t+1}^* - \alpha_t^* \rangle \leq 0. \tag{53} \]
Combining (52) and (53) we obtain
\[ \lambda \|\alpha_{t+1}^* - \alpha_t^*\|^2 \leq \langle \nabla_\alpha f_\lambda(\theta_{t+1}, \alpha_t^*) - \nabla_\alpha f_\lambda(\theta_t, \alpha_t^*), \alpha_{t+1}^* - \alpha_t^* \rangle \leq L_{12} \|\theta_{t+1} - \theta_t\| \|\alpha_{t+1}^* - \alpha_t^*\|, \tag{54} \]
Thus,
\[ \|\alpha_{t+1} - \alpha_t\| \leq \frac{L_{12}}{\lambda} \|\theta_{t+1} - \theta_t\|. \]
Hence, the difference between consecutive optimal solutions computed by the inner loop of the algorithm, are upper bounded by the difference between corresponding \( \theta^* \)’s. Since \( \Theta \) is a compact set, we can find an upper bound \( \Delta \) such that \( g(\theta_t) - f(\theta_t, \alpha_0(\theta_t)) \leq \Delta \), for all \( t \).

We are now ready to show the main theorem that implies convergence of our proposed algorithm to an \( \varepsilon \)-first-order stationary solution of problem (2). In particular, we show that using \( \nabla f_\lambda(\theta_t, \alpha_K(\theta_t)) \) instead of \( \nabla g_\lambda(\theta_t) \) for a small enough \( \lambda \) in the Frank-Wolfe or projected descent algorithms applied to \( g_\lambda \), finds an \( \varepsilon \)-FNE. We are now ready to show Theorem 16.
Proof. **Frank-Wolfe Steps:** We now show the result when Step 7 of Algorithm 2 sets

\[ \theta_{t+1} = \theta_t + \frac{\lambda_t}{L} \hat{s}_t. \]

Using descent lemma on \( g_\lambda \) and the definition of \( \tilde{L} \) in Algorithm 2, we have

\[
g_\lambda(\theta_{t+1}) \leq g_\lambda(\theta_t) + \langle \nabla g_\lambda(\theta_t), \theta_{t+1} - \theta_t \rangle + \frac{\tilde{L}}{2} \| \theta_{t+1} - \theta_t \|^2
\]

\[
= g_\lambda(\theta_t) + \frac{\lambda_t}{L} \langle \nabla g_\lambda(\theta_t), \hat{s}_t \rangle + \frac{\lambda_t^2}{2L} \| \hat{s}_t \|^2
\]

\[
\leq g_\lambda(\theta_t) + \frac{\lambda_t}{L} \langle \nabla g_\lambda(\theta_t), \hat{s}_t \rangle + \frac{\lambda_t^2}{2L}
\]

\[
= g_\lambda(\theta_t) - \frac{\lambda_t}{L} \langle \nabla f_\lambda(\theta_t, K(\theta_t)) - \nabla g_\lambda(\theta_t), \hat{s}_t \rangle - \frac{\lambda_t^2}{2L}
\]

\[
\leq g_\lambda(\theta_t) + \frac{\lambda_t}{L} \| e_t \| - \frac{\lambda_t^2}{2L}
\]

where \( \hat{s}_t \) and \( \lambda_t \) are defined in equations (34) and (35) of the manuscript, and the second and last inequalities use the fact that \( \| \hat{s}_t \| \leq 1 \).

Summing up these inequalities for all values of \( t \) leads to

\[
\frac{1}{T} \sum_{t=0}^{T-1} \lambda_t^2 \leq \frac{2\tilde{L}\Delta}{T} + 4\| e_t \| g_{\max} \leq \frac{2\tilde{L}\Delta}{T} + \frac{\epsilon^2}{4} \leq \frac{\epsilon^2}{2},
\]

where the first inequality holds since

\[
\lambda_t = \langle \nabla f_\lambda(\theta_t, K(\theta_t)) - \nabla f_\lambda(\theta_t, \alpha^*(\theta_t)) + \nabla f_\lambda(\theta_t, \alpha^*(\theta_t)), \hat{s}_t \rangle
\]

\[
\leq g_{\max} + \| e_t \|
\]

\[
\leq 2g_{\max}.
\]

Here the first inequality in (56) holds by (11), Cauchy-Schwartz, and the fact that \( \| \hat{s}_t \| \leq 1 \). The last inequality holds by our choice of \( K \) in Lemma 26

\[
K \geq N_K(\epsilon) \triangleq \frac{\sqrt{8\kappa}}{\log 2} \left( 4\log(1/\epsilon) + \log(2^{17} L^6 \tilde{R}^6 \Delta/L^2) \right),
\]

which yields \( \| e_t \| \leq 1 \leq g_{\max} \) and by choosing \( T \) such that

\[
T \geq N_T(\epsilon) \triangleq \frac{8\tilde{L}\Delta}{\epsilon^2}.
\]
Therefore, using Lemma 26 there exists at least one index \( \hat{t} \) for which
\[
X_{\hat{t}} \leq \varepsilon \quad \text{and} \quad Y_{\hat{t}, K} \leq \frac{\varepsilon}{2}.
\]
Hence,
\[
\mathcal{Y}(\theta_{\hat{t}}, \alpha_K(\theta_{\hat{t}})) = \max_s \langle \nabla \alpha f(\theta_{\hat{t}}, \alpha_K(\theta_{\hat{t}})), s \rangle \quad \text{s.t.} \quad \alpha_K(\theta_{\hat{t}}) + s \in A, \|s\| \leq 1
\]
\[
= \max_s \langle \nabla \alpha f(\theta_{\hat{t}}, \alpha_K(\theta_{\hat{t}})), s \rangle + \lambda (\alpha_K(\theta_{\hat{t}}) - \bar{\alpha})^T s \quad \text{s.t.} \quad \alpha_K(\theta_{\hat{t}}) + s \in A, \|s\| \leq 1
\]
\[
\leq Y_{\hat{t}, K} + \lambda \|\alpha_K(\theta_{\hat{t}}) - \bar{\alpha}\|
\]
\[
\leq \varepsilon
\]
where the first inequality uses Cauchy Shwartz and the fact that \( \|s\| \leq 1 \), and the last inequality holds due to (57), the choice of \( \lambda \) in the theorem and our assumption that \( \|\alpha_K(\theta_{\hat{t}}) - \bar{\alpha}\| \leq 2R \).

**Projected Gradient Descent:**

We start by defining
\[
\Delta_\theta = g_\lambda(\theta_0) - g^*,
\]
where \( g^*_\lambda \triangleq \min_\theta g_\lambda(\theta) \) is the optimal value of \( g_\lambda \). Note that by the compactness assumption of the set \( \Theta \), we have \( \Delta_\theta = g_\lambda(\theta_0) - g^*_\lambda < \infty \).

We now show the result when Step 7 of Algorithm 2 sets
\[
\theta_{t+1} = \text{proj}_\Theta \left( \theta_t - \frac{1}{L} \nabla_\theta f(\theta_t, \alpha_{K(t)}) \right).
\]

Based on the projection property, we know that
\[
\langle \theta_t - \frac{1}{L} \nabla_\theta f(\theta_t, \alpha_{t+1}) - \theta_{t+1}, \theta - \theta_{t+1} \rangle \leq 0 \quad \forall \ \theta \in \Theta.
\]

Therefore, by setting \( \theta = \theta_t \), we get
\[
\langle \nabla_\theta f(\theta_t, \alpha_{t+1}), \theta_{t+1} - \theta_t \rangle \leq -L \|\theta_t - \theta_{t+1}\|^2,
\]
which implies
\[
\langle \nabla_\theta f(\theta_t, \alpha^*(\theta_t)), \theta_{t+1} - \theta_t \rangle \leq -L \|\theta_t - \theta_{t+1}\|^2 + \langle \nabla_\theta f(\theta_t, \alpha^*(\theta_t)) - \nabla_\theta f(\theta_t, \alpha_{t+1}), \theta_{t+1} - \theta_t \rangle
\]
\[
= -L \|\theta_t - \theta_{t+1}\|^2 + \langle e_t, \theta_t - \theta_{t+1} \rangle
\]
where \( \alpha^*(\theta_t) \triangleq \arg \max_{\alpha \in A} f_\lambda(\theta_t, \alpha) \) and \( e_t \triangleq \nabla_\theta f(\theta_t, \alpha_{t+1}) - \nabla_\theta f(\theta_t, \alpha^*(\theta_t)) \).
By Taylor expansion, we have
\[ g_\lambda(\theta_{t+1}) \leq g_\lambda(\theta_t) + \langle \nabla f(\theta_t, \alpha^*(\theta_t)), \theta_{t+1} - \theta_t \rangle + \frac{L}{2} \| \theta_{t+1} - \theta_t \|^2 \]
(60)
\[ \leq g_\lambda(\theta_t) - \frac{L}{2} \| \theta_{t+1} - \theta_t \|^2 + \langle e_t, \theta_t - \theta_{t+1} \rangle. \]
Moreover, by the projection property, we know that
\[ \langle \nabla f(\theta_t, \alpha_{t+1}), \theta - \theta_{t+1} \rangle \geq L \langle \theta_t - \theta_{t+1}, \theta - \theta_{t+1} \rangle, \]
which implies
\[ \langle \nabla f(\theta_t, \alpha_{t+1}), \theta - \theta_t \rangle \geq \langle \nabla f(\theta_t, \alpha_{t+1}), \theta_{t+1} - \theta_t \rangle + L \langle \theta_t - \theta_{t+1}, \theta - \theta_{t+1} \rangle \]
\[ \geq -(g_{\text{max}} + 2LR + \| e_t \|) \| \theta_{t+1} - \theta_t \| \]
(61)
\[ \geq -2(g_{\text{max}} + LR) \| \theta_{t+1} - \theta_t \|. \]
Here the second inequality holds by Cauchy-Schwartz, the definition of \( e_t \) and our assumption that \( \Theta \subseteq B_R \). Moreover, the last inequality holds by our choice of \( K \) in Lemma 23 which yields
\[ \| e_t \| = \| \nabla f(\theta_t, \alpha_K(\theta_t)) - \nabla g(\theta) \| \]
\[ \leq L_{12} \| \alpha_K(\theta_t) - \alpha^* \| \]
\[ \leq L_{12} \rho^{K/2} \sqrt{\frac{\Delta}{2\mu}} \]
\[ \leq 1 \]
(63)
\[ \leq g_{\text{max}}. \] (64)
Hence,
\[ -\mathcal{X}_t \geq -2(g_{\text{max}} + LR) \| \theta_{t+1} - \theta_t \|, \]
or equivalently
\[ \| \theta_{t+1} - \theta_t \| \geq \frac{\mathcal{X}_t}{2(g_{\text{max}} + LR)}. \]
(65)
Combined with (60), we get
\[ g_\lambda(\theta_{t+1}) - g_\lambda(\theta_t) \leq -\frac{L}{8} \frac{\mathcal{X}_t^2}{(g_{\text{max}} + LR)^2} + 2\| e_t \| R, \]
where the inequality holds by using Cauchy Schwartz and our assumption that \( \Theta \) is in a ball of radius \( R \). Hence,
\[ \frac{1}{T} \sum_{t=0}^{T-1} \mathcal{X}_t^2 \leq \frac{8\Delta_0 (g_{\text{max}} + LR)^2}{LT} + \frac{16\delta R (g_{\text{max}} + LR)^2}{L} \]
\[ \leq \frac{\varepsilon^2}{2}, \]
where the last inequality holds by using Lemma 26 and choosing $K$ and $T$:

$$T \geq N_T(\varepsilon) \triangleq \frac{32\Delta g(g_{\max} + LR)^2}{L\varepsilon^2}, \quad \text{and} \quad K \geq N_K(\varepsilon) \triangleq \frac{\sqrt{8K}}{\log 2} (4 \log(1/\varepsilon) + \log(2^{17}R^6\Delta/L^2\lambda)),$$

Therefore, using Lemma 26 there exists at least one index $\hat{t}$ for which

$$\mathcal{X}_{\hat{t}} \leq \varepsilon \quad \text{and} \quad \mathcal{Y}_{\hat{t},K} \leq \frac{\varepsilon}{2}. \quad (66)$$

Hence,

$$\mathcal{Y}(\theta_{\hat{t}}, \alpha_K(\theta_{\hat{t}})) = \max_s \langle \nabla f(\theta_{\hat{t}}, \alpha_K(\theta_{\hat{t}})), s \rangle \quad \text{s.t.} \quad \alpha_K(\theta_{\hat{t}}) + s \in \mathcal{A}, \|s\| \leq 1$$

$$= \max_s \langle \nabla f_{\lambda}(\theta_{\hat{t}}, \alpha_K(\theta_{\hat{t}})), s \rangle + \lambda(\alpha_K(\theta_{\hat{t}}) - \bar{\alpha})^T s \quad \text{s.t.} \quad \alpha_K(\theta_{\hat{t}}) + s \in \mathcal{A}, \|s\| \leq 1, \quad (67)$$

$$\leq \mathcal{Y}_{\hat{t},K} + \lambda\|\alpha_K(\theta_{\hat{t}}) - \bar{\alpha}\|$$

$$\leq \varepsilon$$

where the first inequality uses Cauchy Shwartz and the fact that $\|s\| \leq 1$, and the last inequality holds due to (66), the choice of $\lambda$ in the theorem and our assumption that $\|\alpha_K(\theta_{\hat{t}}) - \bar{\alpha}\| \leq 2R$.
