Abstract—This paper reports on the development of a formal symbolic process virtual machine (FSPVM) denoted as FSPVM-E for verifying the reliability and security of Ethereum-based services at the source code level of smart contracts, and a Coq proof assistant is employed for both programming the system and for proving its correctness. The current version of FSPVM-E adopts execution-verification isomorphism, which is an application extension of Curry-Howard isomorphism, as its fundamental theoretical framework to combine symbolic execution and higher-order logic theorem proving. The four primary components of FSPVM-E include a general, extensible, and reusable formal memory framework, an extensible and universal formal intermediate programming language denoted as Lolisa, which is a large subset of the Solidity programming language using generalized algebraic datatypes, the corresponding formally verified interpreter of Lolisa, denoted as FEther, and assistant tools and libraries. The self-correctness of all components is certified in Coq. Currently, FSPVM-E supports the ERC20 token standard, and can automatically and symbolically execute Ethereum-based smart contracts, scan their standard vulnerabilities, and verify their reliability and security properties with Hoare-style logic in Coq. To the best of authors’ knowledge, the present work represents the first hybrid formal verification system implemented in Coq for Ethereum smart contracts that is applied at the Solidity source code level.

1. INTRODUCTION

Blockchain [1] is one of the emerging technologies developed to address a wide range of disparate problems, such as those associated with cryptocurrency [2] and distributed storage [3]. Recently, Blockchain-as-a-Service (BaaS), where blockchain services are obtained from third-party providers, has established a strong market presence, and is a promising means of utilizing the blockchain technology. Organizations like Oracle, Microsoft, and IBM have launched BaaS offerings. Many BaaS offerings are based on or have been inspired by the Ethereum platform [4], which is one of the most powerful 2.0 blockchain platforms presently available. For example, Amazon partnered with Kaleido to offer cloud services on which to host an Enterprise Ethereum-based architecture. That makes Kaleido the first managed BaaS offering that is available on Amazon web service (AWS) regions across the world.

While BaaS is certainly a rapidly emerging service, the continued rapid development of BaaS is limited by security issues like those affecting Software-as-a-Service (SaaS) products. Presently, one of the security issues of greatest interest for researchers is the reliability and security of blockchain smart contracts. Here, blockchain smart contracts are script programs that provide a kind of special digital contract where the code is the law, which enables blockchain transactions to be conducted automatically [5]. One of the challenges that must be confronted in the development of secure and reliable smart contracts is that the programming process for these programs differs from that of conventional programs. Here, the source code of smart contracts must represent legal considerations in a manner similar to contracts written in natural languages. Therefore, obligations and terms should be presented in smart contracts explicitly. However, smart contract developers are generally programmers, rather than legal experts, and their grasp of legal obligations and terms is secondary to their grasp of programming. As a result, the programming habits of programmers introduce legal loopholes in smart contracts. These loopholes introduce many classes of subtle bugs in smart contracts, ranging from transaction-ordering dependencies to mishandled exceptions [6], that differ significantly from common bugs because, while common bugs are easily detected owing to faulty program execution, these legal loopholes can result in unintended operations, and can also be maliciously exploited to circumvent obligation limitations without affecting the normal
execution of the contract procedure, and ultimately result in direct economic loss to users. For example, some of the largest and best known attacks on smart contracts involved those based on the Ethereum platform, such as the attack on the decentralized autonomous organization (DAO) [7] and the Parity wallet attack [8]. A partial summary of Ethereum-based smart contract attacks are listed in Table 1, which indicates that Ethereum attack cases have already resulted in the loss of billions of dollars worth of virtual currency. Moreover, due to the unique feature of these vulnerabilities, standard software engineering techniques employing such static and dynamic analysis tools as Manticore\(^1\) and Mytril\(^2\) have not yet been proven to be effective at increasing the security and reliability of smart contracts. Thus, an urgent need exists for a verification and validation technology that can guarantee the security and reliability of Ethereum-based services in the most rigorous manner available.

A brief comparison of existing verification and validation technologies is presented in the Table 2. We note from this table that formal verification is the only technology that satisfies both reliability and completeness simultaneously. Hence, formal verification is one of the most rigorous theoretical technologies available for ensuring the security and reliability of software systems. Consequently, the Ethereum community has focused on the formal verification of smart contracts, issuing open calls for formal verification proposals [9] as part of what has been described as a “push for formal verification” [10].

While formal verification is a rigorous approach, different formal verification technologies have their own peculiar strengths and weaknesses. Among these, higher-order logic theorem proving is one of the most rigorous and flexible technologies for verifying the properties of programs. However, numerous problems regarding reusability, consistency, and automation have been encountered when applying theorem-proving technology to program verification [11]. Moreover, the process of model checking is only applicable to finite state programs. In addition, a number of well-known frameworks and tools have been developed recently for the verification of Ethereum smart contracts by symbolic execution. For example, the formal semantic known as KEVM was developed for the formal low-level programming verification of Solidity bytecode on the Ethereum virtual machine (EVM) platform using the K-framework [12]. Since KEVM is executable, it can run the validation test suite provided by the Ethereum foundation. Similarly, a Lem [13] implementation of EVM provides an executable semantics of EVM for the formal verification of smart contracts at the bytecode level. Oyente\(^3\) is an EVM symbolic execution engine written in Python supporting most of the EVM opcodes. Several heuristics-based drivers of the symbolic execution engine are built into the tool for finding common bugs in EVM programs. However, these heuristics may introduce false positives in many cases, and they have not been rigorously proven to accurately capture their bug classes. In addition, it must be noted that most of the many recent tools based on symbolic execution adopt model checking technology as their foundation, and few are developed in a higher-order logic theorem proving system to enable real-world programs to be symbolically executed. In addition, conventional symbolic execution approaches also suffer from limitations such as path explosion, where the number of feasible paths in a program grow exponentially.

program-dependent efficiency, and memory, environment, and constraint solving problems [14]. Moreover, nearly all of these methods have high learning thresholds. These problems obstruct formal verification technologies from being applied commercially.

One of the most important features of the Ethereum platform is that it implements a general-purpose Turing-complete programming language denoted as Solidity that allows for the development of arbitrary applications and scripts that can be executed in the EVM to conduct blockchain transactions automatically. However, most prominent studies have focused on the formal verification of the bytecode of the EVM, and the development of high-level formal specifications for Solidity and relevant formal verification tools has attracted considerably less interest despite its importance in programming and debugging smart contract software. Although some intermediate specification languages between Solidity and EVM bytecode have been developed, such as Scilla [15] and Simplicity [16], the Solidity syntax and semantics have not been formalized in a manner that is consistent with official documentation. However, the formal syntax and semantics of programming languages actually play a crucial role in several areas of computer science, particularly in program verification. For advanced programmers and compiler developers, formal semantics provide a more precise alternative to the informal English descriptions that typically pass as language standards. In the context of formal methods, such as static analysis, model checking, and program proving, formal semantics are required to validate the abstract interpretations and program logic (e.g., axiomatic semantics) used to analyze and verify programs. Formal semantics for the involved languages are also a prerequisite for verifying programming tools, such as compilers, type checkers, static analyzers, and program verifiers. In other computer science fields, several studies have focused on developing mechanized formalizations of operational semantics for different high-level programming languages. For example, the Cholera project [17] formalized the static and dynamic semantics of a large subset of the C language using the HOL proof assistant. The CompCert project [18] has conducted influential verification work for C and GCC, and a formal semantics denoted as Clight was developed for a subset of C. This formed the basis for VST [19] and CompCertX [20]. In addition, several interesting formal verification studies have been conducted for operating systems based on the CompCert project. Tews et al. [21] developed denotational semantics for a subset of the C++ language that were presented as shallow embedding in the PVS prover. Igarashi et al. [22] presented a minimal core calculus for Java and Generic Java, and verified the important core properties. A similar study was conducted to prove Java type soundness [23]. In addition, the operational semantics of JavaScript have been investigated [24], which is of particular interest in the present work because Solidity is similar to JavaScript. However, most of these studies focused on specific domains and programming languages, and cannot be readily extended for the verification of blockchain smart contracts.

This paper addresses the above issues by developing a formal symbolic process virtual machine (FSPVM) denoted as FSPVM-E for verifying the reliability and security of Ethereum-based services at the source code level of smart contracts. The work of this paper was primarily inspired by the symbolic process virtual machine KLEE [25], which is a well-known and successful certification tool based on symbolic execution. The proposed FSPVM-E is formulated in Coq because it is one of the most highly regarded and widely employed proof assistants [26]. The present study capitalizes on our progress over the past year for developing a powerful hybrid FSPVM system in Coq to verify smart contract properties on multiple blockchain platforms [11]. The proposed system combines the advantages of virtual machine platforms, static vulnerability scanning, higher-order logic theorem proving, and symbolic execution technology based on an extension of Curry-Howard isomorphism (CHI) [31], denoted as execution-verification isomorphism (EVI) [11], and avoids their respective disadvantages, to symbolically execute real-world programs and automatically verify the smart contracts of Ethereum-based services. The present report systematically illustrates the FSPVM-E architecture, elaborates on the novel features of each component, presents experimental results, and introduces real-world application examples. Specifically, the present work makes the following contributions.

- **Formal memory model**: We design and implement a general, extensible, and reusable formal memory framework denoted as the GERM framework [11] to virtualize the real-world memory hardware, basic memory operations, and pointer arithmetic in Coq.
- **Formal specification language for Solidity**: We formalize and mechanize an extensible and universal large subset of the Solidity programming language in Coq with generalized algebraic datatypes (GADTs) [28]. This represents a formal intermediate programming language denoted as Lolisa [28]. The supported subset of Solidity is comparable to the subsets commonly recommended for writing common Ethereum-based smart contracts, and includes the built-in functions of the EVM. It also solves the consistency problem associated with existing higher-order logic theorem proving technologies.
Execution and proof engine: An optimized formal verified interpreter is developed in Coq for Lolisa, denoted as FEther [29], which connects the GERM framework and Lolisa, and serves as an execution engine to symbolically execute and verify the smart contracts of Ethereum written in Lolisa within Coq with high level evaluation efficiency [30].

Assisted tools and libraries: We provide assistant tools and libraries, including a specification generator, a language translator, a static analysis library, and an automatic tactic library, that are respectively applied to generate dynamic specifications, translate Solidity into Lolisa, store the specifications of standard smart contract vulnerabilities, and provide an automatic evaluation strategy. These tools and libraries significantly improve the degree of automation and the validation efficiency of FSPVM-E.

The above core components of FSPVM-E are applied to virtualize Coq as an extensible and general-purpose toolchain for Ethereum smart contract verification, which reduces the verification workload and learning threshold. In addition, FSPVM-E has the following novel features.

Executable and Provable: Defining FSPVM-E based on the GERM framework in conjunction with EVI allows, theoretically, for formal smart contracts to be symbolically executed, and their properties simultaneously and automatically verified using higher-order logic theorem-proving assistants, which, when conducted in conjunction with a formal interpreter, is comparable to the execution of real-world programs.

Extensible and Universal: Although FSPVM-E is designed specifically for the Ethereum platform, each component includes many general features applicable to other blockchain platforms. Thus, the core functions can be extended to formalize similar programming languages.

Trusted and certified: The self-correctness of FSPVM-E core components is verified in Coq completely, and the correctness of assistant tools not programmed in Coq is also guaranteed.

Hybrid verification system: In conjunction with Lolisa and the static analysis library, FSPVM-E supports basic static analysis to automatically scan standard vulnerabilities hidden in source code. In addition, FEther supports multiple types of symbolic execution for verification using FSPVM-E. Finally, FSPVM-E provides a debugging mechanism for general programmers to identify the vulnerabilities of source code. In this manner, users of FSPVM-E can flexibly select the most suitable method for analyzing and verifying their programs.

To authors’ best knowledge, this is the first time that a trusted hybrid verification system has been designed and implemented in Coq for automatically validating and verifying the reliability and security of Ethereum-based smart contract services.

The remainder of this paper is organized as follows. Section 2 briefly presents the essential concepts of FSPVM-E. Section 3 describes the overall FSPVM-E architecture. Section 4 discusses the methods by which the self-correctness of FSPVM-E is ensured, and also defines the non-aftereffect property to guarantee the correctness of assistant tools that are not programmed in Coq. Section 5 presents simple case studies to illustrate the advantages and novel features of FSPVM-E for verifying the security and reliability of smart contracts. Section 6 discusses the extensibility and universality of FSPVM-E, and provides a preliminary scheme for systematically extending FSPVM-E to support different blockchain platforms. Section 7 provides a comparison of FSPVM-E with related work for the formal verification of smart contracts. Finally, Section 8 presents conclusions and future directions of research.

2. Fundamental Concepts

Prior to defining the formal specifications of FSPVM-E, it is necessary first to define the basic environment of Lolisa, and the fundamental aspects of CHI and EVI that facilitate the symbolic execution of smart contracts in FSPVM-E.

2.1 Basic Environment of Lolisa

Table 3 lists the state functions used to calculate commonly needed values from the current state of the program. All of these state functions will be encountered in the following discussion. Components of specific states will be denoted using the appropriate Greek letter subscripted by the state of interest. As shown in Table 3, the context of the formal memory space is denoted as $M$, the context of the execution environment is represented as $E$, we assign $A$ to denote a set of memory addresses, and we adopt $V$ to represent the verified logic terms in the proof assistant. Furthermore, we assign $\Omega$ as the native value set of the basic logic system. For brevity in the following discussion, we will assign $F$ to represent the overall formal system. In addition, to avoid ambiguity in the following discussion, we employ the term program to represent a generic program written in a functional specification language, such as Coq, the term program$_{rw}$ represents a generic program written in a general-purpose programming language.
\( \mathcal{L} \), and \( \text{program}_{\text{formal}} \) represents the formal version of \( \text{program}_{\text{rw}} \) written using the formalized version of \( \mathcal{L} \), denoted as \( \mathcal{F}\mathcal{L} \).

### 2.2 Formal Symbolic Process Virtual Machine Framework

The theoretical framework of FSPVM-E consists of two core components: 1) EVI, which proves the isomorphic relationship between symbolic execution and higher-order theorem proving; 2) the theoretical basis of constructing an FSPVM in a formal logic system that supports CHI. This theoretical framework is first clarified by defining CHI and its extension EVI.

Briefly, CHI proposes that a deep correspondence exists between the worlds of logic and computation. This correspondence can be expressed according to three general principles as follows.

\[
\begin{align*}
\text{types correspond to propositions} & \quad (1) \\
\text{proofs correspond to a program} & \quad (2) \\
\text{proofs correspond to the evaluation of programs} & \quad (3)
\end{align*}
\]

These deep correspondences make CHI very useful for unifying formal proofs and program computation. As a result, programs implemented using functional specification languages (FSLs) in proof assistants supporting CHI, such as Coq, can be directly evaluated and defined as lemmas and theorems for property certifications in higher-order theorem proving systems that support CHI. This is summarized below as property 1.

**Property 1** (self-certification): All programs with specifications defined in a higher-order theorem proving context \( \Gamma \) that supports CHI can be proven directly. This self-certification property is represented as \( \Gamma, \mathcal{F}(\text{program}) \vdash \mathcal{V}(\text{program}) \).

However, CHI is limited in that most mainstream general-purpose programming languages, such as C++ and Java, employed in the real world are not designed based on higher-order typed lambda calculus, and are therefore far different from FSLs. Moreover, nearly all FSLs of higher-order logic theorem-proving assistants, such as Gallina, which is implemented in Coq, do not directly support complex values, such as arrays and mapping values, owing to the strict typing system of the trusted core and the adoption of different paradigms. Hence, \( \text{program}_{\text{rw}} \) cannot be directly expressed by FSLs in proof systems, and CHI cannot be directly applied to unify property verification and \( \text{program}_{\text{rw}} \) execution.

The development of EVI in our past work was conducted to alleviate these problems associated with combined symbolic execution and higher-order theorem proving. First of all, an \( \mathcal{F}\mathcal{L} \) that lies intermediate between real-world languages and the formal language system must be defined to directly represent real-world values with an equivalent syntax as that of the formal language system, and translate real-world values into the native values of the formal language system using formal semantics. We note that, according to the Turing-Church thesis [33], any \( \mathcal{L} \) based on a Turing machine can be equivalently formalized into an \( \mathcal{F}\mathcal{L} \) based on higher-order typed lambda calculus. Secondly, a formal verified execution engine \( \mathcal{F}\mathcal{L} \), such as a formal interpreter, can be programmed using an FSL, taking \( \text{program}_{\text{formal}} \) written by the \( \mathcal{F}\mathcal{L} \) as a parameter, based on the formal operational semantics of \( \mathcal{L} \). Then, we note that \( \mathcal{F}\mathcal{L} \) is also a program that can be evaluated in a higher-order logic theorem proving system. We further note that \( \mathcal{F}\mathcal{L} \) can apply the formal operational semantics to symbolically execute a \( \text{program}_{\text{formal}} \) written by \( \mathcal{F}\mathcal{L} \), which is denoted as \( \text{program}_{\text{formal}} \rightarrow_{\mathcal{F}\mathcal{L}} \emptyset \), where \( \rightarrow_{\mathcal{F}\mathcal{L}} \) represents the execution trace under initial state \( \sigma \) and formal operational semantics set \( \{\sigma\} \). Thus, \( \text{program}_{\text{rw}} \) can be executed in a higher-order logic theorem proving system in the form of \( \text{program}_{\text{formal}} \) by evaluating \( \mathcal{F}\mathcal{L} \). This yields the following rule.

\[
\text{the evaluation of } \mathcal{F}\mathcal{L} \text{ corresponds to the execution of } \text{program}_{\text{formal}} \quad (4)
\]

Moreover, the propositions referenced in CHI principle (1) above should be limited and deduced by Hoare logic to accurately define the properties of \( \text{program}_{\text{rw}} \) in the proposed framework, and thereby standardize the verification process and avoid meaningless proofs. First, the Hoare triple \( \{\text{Pre}\}\) \( \text{program}_{\text{formal}} \) \( \{\text{Post}\} \) defines the properties corresponding to \( \text{program}_{\text{formal}} \). This, in conjunction with CHI general principles (1) and (3) above, yields the following rule.

\[
\text{types correspond to limited propositions correspond to the properties of } \text{program}_{\text{formal}} \quad (5)
\]

Next, any Hoare triple \( \{\text{Pre}\}\) \( \text{Code} \) \( \{\text{Post}\} \) can be equivalently represented by the reachability chain \( \{\text{Pre}\} \wedge \text{Code} \quad \vdash \quad \emptyset \wedge \{\text{Post}\} \) based on formal operational semantics, where \( \emptyset \) is a pattern representing the empty program. In other words, a Hoare
logic proof derivation is equivalent to the evaluation of formal operational semantics under a first-order logic system, and thereby provides a mechanical translation from Hoare logic proofs to formal operational semantics proofs [34]. Therefore, formal operational semantics can be applied as axiom rules in Hoare style proof derivations, such that the process $\text{Code} \xrightarrow{\text{deduction}} \emptyset$ is equivalent to the process $\text{Code} \rightarrow_{\ell} \emptyset$. Hence, when $\text{Code}$ is replaced with $\text{program}_{\text{format}}$, we obtain the rule $(\{\text{Pre}\} \text{program}_{\text{format}} \{\text{Post}\}) \equiv (\{\text{Pre}\} \land \text{program}_{\text{format}} \rightarrow_{\ell} \emptyset \land \{\text{Post}\})$ that relates the evaluation of $\mathcal{F}\mathcal{L}$ with the properties of $\text{program}_{\text{format}}$. This can be summarized as principle (6) below. Conjoining this with principle (4) facilitates the inference of principle (7) below, which is denoted as EVI.

$$\text{proofs correspond to the evaluation of } \mathcal{F}\mathcal{L} \text{ corresponds to the verification of properties}$$

(6)

$$\text{execution of } \text{program}_{\text{format}} \text{ corresponds to the verification of properties}$$

(7)

In this manner, FSPVM-E accurately simulates the execution behavior of $\text{program}_{\text{rw}}$ in the real world.

As shown in Fig. 1, the second core component of FSPVM-E discussed above is a blueprint of the logic virtual machine based on EVI, and ensures that EVI extends the theorem proving system as a logic operating environment to verify $\text{program}_{\text{rw}}$. Specifically, constructing a deeply embedded computational virtual machine in a higher-order logic theorem proving system should contain at least three key elements: a formal memory model that can directly store native higher-order logic information, an intermediate $\mathcal{F}\mathcal{L}$ that is consistent with the target $\mathcal{L}$, and a corresponding formal interpreter that can symbolically execute $\text{program}_{\text{format}}$. The general workflow of FSPVM-E is illustrated in Fig. 2, which includes translating $\text{program}_{\text{rw}}$ into $\text{program}_{\text{format}}$, analyzing syntactic tokens, and generating a logic memory state that can be operated on directly by induction, simplification, and equational reasoning.

Fig. 1. Equivalence between real world program ($\text{program}_{\text{rw}}$) execution and formal program ($\text{program}_{\text{format}}$) execution in a logic environment.

Fig. 2. General workflow of FSPVM-E.

3. FSPVM-E Architecture and Implementation

The kernel of the FSPVM-E framework was developed entirely in Coq, and Coq was employed as the trusted computation base (TCB) [35]. Here, Coq served not only as a prover for conducting semantic preservation proofs, but also as a programming language for programming all verified components of the FSPVM-E framework. The specification language of Coq includes a small, purely functional language denoted as Gallina, which features recursive functions that operate by pattern matching over inductive types (i.e., ML- or Haskell-style tree-shaped data types). With some ingenuity, Gallina is sufficiently sophisticated for programming a process virtual machine. However, the highly imperative algorithms found in programming language and interpreter textbooks must rewrite in a purely functional style.
The overall architecture of FSPVM-E is illustrated in Fig. 3, where a dashed arrow (→) represents a logical dependency relation, and a solid arrow (⟶) represents data transmission. Here, FSPVM-E is designed according to Von Neuman architecture, and it is logically constructed based on two sectors: a foundational sector and an extensible sector. In the foundational sector, the higher-order logic proof environment of Coq is virtualized as the FSPVM-E execution environment, which serves as the logic operating environment, and the trusted core of Coq (TCOC) is virtualized as a central processing unit, and takes Gallina as the logic machine-level language. The extensible sector consists of four components. The first component is the GERM framework. The second component is Lolisa. The third component is FEther. The final component is the set of assistant tools and libraries. These components in the current version of FSPVM-E include about 16,000 lines of Coq source code and 4,000 lines of C++ source code. The specific workload for constructing the FSPVM-E framework is itemized in the Table 4. In this manner, FSPVM-E simulates the process of program execution in the real world, in that a program written in a high-level programming language is interpreted into machine code and executed on the hardware of the operating environment in Coq. The details of these four components are respectively discussed in Subsections 3.1 to 3.4.

### 3.1 General Formal Memory Model

The GERM framework simulates physical memory hardware structure, including a low-level formal memory space, and provides a set of simple, nonintrusive application programming interfaces using Coq that can support different formal verification specifications simultaneously, particularly at the code level. In theory, it is well suited as a basis for arbitrary high-level specifications in different formal models for program verification.

The overall GERM framework structure is illustrated in Fig. 4. According to the figure, the GERM framework is based on...
the TCOC, and can be used as a basis for high-level formal specifications.

The first component of the formal memory model is the formal memory space, which is modeled as a collection of disjoint blocks, and we adopt persistent data structures that support efficient updates without modifying data in-place. Likewise, a monadic programming style enables us to encode exceptions and states in a legible, compositional manner. The data structure of the formal memory space is illustrated by the example given in Fig. 5, where each memory record field specifies a logic memory block with type value. Users can define specific memory sizes according to their requirements with the help of assistant tools, which are introduced in Subsection 3.4. The details regarding the formal memory space of the GERM framework are presented as follows.

```
Record memory: Type = new {
  m_0xinit: value
  m_0x00000000: value
  m_0x00000001: value
  m_0x00000002: value
  m_0x00000003: value
  ...
  m_0x0000000F: value
}
```

According to the following rule

\[
\frac{\mathcal{F} \vdash \text{id: field name} \quad \mathcal{F} \vdash r_v: \text{record}}{\mathcal{F} \vdash b_{\text{id: field name}}: \text{record} \Rightarrow \text{field block}(b_{\text{id}})}(\forall i \, \text{id}_i, \text{id}_j \in r_v, \text{id}_i \neq \text{id}_j),
\]

(8)

each field block \(b_{\text{id}}\) in Coq has a unique corresponding field name \(\text{id}\), and the data stored in the \(b_{\text{id}}\) block of a specific record value \(r_v\) can be directly accessed by its corresponding \(\text{id}\). In memory, \(b_{\text{id}}\) represents the logic memory block, and the corresponding \(\text{id}\) is formalized as the memory absolute address \(M_{\text{address}}\). In this manner, the GERM framework statically guarantees that each memory block has a unique \(M_{\text{address}}\) at the type level. Additionally, in contrast to relevant data structures based on a tree or graph structure [36], which must search all nodes individually to modify a memory block, the GERM framework can access and modify the block directly through its corresponding \(M_{\text{address}}\) according to the following rule.

\[
\frac{M \vdash \text{addr: address} \quad M + m: \text{memory} \quad \mathcal{F} \vdash b_{\text{addr: address}}: \text{memory} \Rightarrow \text{value}}{\mathcal{F}, M \vdash b_{\text{addr: address}}(\text{addr}, m): \text{value}}
\]

(9)

To improve the flexibility of memory operations, the GERM framework in its current form also provides a label memory...
address level. In detail, this level first provides a special identifier denoted as a label address \( L_{\text{address}} \), which is a metavariable defined as an enumeration type in Coq as follows.

\[
L_{\text{address}} ::= _\text{0x00000000} | \ldots | _\text{0xFFFFFFF} | A_{\text{special}}
\]

**Special address:** \( A_{\text{special}} ::= _\text{0xinit} | _\text{0xsend} | _\text{0xsend_re} | _\text{0xcall} | _\text{0xmsg} | _\text{0xaddress} | _\text{0xblock} \)

Here, \( A_{\text{special}} \) is used as the reference for data structures and functions in the EVM standard library. Accordingly, programmers can define custom mapping strategies \( \text{Map}_{\text{tac}} \) to map \( L_{\text{address}} \) to \( M_{\text{address}} \) as follows.

\[
\text{Map}(L_{\text{address}}) = \begin{cases} 
\text{match Map}_{\text{tac}}(L_{\text{address}}) \text{with} \\
\text{Error} \to \text{Error} \\
\text{OK}(M_{\text{address}}) \to M_{\text{address}} 
\end{cases}
\]

Here, if the return value is \( \text{Error} \), the mapping is deemed to have failed, and the mapping is successful if the return value is \( \text{OK}(M_{\text{address}}) \). Similarly, \( L_{\text{address}} \) can be employed in the GERM framework to accurately model pointer arithmetic. Briefly, users can define pointer objects in high-level specifications, apply \( \text{Map}(L_{\text{address}}) \) to reference a location in memory, and obtain the logic expressions stored at that location. The pointer arithmetic mechanism defined in Lolisa based on \( L_{\text{address}} \) is briefly introduced in Subsection 4.2. Moreover, the label address level reserves the extension space for simulating virtual memory and memory isolation mechanisms, such as a memory management unit and a TrustZone.

A benefit of designing FSPVM-E according to von Neumann architecture is that the GERM framework memory space is able to store the program instructions and data values simultaneously, and thereby accurately simulate a real-world memory space and guarantee the reliability of the formal memory model. Hence, the memory value type \( \text{value} \) is inductively defined as

\[
\text{value} ::= \text{block}_v \to \text{size} \to \text{env} \to \text{fenv} \to \text{occupy} \to \text{auth} \to \text{value}
\]

in conjunction with logic memory value \( \text{block}_v \), the corresponding block size, the current and super logic execution environment information \( \text{env} \) and \( \text{fenv} \), respectively, block allocation flag \( \text{occupy} \), and modification authority \( \text{auth} \). Currently, \( \text{block}_v \) supports 14 datatypes, including basic arithmetic data values (\( \text{undef}, \text{integer}, \text{float}, \text{Boolean}, \text{string}, \text{byte}, \text{structure}, \text{array}, \) and \( \text{mapping} \)), program instructions (\( \text{statement} \), and pointer objects (\( \text{variable pointer}, \text{parameter pointer}, \text{function pointer}, \) and \( \text{contract pointer} \)). One of the benefits of the type constructor of \( \text{value} \) is that the safety of memory specifications can be readily ensured in the GERM framework. For example, a \( \text{block}_v \) corresponding to an uninitialized memory block will be initialized as \( \text{Undef}(tt) \) rather than as a random value. Similarly, all information regarding the current memory state is explicitly stored by the corresponding typing constructors. In this manner, high-level specifications can maintain the type safety of each memory block by checking the typing judgement stored in \( \text{env} \) and \( \text{fenv} \) according to the following rule.

\[
\frac{\text{let}_{\text{check}}(\text{mstate}, \text{addr}, \text{env}, \text{fenv}) \to \text{m}_0}{\text{read}_{\text{check}}(\text{mstate}, \text{addr}, \text{env}, \text{fenv}) \to \text{m}_0}
\]

As such, conventional memory safety problems, such as buffer overflows and dangling pointers, can be readily exposed in the GERM framework by symbolic execution.

Although the current version of the GERM framework is adjusted to support FSPVM-E, users can easily modify and extend the \( \text{value} \) specifications because the GERM framework can function independently with other formal models. Here, according to the following abstraction of the \( \text{value} \) definition:

\[
\text{value}: \text{block}_v \to \text{infor}_0 \to \text{infor}_1 \to \ldots \to \text{infor}_n \to \text{value},
\]

programmers can add new specifications \( \text{infor}_i \) into the \( \text{value} \) constructor to represent and store new logic information according to the specific requirements of different projects and situations.

Finally, we provide 9 classes of basic operations in the GERM framework, which include \( \text{map}, \text{initialize}, \text{read}, \text{write}, \text{address offset}, \text{search}, \text{allocate}, \) and \( \text{free} \). Any higher-order specifications can take the GERM framework as their fundamental logic state, and apply memory operation APIs to formalize memory-based or memory-related higher level specifications in Coq, such as formal semantics and operating systems.

### 3.2 Lolisa

Following the process illustrated in Fig. 6, most of the syntax and respective semantics of Lolisa are formalized strictly following the official Ethereum documentation of Solidity.
All reference data structures can be formalized in Lolisa because each variable identifier \( v_{id} \) is allocated a memory address based on the GERM framework, and can be abstracted as an \( \lambda \)-application form according to the following rule.

\[
v_{id} \equiv (\lambda (x : L_{address}). x)(a : L_{address}),
\]

where \( x \) is a \( \lambda \)-bounded parameter and \( a \) is a label address. As such, the syntax of Lolisa not only includes nearly all the characteristic components of Solidity, such as \textit{array}, \textit{mapping}, \textit{modifier}, \textit{contract}, and \textit{gas} types, but it also contains general-purpose programming language features, such as \textit{multiple return values}, \textit{pointer arithmetic}, \textit{struct}, \textit{field access}, \textit{module}, and the full power of functions, including \textit{recursive functions} and \textit{function pointers}. These abstract syntax components are defined as an inductive type \textit{statement}, and connected by a \textit{list} type. The main omissions in Lolisa are \textit{inline assembly}, the explicit \textit{ether unit} of Solidity, the \textit{goto} statement, and non-structured forms of switching such as Duff’s device [37].

In particular, the formal syntax of Lolisa is defined using GADTs. As indicated by the following rule:

\[
T :: \tau_0 \rightarrow [\ldots] \rightarrow \tau_n \rightarrow \text{Type},
\]

a syntax token \( T \) is specified by static type annotations \( \tau_i \) for all values and expressions of Lolisa. This ensures that the formal syntax of values and expressions is more clear and abstract, and facilitates the strict maintenance of type safety for Lolisa expressions. In addition, employing a combination of type annotations facilitates the definition of a very large number of different expressions based on equivalent constructors. Of course, the use of \( \tau_0 \) and \( \tau_1 \) may be subject to different limitations depending on the condition. However, the application of GADTs provides Lolisa with a stronger static type system than Solidity because the type system of Lolisa strictly defines the syntax rules and relevant limitations in the formal specifications as typing judgments. For example, in the \textit{If} statement

\[
\text{If} : \forall (t : \text{type}), \text{expr}_{\tau_{bool}} \rightarrow \text{statement} \rightarrow \text{statement} \rightarrow \text{statement},
\]

its condition expression is limited by type \( \text{expr}_{\tau_{bool}} \), which specifies that the normal form of a specific condition must be a Boolean type. As such, an ill-typed \textit{If} statement, such as \( \forall \ s' : \text{statement}, (\text{If} (E_{const}(V_{undef}(t))) \ s') \), would be disclosed by the type-checking mechanism of Coq, which would then present the error message shown in Fig. 7. An additional benefit to the use of GADTs in Lolisa is that the resulting strong static type-checking system assists in discovering errors imported when translating Solidity into Lolisa. This is particularly beneficial because, although syntax errors would be discovered during compilation in the EVM, implementing a compiler mechanism in Coq to check for syntactical correctness when translating Solidity into Lolisa would be an extremely challenging task. Moreover, such errors can seriously affect the evaluation of programs in higher-order theorem-proving assistants. In addition, because Solidity can be equivalently translated into Lolisa directly, the strong static type-checking system also assists in discovering ill-typed terms in Solidity source code. To our knowledge, Lolisa is the first FSL of Solidity using GADTs.

![Fig. 6. Relationships between Solidity and Lolisa.](image)
∀ s s': statement, \( \{ \text{if } \text{Econst(Vudeof(t))} \} \text{ s s'} \) in Lolisa.

The semantics of Lolisa are formally defined as big-step operational semantics with inductive relational forms and executable function forms. Because Lolisa is employed as the equivalent intermediate language for Solidity, which should be able to be parsed, executed, and verified in Coq or a similar proof assistant, the semantics of Lolisa are deterministic, and are also based on the GERM framework. The equivalence between the inductive relational forms and the executable function forms of the operational semantics of Lolisa is certified by the following simulation diagram theorem.

**Theorem** (simulation diagram): Let \( E, M, \mathcal{F} \vdash \text{ins } \sigma, \text{opars}, \text{env}, f \text{env}, b \text{infor} \) be the initial evaluation environment, and let \( R_{eq} \) represent an equivalence relationship between any two terms. Then, any relational semantic \( S_{rel} \) and executable semantic \( S_{exe} \) must satisfy the following simulation diagram.

\[
\begin{align*}
S_{rel} & \xrightarrow{R_{eq}} E, M, \mathcal{F} \vdash \text{ins } \sigma, \text{opars}, \text{env}, f \text{env}, b \text{infor} \\
\downarrow & \\
S_{exe} & \xleftarrow{R_{eq}} E, M, \mathcal{F} \vdash \text{ins } \sigma, \text{opars}, \text{env}, f \text{env}, b \text{infor}
\end{align*}
\]

In addition, the development of FEther in Coq and its verification process will be simplified if a *program formal* written in Lolisa is maintained as a structural program. To ensure this condition, the semantics of Lolisa are made to adhere to the following program counter axiom.

**Axiom** (Program Counter): Suppose that, for all statements \( s \), if \( s \) is the next execution statement, it must be the head of the statement sequence in the next execution iteration.

It must also be noted that the formal syntax of Lolisa contains numerous typing limitations, and is overly complex to accommodate its adoption by general users, as illustrated by the example If statement given in Figs. 8(a) and (b). Therefore, Lolisa is made more intuitive by encapsulating the abstract syntax tree of Lolisa into symbol abbreviations based on the macro-mechanism of Coq, which is denoted as the notation mechanism. A notation is a symbolic abbreviation denoting some term or term pattern, which can be parsed by Coq automatically. For example, the notation shown in Fig. 8(c) can be employed to encapsulate the If statement given in Fig. 8(b), with the result shown in Fig. 8(d). The use of the notation mechanism in Lolisa is illustrated by the components enclosed within the dashed-line box in Fig. 6. As a result, the fixed formal syntax components of Lolisa used in verification are transparent to users, and thereby provide users with a simpler syntax. Moreover, this mechanism makes the equivalence between real-world languages and Lolisa far more intuitive and user friendly. An additional benefit of this mechanism is that it provides for improved automation of the formalization process. Here, as was conducted when converting Fig. 8(b) to Fig. 8(d), programmers can easily develop a simplified translator, such as a compiler frontend or even a simple parser, to automatically convert a Solidity program to the macro-definitions of the Lolisa abstract syntax tree. In addition, these macro-definitions are helpful for promoting extensibility to other programming languages, the details of which are discussed in Section 6.
Finally, we have developed a small standard library in Coq that incorporates the built-in data structures and functions of the EVM to facilitate the execution and verification of Solidity programs rewritten in Lolisa using higher-order logic theorem-proving assistants directly. Currently, this standard library is a small subset that includes the syntax components msg, address, block, send, call, and requires. Lolisa is the first mechanized and validated formal syntax and semantics developed for Solidity. The equivalence relationship between Solidity and Lolisa is defined according to the following rule:

$$\forall s, s \in \text{Solidity} \land T(s) \in \text{Lolisa} \implies s \equiv T(s).$$

where all Solidity statements $s$ subjected to translation process $T$ are equivalent with their formal version in Lolisa.

### 3.3 FEther

FEther is an extensible definitional interpreter that is completely developed in Coq based on the GERM framework and Lolisa. The overall FEther structure is illustrated in Fig. 9. FEther is entirely constructed in the TCOC, and logically comprises three main components from left to right: a parser, an instruction set architecture (ISA) based on Lolisa semantics, and a validation checking mechanism.

The parser is employed to analyze the syntax of a $\text{program}_{\text{format}}$ written in Lolisa, extract the tokens from $\text{program}_{\text{format}}$, and invoke corresponding semantics. As mentioned above, Lolisa $\text{types}$ are used as the type signatures in Lolisa $\text{value}$ and $\text{expression}$ layers, and are dependent on corresponding Lolisa $\text{values}$. Therefore, the parsing and execution processes of $\text{types}$ and $\text{values}$ are combined together.

With respect to the ISA, FEther is essentially a very large function written in the Gallina specification language. Hence, FEther differs from the kernel of other real-world virtual machines of high-level programming languages, such as Smalltalk, Java, and Net, which support bytecode as their ISA, and are implemented by translating the bytecode for commonly used code paths into native machine code. In our work, FEther takes the executable semantics of Lolisa as the ISA, which is employed to specify the semantics of the syntax tokens to represent their execution behaviors accurately. Currently, FEther fully supports all semantics of Lolisa.

The validation checking mechanism includes both checking the validation of the results (including memory states and memory values) and checking the execution condition. Because all functions are vulnerable to undefined conditions due to various causes, we develop functions with the help of a monad [38]. Here, all functions are tagged by an $\text{option}$ type. If a function generates a valid result, the result will be returned in the form of $\text{Some } t$. Otherwise, it will be returned as an undefined value $\text{None}$. In addition, the symbol $[t]$ represents a term $t$ tagged by the $\text{option}$ type.

To avoid the execution of infinite loops in programs, FSPVM-E also adopts a $K$-step limitation mechanism, where, similar to Bounded Model Checking (BMC) [39], we limit FEther to executing a $\text{program}_{\text{format}} K$ times at most. In addition, we note that the EVM also does not support infinite execution processes because each execution step in a smart contract incurs a gas penalty, and the execution terminates once the gas balance is reduced to zero. This design well suits the BMC approach. Therefore, our implementation uses gas to limit the execution of Lolisa programs in FEther. The rules governing the execution of a Lolisa program in FEther are defined by (17) and (18) below, where the symbol $\infty$ refers to infinite execution, and $T$ is the termination condition limit that ensures a finite execution.
\[\epsilon \vdash \text{env}, \text{env} \quad M \vdash \text{binfor} 
\begin{array}{l}
F \vdash \text{opars} \\
\epsilon, M, F \vdash \text{P}(\text{stt}) \\
\epsilon, M, F \vdash \text{lib}
\end{array}
\]
\[\text{env} = \text{set}_\text{gas}(\text{init}_\text{env}(\text{P}(\text{stt})))
\quad \text{fenv} = \text{init}_\text{env}(\text{P}(\text{stt}))
\quad \sigma = \text{init}_\text{mem}(\text{P}(\text{stt}), \text{lib})
\]
\[\epsilon, M, F \vdash \text{FEther}(\left[\begin{array}{l}
\text{m}_{\text{state}} \\
\text{environ vars, P}(\text{stt})
\end{array}\right])
\quad \text{execute}_\text{F}
\quad (\sigma', \text{env}', \text{fenv})
\]
\[\epsilon \vdash \text{env, env} \quad M \vdash \text{binfor} 
\begin{array}{l}
F \vdash \text{opars} \\
\epsilon, M, F \vdash \text{P}(\text{stt}) \\
\epsilon, M, F \vdash \text{lib}
\end{array}
\]
\[\text{env} = \text{set}_\text{gas}(\text{init}_\text{env}(\text{P}(\text{stt})))
\quad \text{fenv} = \text{init}_\text{env}(\text{P}(\text{stt}))
\quad \sigma = \text{init}_\text{mem}(\text{P}(\text{stt}), \text{lib})
\]
\[\epsilon, M, F \vdash \text{FEther}(\left[\begin{array}{l}
\text{m}_{\text{state}} \\
\text{environ vars, P}(\text{stt})
\end{array}\right])
\quad \text{execute}_\text{F}
\quad (\sigma', \text{env}', \text{fenv})\]

In addition, FEther benefits from Lolisa by achieving low coupling between the executable semantics at equivalent levels and at different levels. Specifically, the executable semantics at equivalent levels are independent of each other, and are encapsulated as modules with a set of interfaces. At different levels, the higher-level semantics can only access lower-level semantics via interfaces, and the implementation details of lower-level semantics are transparent to higher-level semantics, which is represented by the dashed-line box in Fig. 6. The implementation of higher-level semantics is also not dependent on the details of lower-level semantics. In this manner, FEther can be easily extended, as is discussed in Section 6.

### 3.4 Assistant Tools and Libraries

The assistant tools and automation-assisting libraries of FSPVM-E are used to reduce the manual workload and increase the degree of automation when users deploy FSPVM-E, formalize target smart contracts, and verify properties.

#### 3.4.1 Assistant Tools

As discussed previously, FSPVM-E includes customizable components for implementing the specific requirements of users, such as memory space and label addresses, that must be defined dynamically. Taking the memory space given in Fig. 5 as an example, the size of the specific formal memory space depends on the size that users require. The enumeration of memory blocks is conducted manually as follows.

\[\text{memory} \equiv \text{Record}(m_{\text{addr}}^*, m_{\text{value}}^*)\]  

Clearly, defining a specific memory space by enumerating blocks manually would be very tedious work. Fortunately, all dynamic specifications like rule (19) above have fixed abstract models. Therefore, these dynamic specifications can be easily generated recursively by a generator written in a high-level programming language such as Java or C++. In addition, the strict equivalence between Lolisa and Solidity discussed above guarantees that programs written in Solidity can be translated into Lolisa, and vice versa, with a line-by-line correspondence without rebuilding or abstracting, which are operations that can negatively impact consistency. Similar to the process of converting Fig. 8(a) to Fig. 8(d), we develop a translator as a compiler front end to automatically convert Solidity programs into the macro definitions of the Lolisa abstract syntax tree. The abstraction process is given formally by the following rule.

\[\Gamma, \mathcal{R} \vdash \text{Tools}(r) \rightarrow \text{specifications} \quad \text{yields} \quad \text{\# of files}\]

Here, assistant tools function within a theorem verification context \(\Gamma\) with requirements \(\mathcal{R}\), and employ specific user requirements \(r \in \mathcal{R}\) as parameters. Assistant tools then generate the respective formal specifications and export them as .\(v\) files that can be loaded in Coq directly. In this manner, the mechanical processes of FSPVM-E initialization and translation from Solidity into Lolisa can be completed automatically.

#### 3.4.2 Assistant Libraries

In standard manual modeling technology, different formal models with significantly different structures and verification processes can be constructed in various programs. Hence, designing a set of tactics that automatically verifies models in different programs is nearly impossible. However, according to EVI theory, symbolic execution in FSPVM-E corresponds to both function evaluation and program verification, as indicated by the following rule.

\[\Omega, M, F \vdash \text{ins} \quad P_{\text{ex}} \equiv P_{\text{eval}} \equiv P_{\text{verify}}\]

As such, the verification process \(P_{\text{verify}}\) of different programs is equivalent with the respective symbolic execution process \(P_{\text{ex}}\) in FSPVM-E. In other words, the symbolic execution process unifies the verification processes of different programs in higher-order theorem-proving assistants by simplifying the program evaluation process of FEther with different programs \(\text{programs}_f\).
in FSPVM-E. Because FEther takes the executable semantics of Lolisa as the ISA, FEther execution constitutes a fixed and finite semantics set \( \{ E_{S_0}, E_{S_1}, \ldots, E_{S_m} \} \). Accordingly, we can design a corresponding automatic tactic set \( t_i \) for each executable semantic \( E_{S_i} \), as follows.

\[
\forall i, E_{S_i} \leftrightarrow t_i \leftarrow T_i \left[ s_{t_0}^i, s_{t_1}^i, \ldots, s_{t_n}^i \right] \quad (22)
\]

This can be expanded to accommodate all possible semantic conditions. We exploit this advantage for designing primitive automatic tactics to automatically execute and verify the properties of smart contracts using the Ltac mechanism provided by Coq. As shown in Fig. 10, the Ltac-based tactic modeling is constructed from three components: memory operating tactics (MTS), execution tactics (ETS), and verification tactics (VTS). As the component names suggest, MTS is applied to evaluate the requests of GERM APIs, ETS is used to simplify the executable semantics of Lolisa, and VTS can simplify the pre-conditions and post-conditions and complete the mathematical reasoning during property verification. The workflow of the tactic modeling is also defined in Fig. 10. For Coq operating in the proof pattern, the observe (OB) function scans the current context \( C \) to obtain the current goal. Each component in sequence attempts to capture the operational characteristic of the current goal and select the matching tactics. The selected tactics are combined into a solution tactic \( Ltac_i \) that solves the goal in the TCOC. The new context \( C' \) is compared with \( C \) in context\(_{dec} \). If \( C' \) and \( C \) are identical, the current tactics cannot solve the goal automatically, and the tactic modeling process is terminated. Otherwise, the tactic modeling continuously attempts to simplify the goal of \( C' \).

Fig. 10. Automatic tactic modeling process based on the Ltac mechanism provided by Coq. The process is constructed from three components: memory operating tactics (MTS), execution tactics (ETS), and verification tactics (VTS), where each component in sequence attempts to capture the operational characteristic of the current goal and select the matching tactics that are combined into a solution tactic \( Ltac_i \).

An example of the Ltac-based tactic modeling is given as follows.

\[
Ltac \ unfold\_modify := \\
match \ context \ with \\
[ [ \ [ - \ context \ [ ? Y ( ?X: memory)(? Z: value) ] ] ] \Rightarrow unfold \ Y \ in \ * ; \ cbn \ in \ * \\
end.
\]

Here, the \( unfold\_modify \) tactic is a sub-tactic of a memory operation that captures parts of the operational characteristics of a specific \( write_{dir} \) function, and evaluates \( write_{dir} \) using basic built-in tactics.

Another assistant library is the static analysis library that is used to collect the formal specifications of standard vulnerabilities relevant to coding conventions. These formal specifications are used to construct a static analysis mechanism to quickly scan for bugs in the source code. The details of this library are discussed in Subsection 5.1.1.

4. SELF-CORRECTNESS CERTIFICATION

An essential issue that must be addressed before we can verify smart contracts in FSPVM-E is the self-correctness of FSPVM-E. Because FSPVM-E is employed as the TCB solver for the evaluation and derivation of the formal specification models and properties of smart contracts, the credibility of the analysis results is strongly associated with the correctness of the TCB. Similarly, ensuring the self-correctness of the verification TCB for all static analysis tools is an unavoidable issue. However, the work of Gödel has established that a logic cannot prove its own consistency. As such, the fact that verifiers cannot verify themselves presents a paradox. Actually, most theorem proving assistants based on satisfiability modulo theories (SMT) [40] and other types of static analysis tools based on symbolic execution technologies assume that their computation cores are correct, although correctness has not been certified. Therefore, these tools are classified as untrusted in many studies. In contrast, one of the most important features of FSPVM-E is that its self-correctness can be ensured with a very high degree. This is explained in the following subsections. Here, we first demonstrate that the components of FSPVM-E in the trusted domain of Coq can be verified directly. Secondly, we demonstrate that the components in the untrusted domain have no effect on the self-correctness of
FSPVM-E from the perspectives of the minimum trusted computational base and the non-aftereffect property.

4.1 Minimum Trusted Computational Base

The development of methods to avoid the above-discussed paradox has been conducted since the 1940s, and these approaches have been summarized for proof assistants [35]. Briefly, the manual review of a very small kernel by experts and the de Bruijn criterion [41] are two key approaches for ensuring the trustworthiness of a proof assistant. However, the TCB of most static analysis tools is an untrusted black box with a very large kernel that cannot be certified mathematically. Nor does it satisfy the de Bruijn criterion. This has been addressed by the Coq team by making the TCOC very small, which has enabled the correctness of the core code to be verified by the manual review of experts. Moreover, the TCOC also completely satisfies the de Bruijn criterion. In addition, Harrison [42] has proven the consistency of the HOL Light logical core (or, strictly speaking, a subset of the logical core) using HOL Light itself based on the self-verification concept denoted as reflection, which is also supported in the TCOC. This proof is also completed supported by Coq. Therefore, the TCOC, including the fundamental theory and specific implementation, is currently widely recognized as one of the most reliable trusted cores available. Accordingly, FSPVM-E has a natural advantage compared with other program verification or analysis tools in that its three essential components are wholly developed in Coq, and it employs the TCOC as the TCB. In addition, the core components of FSPVM-E, including the GERM framework, Lolisa, and FEther, are all implemented using the Gallina specification language. In terms of property 1, these are respectively denoted as $\mathcal{F}(\text{GERM})$, $\mathcal{F}(\text{Lolisa})$, and $\mathcal{F}(\text{FEther})$. As such, the correctness of these three components can be directly certified in Coq based on property 1 without the use of any other procedures. Thus, compared with other static analysis tools that must assume the correctness of the TCB, the smart contract verifications that take the proposed FSPVM-E as the TCB must only trust the TCOC. The corresponding verification details are given elsewhere [11, 28, 29]. At present, the core functions of FSPVM-E, which includes 74 theorems and 183 lemmas in Coq, have been completely verified.

4.2 Non-aftereffect Property

Although the kernel of FSPVM-E in Coq is verified, the assistant tools are developed in the untrusted domain using general-purpose programming languages. Therefore, these tools are obviously vulnerable to incorrect specifications that can have an impact on the correctness of FSPVM-E. However, the correctness of assistant tools is difficult to audit and certify. Fortunately, the relationship between the assistant tools and their respective results satisfies the non-aftereffect property. Here, although the assistant tools are developed in the untrusted world to automatically generate the dynamic situation-dependent specifications of FSPVM-E, these generated specifications are defined in Gallina, and therefore satisfy property 1. Hence, as illustrated in Fig. 11, the self-correctness of generated specifications can be certified in Coq directly. As such, we can conclude that the component of FSPVM-E affected by generated specifications is correct if the generated specifications pass their correctness certifications. As such, the correctness of FSPVM-E is not influenced by the means through which the assistant tools are implemented.

![Non-aftereffect relation between the dynamically generated specifications of assistant tools with the direct certification of their self-correctness in Coq.](image)

5. Experiment

We demonstrate the workflow and novel features of our new toolchain in real-world practice by applying FSPVM-E to formalize and verify a Smart Sponsor Contract (SSC). An SSC is a simple but classic Ethereum sponsor contract demo for new users on the IBM Cloud Laboratory website\(^4\). Its simplicity makes it an ideal example in the present work. This example offers an additional benefit, in that we have verified this smart contract in our past work using a standard theorem proving approach in Coq [43], and the source code can be downloaded from our Gitee site\(^5\). Therefore, we can clearly illustrate the advantages of FSPVM-E by comparison with our past work. Only the necessary code segments are presented in the following discussion to enhance the readability; however, the complete code of this example is given in the Appendix, and can also be downloaded from the cited IBM

\(^4\) https://developer.ibm.com/clouddataservices/2016/05/19/block-chain-technology-smart-contracts-and-ethereum/
\(^5\) https://gitee.com/zyangFV/SSC-manual-verification
website. The experimental environment employed 5 identical personal computers with equivalent hardware, including 8 GB RAM and a 3.20 GHz CPU, and equivalent software, including Windows 10 and CoqIDE 8.6.

5.1 Case Study: Hybrid Verification System

5.1.1 Workflow

The general workflow of FSPVM-E can be defined in conjunction with Fig. 12. First, users provide a smart contract, the properties of user requirements, and an expected execution environment. Next, users deploy this system in a specific circumstance by applying the generator and translator provided by the assistant tools. The generated formal specifications are certified by the self-correctness theorems stored in the assistant libraries before initializing. These specifications are adopted in FSPVM-E if they satisfy the self-correctness theorems; otherwise, the verification process is terminated. The translator automatically reads the .sol file, translates the Solidity smart contract into the respective formal form in Lolisa, defines the program model, and allocates logic memory blocks for all variables. A section of the SSC generated by the translator is shown in Fig. 13, where $C$ represents the code segment, $\Gamma[C]$ denotes the current global context of $C$, $c_i$ represents a single instruction, $d$ represents a child definition, $\tilde{d}$ denotes possible sequences $d_0, \ldots, d_n$, and $D$ is a set of definitions. It should be noted that the essence of smart contract segment specifications in Coq is a logic term with a specific logic type list statement declared by a definition, and FEther is driven by the executable semantics of each abstract syntax. The abstract syntax of code segment definition is also summarized in Fig. 13. Hence, FEther has no limitations on the size and continuity of an input program format and even a single statement can be defined in the proof context of FSPVM-E and symbolically executed by FEther. As an example of the translation process, a formal model of a partial SSC (please see the Appendix) is shown in Fig. 14. In addition, the formal version of the pledge function of the SSC is presented in Fig. 15. We note that the formal version of the pledge function is very intuitive, in that the pledge operation succeeds if the input value is not 0, and the smart closed flags complete and refunded are false. Finally, users need only operate Coq in its proof pattern, and launch FSPVM-E to automatically analyze and verify the smart contracts based on the requirements specified by the user. We provide the following three basic analysis and verification mechanisms in FSPVM-E: static analysis, hybrid verification, and a debugging mechanism. In the following subsections, the pledge function is employed as an example to illustrate the analysis and verification process in detail.

![Figure 14. Partial Smart Sponsor Contract (SSC) model](image)

Fig. 15. 5.1.2 Static Analysis Mechanism

The static analysis mechanism is embedded within FSPVM-E to identify standard vulnerabilities related to coding conventions and coding mechanisms in smart contracts, such as integer overflow and send check bug, rather than the logic of the service design. Of course, these vulnerabilities can be accurately identified by defining and verifying corresponding theorems, but this process generates a heavy and tedious workload. However, these vulnerabilities have distinct features that clearly distinguish them from logical vulnerabilities, and are accordingly identified easily and quickly using conventional static analysis technology. Therefore, static analysis is a better choice for supporting this type of security. Moreover, the equivalence between Lolisa and Solidity ensures that the source code of smart contracts can be translated line-by-line into FSPVM-E without the loss of features.

As introduced in Subsection 3.4, FSPVM-E includes a static analysis library that contains standard vulnerability features and scanning functions. Here, a \( \text{scan} \) function takes a signed by \( \text{option} \) type according to the following rule.

\[
\Gamma^{'}[c] \vdash \text{scan}(\text{program}^{\text{formal feature}}) \Rightarrow [c]
\]  

If the \( \text{scan} \) function locates vulnerabilities, it will return \( \text{Some} \ c_{\text{error}} \). Otherwise, it will return \( \text{None} \). For example, if we want to check if a \( \text{send check bug} \) problem exists in the \( \text{pledge} \) function, we need only apply the corresponding scan function to validate the source code, as shown in Fig. 16. A scanning result of \( \text{None} \) indicates that the target \( \text{program}^{\text{formal}} \) contains no code segment with a potential risk of the corresponding feature. Otherwise, the code segment with the potential vulnerability will be located in the proof context. We have encapsulated rule (24) in the current version of FSPVM-E with fixed features to obtain the following particular scan functions.

\[
\text{scan}_{\text{feature}} : \text{list statement} \rightarrow \text{option statement}
\]

\[
\text{scan}_{\text{feature}} := \lambda (p:\text{list statement}). \text{scan}(p, \text{feature})
\]

In this manner, the generator can automatically replace \( p \) with the target \( \text{program}^{\text{formal}} \) in all feature scanning functions, and automatically analyze \( \text{program}^{\text{formal}} \) according to all of its vulnerability features. This mechanism provides FSPVM-E with...
the following advantages. First, it provides an optional choice for users to check individual security vulnerabilities efficiently. Second, higher-order logic can be employed to formalize specifications that are more complex than standard specifications. Thirdly, the static analysis library can be easily extended by adding new specifications and functions for new vulnerabilities. Finally, as discussed in Subsection 4.1, this mechanism is completely developed in Coq, so its correctness can be certified in Coq.

![Image](image-url)  
Fig. 16. Simple case study of scanning send check vulnerability.

Of course, like similar conventional mechanisms, this mechanism also has the potential for issuing false alarms and providing insufficient error reporting. Therefore, it is provided only as an optional and independent assistant mechanism for users to employ prior to property verification. To our best knowledge, this is the first time that a static analysis mechanism has been embedded within a Coq proof system for Ethereum validation.

5.1.3 Hybrid Hoare Style Property Verification

As discussed in Section 1, potential legal loopholes in smart contracts represent subtle bugs that cannot be detected by standard scanning technologies because these loopholes are closely related to the logic of the specific source code. Solving this problem by means of automated theorem proving represents the most important core function of FSPVM-E. Here, FSPVM-E automatically verifies the requirement properties defined by users based on higher-order logic using Hoare style proof derivations according to the following abstract expression.

\[ P(m_{\text{init}}) \land \text{FEther}(m_{\text{init}}, \text{program format}, *) \rightarrow Q(m_{\text{final}}) \]  

(25)

First, the precondition \( P \) is defined by the initial memory state \( m_{\text{init}} \), which stores the essential logic invariants of variables. Second, \( \text{FEther}(m_{\text{init}}, \text{program format}, *) \) is the entry point of the symbolic execution engine, and takes \( m_{\text{init}} \), the target smart contract \( \text{program format} \), and other inputs as parameters. Third, the postcondition \( Q \) is defined by the expected final memory state \( m_{\text{final}} \), which represents the expected obligation of \( \text{program format} \).

As discussed in Section 2, the Hoare logic derivation is equivalent to the trusted execution of operational semantics. Therefore, the execution of F Ether can be seen as a derivation process based on Hoare logic following the executable semantics of Lolisa. The inference process is given by the following expression.

\[ P(m_{\text{init}}) \land \text{FEther}(m_{\text{init}}, c_0, *) \rightarrow \left\{ \begin{array}{l} \text{FEther}(m_{\text{init}}, c_0, *) \rightarrow Q_0(m_0)^c_1 \\ \text{FEther}(m_{\text{init}}, c_0, *) \rightarrow Q_0(m_0)^c_1 \\ \vdots \\ \text{FEther}(m_{\text{init}}, c_0, *) \rightarrow Q_0(m_0)^c_1 \end{array} \right. \rightarrow \left\{ \begin{array}{l} c_n Q_n(m_n)^c_i \\ \vdots \\ c_n Q_n(m_n)^c_i \end{array} \right. \rightarrow Q(m_{\text{final}}), i \geq 0, j \geq 0. \]  

(26)

Beginning with \( m_{\text{init}} \) as the precondition of program verification, F Ether generates all possible proof subgoals, and logically modifies the current memory state \( m_{i-1,j} \) (\( j \in \mathbb{N} \)) according to the semantics of each statement \( c_1 \) to generate all possible new postconditions \( Q_i(m_j)^c_1 \) (i.e., the preconditions of \( c_{i+1} \)). The theorems need only judge whether the final output memory state \( m_n \) obtained after executing the final statement matches the correct memory state \( m_{\text{final}} \). Specifically, users need only apply the automatic tactics to automatically complete the symbolic execution of \( \text{program format} \), and prove the equivalence between the results of \( \text{FEther}(m_{\text{init}}, \text{program format}, *) \) and \( Q(m_{\text{final}}) \). If the equivalence is true, \( \text{program format} \) satisfies the respective property theorem.

Because the F Ether is a black box for users, general programmers need only be familiar with the mechanical process of applying assistant tools and defining the initial and final memory states with Hoare style logic. Therefore, FSPVM-E reduces the difficulty with which general programmers can apply higher-order theorem proving technology to verify their smart contracts in Coq. In addition, users can alter the symbolic execution process (including static, concolic, and selective symbolic execution) during the verification process by defining the preconditions in different ways. This is explained in the following subsections taking the \( \text{pledge} \) function of the SSC as an example.

5.1.3.1 Static Symbolic Execution

The basic verification process is based on conventional symbolic execution. When the initial arguments are inductively defined with quantifiers such as \( \forall \) and \( \exists \), the verification engine F Ether will follow the logic of the source code to traverse all
cases that satisfy the preconditions. Specifically, if one of the sponsor termination flags \( \text{complete} \) and \( \text{refund} \) is set as true or the donation amount is zero, the smart contract must be discarded. The Lemma pledge\_false defined in Fig. 17 initializes \( (\text{Bool}(\text{Some} \, ?X)), \, (\text{Bool}(\text{Some} \, ?Y)), \) and \( (\text{INT} \, I64 \, \text{Signed} \, ?Z) \) by specifying \(?X, \, ?Y, \) and \(?Z\) as inductive values representing all possible conditions of initial termination flags and the donation amount, namely, as
\[∀ \, (cp: \text{bool})(\text{Bool}(\text{Some} \, cp)) \] \[∀ \, (rf: \text{bool})(\text{Bool}(\text{Some} \, rf)) \] \[∀ \, (\text{num}: \text{int})(\text{INT} \, I64 \, \text{Signed} \, ?Z) \] respectively. Specifically, the initial memory states \( m \) to \( m_a \) that satisfy the pledge function and other essential preconditions are defined first. Second, the formal specification \( \text{fun}\_\text{pledge} \) and preconditions are given into the entry pointer of FEther, denoted as \( \text{test} \). Next, the expected postcondition that the pledge function is not applied successfully is defined as \( \text{Some} \, \text{init} \, \text{m}' \) in Fig. 17. Finally, users need only mechanically apply the compositive automatic tactics to initialize the preconditions as the initial execution environment, symbolically execute \( \text{fun}\_\text{pledge} \), and verify the equivalence between the execution result and the postcondition by forward reasoning. This represents the complete property verification process. Programmers can execute and complete this property verification using the automatic tactics of FEther within 0.861 s (right-hand side of Fig. 17).

Fig. 17. Static symbolic execution process for verifying the pledge function with abstract symbol arguments.

### 5.1.3.2 Concolic Symbolic Execution

Because Coq is also a kind of functional programming language, it supports the evaluation of specific real inputs. As shown in Fig. 18, the entry points \( \text{test} \) and code \( \text{pledge} \) are unmodified, and \( \text{complete} \) and \( \text{refund} \) are replaced with specific values true and false, respectively. The other constraints are still inductively defined as abstract symbols. The functional correctness with the specific inputs is then proven by the lemma pledge\_false. Because the inputs are specified, the number of possible execution paths is limited, and the execution time is reduced to 0.222 s (right-hand side of Fig. 18). This mechanism leaves extensible space support for standard testing. Users can extend the generator or implement a new test mechanism to automatically generate test script to modify the initial arguments and validate target programs.

Fig. 18. Concolic symbolic execution process for verifying the pledge function.

### 5.1.3.3 Selective symbolic execution

This verification process allows programmers to extract segments of code from target programs, verify the properties of the selected code segments separately, and apply these verified properties to simplify the verification process of target programs. For example, a code segment \( C \) can be redefined as follows.

\[ C \equiv d = [c_0, \ldots, c_l] + \cdots + [c_{j_1}, \ldots, c_k] + \cdots + [c_{m_1}, \ldots, c_n] + \cdots + [c_{m_2}, \ldots, c_n] \Rightarrow \Gamma'(d_i \equiv [c_{j_1}, \ldots, c_k], d_j \equiv [c_{m_1}, \ldots, c_n]) \]

\[ = [c_0, \ldots, c_l] + \cdots + d_i + \cdots + d_k \Rightarrow \Gamma''(d_i \equiv [c_{j_1}, \ldots, c_k], d_j \equiv [c_{m_1}, \ldots, c_n]) \]

\[ \text{Verify}(C) = \text{Verify}(c_0, \ldots, c_l) + \cdots + d_i + \cdots + d_k \] 

Therefore, the key point is whether \( \text{Verify}(c_0, \ldots, c_l) + \cdots + d_i + \cdots + d_k \) is equivalent to \( \text{Verify}([c_0, \ldots, c_l]) + \cdots + \text{Verify}([d_i, \ldots, d_k]) \).
\[ + \cdots + \, + \text{Verify}(d_i) + \cdots + \, + \text{Verify}(D_k). \]

First of all, any code segment \( d \) that satisfies the syntax given in Fig. 13 will not be unfolded and executed and verified in FEther according to the following rule.

\[
P(m_{\text{init}}) \xrightarrow{\text{FEther}(m_{\text{init}}, \epsilon, \ast)} Q_0(m_d) \xrightarrow{\text{FEther}(m_d, d, \ast)} Q_1(m_d) \rightarrow \cdots \xrightarrow{?} Q(m_{\text{final}})
\]  

(27)

Obviously, we obtain the result \( P_d(m_d) \, d \, Q_d(m_{df}) \), which means that, according to the purposed precondition \( P_d(m_d) \), \( \text{FEther}(m_d, d, \ast) \) will obtain the expected logic state \( Q(m_{df}) \). In addition, because Coq employs a call-by-name evaluation strategy [44], the bodies of all definitions, including functions and values, are stored in their own contexts, and are not evaluated until they are needed in the current proof context \( \Gamma_c \). Therefore, any segment \( d \) of the logic expression \( \epsilon \) in the current proof context will not be unfolded during the proof process until all instructions prior to \( d \) have been executed in the proof context, as indicated by the following rule.

\[
\Gamma \vdash d_1, d_2, \ldots, d_r \vdash (d_{r+1}, d_{r+2}, \ldots, d_{r+n}) \xrightarrow{\text{reduction}} \epsilon_{df} \quad \text{and} \quad \Gamma \vdash d_r, d_{r+1}, \ldots, d_{r+n} \vdash \epsilon_{df} \oplus d_r.
\]

(28)

Moreover, if a proposition \( Q \) is a subset of a proposition \( P \), \( P \) can imply \( Q \), which is denoted as \( \forall Q. \, Q \subseteq P \vdash P \rightarrow Q \). This is formalized as the following rule.

\[
P(m_{\text{init}}) \xrightarrow{\epsilon} Q_c(m_c) \subseteq P_d(m_d) \xrightarrow{\text{specify}} Q_d(m_{df}) \xrightarrow{\epsilon} \cdots \xrightarrow{?} Q(m_{\text{final}})
\]

(29)

Here, if the final logic memory state \( Q_c(m_c) \) of the instruction set \( \epsilon \) prior to \( d \) is a subset of the precondition \( P_d(m_d) \), which has already been verified, \( P_d(m_d) \) can be specified as \( Q_c(m_c) \) by applying \( P_d(m_d) \rightarrow Q_c(m_c) \), and \( Q_d(m_{df}) \) can also be determined according to the specific \( P_d(m_d) \). This process is easily executed, and can be automatically completed in Coq using the eapply, eauto, and Hint Resolve tactics. As introduced previously, FSPVM-E takes the GERM logic memory state as the pre and post conditions in the Hoare triple. Therefore, the excepted abstract or specific final memory state of \( \epsilon \) can be taken as the initial memory state of \( d \). Obviously, if \( \epsilon \) is correct, its final logic memory state is a subset of its expected logic memory state. The same procedure can be easily adapted to an arbitrary definition set \( D \). Hence, specifying all preconditions of \( d \) and \( D \) by the input post conditions yields \( \text{Verify}([c_0, \ldots, c_i] + \cdots + d_1 + \cdots + +D_k) = \text{Verify}([c_0, \ldots, c_i]) + \cdots + +\text{Verify}(d_i) + \cdots + +\text{Verify}(D_k) \).

As shown by the example in Fig. 19, the pledge function can be varied by exploiting the selective symbolic execution of FEther. Programmers can extract the core code segment if \((\text{msg. value} = 0 \, \mid \, \text{complete} \mid \text{ref nd}) \{\text{throw}();\} \) from the pledge function and redefine it as a new formal definition \( d \) denoted as \( \text{fun_pledge_if} \), as shown in the red box, which can in turn be independently verified by the pledge_false_select lemma. After combining the verified \( \text{fun_pledge_if} \) code segment into the pledge function, the verification of the pledge_false theorem can be completed by invoking the pledge_false_select lemma. Clearly, the pledge_false_select lemma can also assist in any other proofs that use the \( \text{fun_pledge_if} \) code segment. Capitalizing on this feature, FSPVM-E is able to improve its reusability and mitigate the effects of path explosion by extracting important or universal code segments, and verifying them separately. The details of this process are discussed in Subsection 5.4.
Fig. 19. Selective symbolic execution process for verifying the pledge function.

5.1.4 Debugging Mechanism

Finally, FEther provides an interactive debugging mechanism for users. Because FEther is developed based on the GERM memory model, the formal intermediate memory states record the proof information, such as logic invariants and expressions, of all variables during the execution and verification process in accordance with EVI theory. The proposed mechanism employs the debugging tactic step_debug to enable the step-by-step debugging of a smart contract by manually tracing these intermediate memory states. As shown in Fig. 20, the states of all memory blocks at the current break point are printed in the proof context.

Programmers can extract a target code segment using selective symbolic execution with debugging tactics, and trace the intermediate memory states to locate bugs. Fig. 21 shows the formal intermediate memory states obtained during the execution and verification of the pledge function using FEther in the proof context. Then, we can compare the mechanized verification results and the manually obtained results to validate the semantics of Lolisa. In addition, the application of FEther based on Lolisa and the GERM framework also certifies that our proposed EVI theory is feasible. Here, the logic memory states during execution can be observed in the proof context.
5.2 Advanced FSPVM-E Features

The advanced features of the purposed FSPVM-E include consistency, automation, evaluation efficiency, and modular verification, which are discussed individually in the following subsections.

5.2.1 Consistency

The consistency feature of FSPVM-E includes language formalization consistency and execution and verification consistency.

5.2.1.1 Language Formalization Consistency

This consistency feature refers to the equivalence between Solidity and Lolisa. Many well-known higher-order logic theorem proving frameworks, such as deep specifications [20], require researchers to manually abstract or rebuild the resource code of target programs as computational formal specifications in higher-order logic theorem proof assistants, and the overall process depends entirely on the experience, knowledge, and proficiency of researchers rather than on a standardized and mechanized criterion. As a result, the consistency between the formal model and the original program cannot be ensured formally, which represents one of the most troubling problems associated with higher-order theorem proving technology. As shown in Fig. 22, which was extracted from our previous work [43], the abstract formal specification of the pledge function in the Gallina specification language is far different from the corresponding source code given in Fig. 15 and the Appendix, even though it accurately defines the behavior of the pledge function. This flexibility in the abstraction and translation processes leads to a general lack of consistency between the formalization results obtained by different researchers, and the consistency between formal specifications and corresponding source programs is also very difficult to certify. As a result, the formal model runs the risk of misunderstanding the source program logic and implementation, and may import vulnerabilities not existing in the original program, or remove vulnerabilities existing in the source code as an unintended result of the abstraction and translation processes.

![Fig. 22. Manually translated version of the formalized pledge function [43].](image)

In contrast with conventional approaches, Lolisa has equivalently mechanized most syntax and corresponding semantics of Solidity into Coq, as indicated by the following rule:

\[ \text{program}_{\text{rw}} \in \text{Solidity} \land \mathcal{T}(\text{program}_{\text{rw}}) \in \text{Lolisa} \vdash \text{program}_{\text{rw}} \equiv \text{program}_{\text{formal}}. \]

(30)

where the symbol \( \mathcal{T} \) represents the translation process. In addition, the formal syntax of Lolisa has also been encapsulated into the syntactic abbreviations using the Notation macro mechanism, and hides the fixed formal syntactic components. Hence, as demonstrated by Figs. 14 and 15, smart contracts can be equivalently translated from Solidity into Lolisa line-by-line. Therefore, rule (30) above can be transformed into the following rule:
\[ \text{program}_{\text{format}} \equiv \text{program}_{\text{model}}, \] (31)

and \( \text{program}_{\text{format}} \) can be directly executed and verified in Coq with the help of FEther. Accordingly, \( \text{program}_{\text{format}} \) is actually the corresponding formal specification model \( \text{program}_{\text{model}} \) at the code level. Furthermore, according to logic transitivity, rules (16), (30), and (31) can be combined to obtain the following rule.

\[ \text{program}_{\text{rw}} \in \text{Solidity} \wedge \mathcal{T}(\text{program}_{\text{rw}}) \in \text{Lolisa} \Rightarrow \text{program}_{\text{rw}} \equiv \text{program}_{\text{format}} \equiv \text{program}_{\text{model}} \] (32)

Therefore, the target smart contract \( \text{program}_{\text{rw}} \) is equivalent with its formal model \( \text{program}_{\text{model}} \) in the proposed FSPVM-E.

This formalization by line-by-line translation in the proposed FSPVM-E is a mechanical process without any of the abstraction and rebuilding procedures that are employed in conventional higher-order theorem proving approaches for target programs. Because a simple translator can generate equivalent formal models of respective target programs, and researchers can easily check the consistency between \( \text{program}_{\text{format}} \) and \( \text{program}_{\text{model}} \), this process ensures the objectivity of the formal model, and depends in no way on the experience, knowledge, and proficiency of researchers. Thus, this process guarantees consistency between the source program and the respective formal model.

5.2.1.2 Execution and Verification Consistency

Execution consistency refers to the accuracy with which the symbolic execution of smart contracts in FSPVM-E simulate the actual behaviors of smart contracts when they are executed in the real world. This is facilitated by FSPVM-E in several ways. First, the GERM framework virtualizes the architecture and operations of real world memory hardware, and the semantics of Solidity are equivalently mechanized into Coq as the core of FEther. Moreover, Ethereum smart contracts written in Lolisa can be directly executed in FSPVM-E. Hence, the execution and verification level of FEther functions directly on what is essentially Solidity code rather than byte code, which avoids the risk of errors during compilation. Therefore, the symbolic execution of target smart contracts in FSPVM-E accurately reflects their behaviors in the formal systems.

5.2.2 Automation

As demonstrated by the case studies, another very important feature of FSPVM-E is its high level automation of higher-order theorem proving. The ratio of source code size to proof code size in many conventional higher-order theorem proving approaches (e.g., [20]) varies linearly in the range of about 20:1 to 40:1, and the workload can be summarized by the following rule.

\[ \text{workload}_{\text{manual}} = \text{size(formalization)} + \text{size(verification)} + \text{size(property)} \] (33)

Similar to these conventional approaches, properties must be manually defined in FSPVM-E. However, the size of the source code and the size of the proof code no longer have any direct relationship in FSPVM-E owing to the high level of automation of the formalization and verification processes.

The individual components of the workload for FSPVM-E (i.e., \( \text{workload}_{\text{FSPVM-E}} \)) can be analyzed as follows. First, as introduced in the above discussion regarding language formalization consistency, the formalization process is entirely unified as a line-by-line translation from Solidity to Lolisa, and we have already implemented a translator to make the translation process fully automatic. Therefore, \( \text{size(formalization)} \) is zero. Second, the ability of most mainstream interactive proof assistants, such as Coq and Isabelle, to reduce the workload associated with verification is limited, despite the fact that they provide tactic mechanisms to help users design proving tactics to simplify the program evaluation process and construct proofs automatically. This is because the above discussed differences among the different formal models derived from manual design make it difficult to design tactics that can verify formal models in a fully automatic fashion. However, in contrast to conventional verification approaches and frameworks, FSPVM-E standardizes the verification process as the execution of smart contracts in FSPVM-E according to rule (21). In addition, as discussed in Subsection 3.4, the finite number of executable semantics and operations in FSPVM-E facilitates the development of design strategy sets to automatically accommodate all possible semantic conditions, and these strategies are encapsulated as three basic tactics. The substantial reduction in \( \text{size(verification)} \) facilitated by FSPVM-E is well illustrated by comparing the verification of the \text{pledge_false} theorem shown in Fig. 17, which requires only a single line of code, with that obtained by directly verifying \text{pledge_false} using the conventional tactics of Coq, as shown in Fig. 23, which requires 20 lines of complex tactics. These three basic tactics can be applied manually or invoked automatically with the help of script programs. According to these features of FSPVM-E, \( \text{size(verification)} \) can be reduced to zero theoretically. Finally, the above discussion indicates that \( \text{workload}_{\text{FSPVM-E}} \) is related only to the size of the verification properties, i.e., \( \text{workload}_{\text{FSPVM-E}} = \text{size(property)} \), which depends on the complexity of the requirements of target programs rather than on
the size of their source code.

Fig. 23. Verification of the pledge function using the built-in tactics of Coq.

Fig. 24 shows that, compared with our previous work for SSC verification [43], the workload of FSPVM-E has been significantly reduced. Here, the workload of the formalization and verification processes in our previous work are 1283 lines of Coq, which represents a source code size to proof code size ratio of about 27:1. However, the manual workload in FSPVM-E is only 210 lines of Coq, which represents a source code size to proof code size ratio of about 4:1.

5.2.3 High Evaluation Efficiency

Although high level automated verification is very important, the computing efficiency of the formal verification engine is also an essential evaluation criterion. Our previous version of FEther obtained good computing efficiency during verification relative to most verification tools for which the computing efficiency is generally quite low. However, we found that call-by-name termination (CBNT), information redundancy explosion (IRE), and concurrent reduction (CR) problems could greatly reduce the computational efficiency of FEther when verifying large programs [30]. Briefly, if the CBNT, IRE, and CR problems are triggered simultaneously, the evaluation strategy of higher-order logic proof assistants will cause FEther to employ the entire \( \text{Program}_{\text{formal}} \) rather than a single statement as an evaluation unit, which generates a very large amount of redundant logic information. This condition is summarized by the following formulae:

\[
inf_{\text{size}} \sum_{i=0}^{n} \left( e_i + d_{i} + c_{\text{noSub}_i} + \left[r_0 \cdots r_i\right] \right) + \text{size}(\text{program}_{\text{formal}}).
\]

where \( c_{\text{noSub}} \) represents the average number of constructors without sub-branches, \( c_{\text{sub}} \) represents the average number of constructors with sub-branches, \( c_{\text{sub}_j} \) and \( c_{\text{noSub}_j} \) represent the number of sub-branches of \( c_{\text{sub}_i} \) (\( i, j \in \mathbb{N}, 0 \leq i \leq j \), \( r_0 \) to \( r_i \)

Fig. 24. Comparison of the verification workloads of a conventional theorem proving approach and FSPVM-E for SSCs.
represent the number of values constructed by different datatypes, and $size_0$ to $size_l$ represent the number of constructors for each respective datatype. In addition, $infor_{size}$ also contains basic expressions and definitions that can be evaluated directly, and the average number of these basic expressions and definitions are defined as $es_i$ and $ds_j$, respectively. The previous version of FEther was developed strictly following standard interpreter tutorials that explicitly declare sequence statement semantics. As such, the basic functionality of this version can be illustrated by the following simple conditional statement of $pledge\_obligation$.

$$\text{obligation}_\text{throw} \equiv \forall (s, s'): \text{statement}, if \ (true)\{ \text{throw} () \}; \text{else} \ {s; \ s'}$$  \hspace{1cm} (35)

This simple code segment will execute $\text{throw} ()$ to throw out an executing program and return the initial memory state $m_{init}$ when the condition ($\text{value} == 0 \lor \text{completed} \lor \text{refund}$) is evaluated as true. However, the evaluation process of $\text{obligation}_\text{throw}$ generates 10,736 lines of logic expressions, and, as shown in Fig. 25, executing (i.e., verifying) this very simple code segment using the non-optimized development of FEther requires an execution time of 92.546 s, which is unacceptably long.

In response to this issue, we optimized FEther [29] by applying three proposed optimization schemes, including redefining semantics, deeply embedding, and multiple pumps. This optimized version of FEther is that employed for the proposed FSPVM-E discussed in the present report. The current version of FEther takes a single statement as an evaluation unit, as indicated by the following rule.

$$infor_{size} \equiv es_r + ds_r + ds_g + size (\text{statement})$$  \hspace{1cm} (36)

Here, we assign $es_r$ as the number of basic optimal expressions in the context $\Gamma$, and assign $ds_r$ and $ds_g$ as the number of all bound names of definitions and general definitions, which are the entry points of the respective definition bodies. In this manner, the logic information size of an evaluation unit is maintained within a stable range without being affected by the size of the program. A comparison of the result given in Fig. 25 for the verification of $\text{obligation}_\text{throw}$ using the non-optimized version of FEther with the result given in Fig. 26 using the current version of FEther indicates that the symbolic execution time was decreased from 92.546 s to 0.035 s. As such, the optimized version requires just 3/10000 of the time required by the non-optimized version. In fact, all of the example verifications presented in Subsection 5.1 required less than 1 s. In addition, we also compared the results obtained with the optimized and non-optimized versions of FEther under equivalent experimental environments with an equivalent data set extracted from a previous study [4]. Under the experimental environment given above, each computer executed the same data set 150 times to obtain the average number of executions required by the FEther evaluation process. In addition, we set an execution time limit of 3600 s to obtain sufficient experimental data. The experimental environments included a specific initial state and an abstract initial state, whose initial arguments of the programs are defined inductively using quantifiers (such as $\forall$ and $\exists$) to logically express all possibilities. As shown in Fig. 27, the average execution times of the non-optimized version of FEther with both the specific initial state ($\text{SpecNOp}$) and the abstract initial state ($\text{AbsNOp}$) increase rapidly with an increasing number of program lines, and exceed the time limitation of 3600 s after executing about 30 and 20 program lines, respectively. Moreover, the ranges of fluctuations in the execution times are large, as indicated by the error bars. In contrast, the optimized version of FEther with both the specific initial state ($\text{SpecOp}$) and the abstract initial state ($\text{AbsOp}$) exhibit a steadily increasing average execution time with respect to an increasing number of program lines. In addition, the error bars are much smaller in this case. These results indicate that the execution efficiency of the current version of FEther far exceeded that of the previous non-optimized version of FEther developed in Coq in accordance with the standard tutorial.
5.2.4 Modular Verification

The selective symbolic execution process allows FSPVM-E to be extended to support modular verification. This feature is helpful for addressing the reusability and path explosion problems caused by symbolic execution.

First, we note that reusability is another very important feature of FSPVM-E. The discussed differences among the different formal models derived from manual design in conventional verification approaches make it impossible for a verified program to be reused for assisting in the verification of other similar programs. This problem generates a considerable volume of redundant and duplicate work. Modular verification facilitated by the selective symbolic execution process of FSPVM-E can solve this problem to some degree. As discussed above, the proof mechanism of Coq for a verified program segment can directly invoke the relevant theorems of the segment according to the definition name of the program segment. This process is illustrated in Fig. 28. Here, we note that the verified code segment definitions can be used in other programs to assistant with property verification. Therefore, generic code segments, such as abstract obligations and functions of built-in libraries, can be selected and verified in advance, and then combined as a verification library. Clearly, the application of this process would result in the accumulation of universal validation libraries as verification frameworks continued to be used. As discussed in Subsection 3.3, this process has already been applied to formalize and verify the built-in functions of the EVM. In general, smart contracts are designed as concise as possible and forbid the implementation of infinite loop iterations due to the gas limitation mechanism. However, a risk of path explosion arises in FSPVM-E because its reasoning engine is based on symbolic execution. Modular verification can avoid this risk if the source of path explosion is caused by complex branch statements rather than loop iterations, as well as by simplifying loop proofs.

First, modular verification can mitigate the risk of path explosion not caused by loop iterations by sequentially dividing $\textit{program}_{\text{formal}}$ into separate modules $M_i$ according to the complexity and contract structure $C$, as defined by the following rule.

$$\textit{program}_{\text{formal}} \equiv C(M_0) \ldots | M_i \rangle$$  \hspace{1cm} (37)

Here, users only need verify each $M_i$, and follow $C$ to invoke verified modules $\mathcal{V}(M)$ to verify $\textit{program}_{\text{formal}}$. In this manner, the risk of path explosion caused by complex branch statements can be reduced in theory, as demonstrated by the following rule.

$$P(m_{init}) \xrightarrow{\text{F Ether}(m_{init},M_0,s)} Q_0[m_0] \xrightarrow{\mathcal{V}(M_1)} \ldots \xrightarrow{\mathcal{V}(M_i)Q[m_i]} Q[m_{final}]$$  \hspace{1cm} (38)

Second, modular verification can simplify loop proofs. Conventional higher-order theorem proving approaches often require
that additional loop invariants be manually supplied for reasoning about circular behavior during execution. However, searching the loop invariants of simple loops is a tedious and difficult process. In contrast, the combination of symbolic execution and higher-order theorem proving employed in the present work facilitates the simultaneous use of BMC with the search for loop invariants. We first limit the executions of \( \text{program}_{\text{formal}} \) by FEther via \( K \)-step limitation based on the Ethereum gas limitation. In general, if \( L \) executions (where \( L \leq K \)) of \( \text{program}_{\text{formal}} \) can generate the corresponding final memory state, the loops existing in \( \text{program}_{\text{formal}} \) can be directly unfolded as a set of identical normal-sequence statements within a finite time, as inferred from rule (18). However, if \( \text{program}_{\text{formal}} \) fails to generate the corresponding final memory state after \( \text{gas} \) executions, we can step to the front of the loop in question, copy the existing state, employ the selective symbolic execution process to set the loop statement as a breakpoint, and separate \( \text{program}_{\text{formal}} \) into two segments, denoted as the head and tail segments. Next, we must locate the loop invariants and encapsulate them into an invariant memory state \( I \{m_i\} \), which serves as the final memory state of the head segment and the initial memory state of the tail segment. This procedure is embodied in the following rule.

\[
P(m_{\text{init}})c_0 \rightarrow c_i(m_i)\text{(head)} \quad \text{and} \quad c_i(m_i) \rightarrow c_nQ(m_{\text{final}})\text{(tail)}.
\]  

(39)

Under the composition rule of Hoare logic, \( P(m_{\text{init}})c_0 \rightarrow c_iQ(m_{\text{final}}) \) guides the construction of a loop invariant and proof of the target property. In this way, simple loops can be proven automatically, which reduces the workload of searching for loop invariants. Moreover, complex loops, such as unbounded loop iterations, that cannot be verified by model checking and symbolic execution technology can be proven by higher-order theorem-proving technology.

![Diagram](Fig. 28. Abstract modular verification process of FSPVM-E.)

However, the development of an automated modular verification mechanism has not yet been completed in the current version of FSPVM-E. Therefore, users must manually select and define the verification module.

### 6. Extensibility and Universality

While ensuring that the developed Ethereum-based verification platform faithfully captures the intended service properties of smart contracts written in Solidity is essential, further ensuring that this development can be applied to multiple blockchain platforms is also of great value. Therefore, implementing extensibility and universality in the FSPVM-E design was a goal considered from the beginning of its development.

First, we note that the implementations of the GERM framework and the assistant tools and libraries are not dependent on high-level specifications. Therefore, these components of FSPVM-E can be easily extended by adding new independent types, function specifications, and theorems to support new requirements. The means of facilitating this extensibility were briefly introduced in previous sections. Thus, the extensibility and universality of FSPVM-E are highly dependent on the extensibility of Lolisa and FEther. We deliberately incorporated sufficient extensible space in Lolisa and FEther to extend features, such as pointer formalization and the implementation of independent operator definitions. Extensibility is further realized by the independence of syntax inductive predicates in the same level, which is further supported in the definitions of the semantics. Therefore, Lolisa can be easily extended to incorporate the features of other languages by adding new typing rule constructors in the formal abstract syntax and the corresponding formal semantics in FEther. Moreover, except for the accommodation of specific Solidity data structures, such as contracts and mapping, the remainder of the Lolisa syntax definitions and semantics were designed to be
universally applicable to any other general-purpose programming language. Furthermore, Lolisa and FEther were designed based on the GERM framework and EVI, which are appropriate for the formalization of any programming language. Finally, as discussed previously, the complex Lolisa formal syntax is hidden in the syntactic abbreviations, which improves user-friendliness significantly.

The architecture of the proposed preliminary scheme for extending Lolisa and FEther to other general-purpose programming languages is illustrated in Fig. 29. We treat Lolisa as the core formal language, which is transparent for real-world users, and we logically classify the formal syntax and semantics of Lolisa according to a general component \( G \) and \( n \) special components \( S_i \), as defined by the following rule.

\[
Lolisa \equiv G \cup \bigcup_{i=0}^{n} S_i
\]  

(40)

As a result, a general-purpose programming language \( L_i \) can be formalized by the Lolisa subset \( G \cup S_i \) by encapsulating the subset using notation as a symbolic abbreviation \( N_i \) for \( L_i \), which adopts syntax symbols that are nearly equivalent to the original syntax symbols of \( L_i \). With this method, each \( L_i \) has a corresponding notation set \( N_i \) that satisfies \( N_i \subseteq Lolisa \). This relation is defined by the following rule.

\[
\forall i \in \mathbb{N}, L_i \leftrightarrow N_i \equiv G \cup S_i
\]  

(41)

As the corresponding definitional interpreter of Lolisa, FEther inherits the extensibility advantages of Lolisa. At the same level, any executable semantic \( S_i \) is independent of any other semantic, and all same-level semantics are encapsulated into an independent module \( M \) according to the following rules.

\[
\text{Module}_G \left[ \forall i, j \in \mathbb{N}, i \neq j \land S_i \cap S_j = \emptyset \right] .
\]  

(42)

\[
S_{h,m} := M_M \left( \left[ l_i \right] S_i \right) \oplus M_M \left( \left[ l_j \right] S_j \right) \ldots \oplus M_M \left( \left[ l_n \right] S_n \right) .
\]  

(43)

Therefore, FEther is also easily extendable to new executable semantics to support new abstract syntax of Lolisa without affecting the old semantics.

Fig. 29. Architecture for extending the core components of FSPVM-E to support other general-purpose programming languages of multiple blockchain platforms.

7. COMPARISON WITH RELATED WORK

Compared with most recent tools based on symbolic execution, FSPVM-E supports symbolic execution in higher-order logic systems. Benefiting from this feature, FSPVM-E not only can formalize and verify more complex properties of Ethereum-based services, but also obtains higher evaluation efficiency and degree of automation compared to standard higher-order logic theorem proving technologies. Moreover, FSPVM-E provides a formal memory model, a virtual symbolic execution environment, and single statement unit evaluation, which solves the memory, environment, and constraint solving problems of conventional tools based on symbolic execution. In addition, the modular verification process of FSPVM-E reduces the influence of the path explosion problem in symbolic execution. Moreover, FSPVM-E is first the verification system that provides a large subset of
Solidity formal syntax and semantics with GADTs, and it is also the first proof virtual machine can directly execute and verify Solidity programs in Coq.

To compare differences between FSPVM-E and related works more intuitively, we summarized the differences in Table 5. The compared features are listed and defined as follows:

- Spec.: suitable as a formal specification of the EVM language;
- Exec.: executable on concrete tests;
- Certif.: certifiable self-correctness;
- Verif.: verifiable properties of EVM programs;
- Debug.: provision of an interactive EVM debugger;
- Gas: tools for analyzing the gas complexity of an EVM program;
- Level: analysis or verification level of code;
- Logic: types of essential logic supported;
- Hybrid: support for hybrid verification methods.

8. CONCLUSIONS AND FUTURE WORK

We have presented a hybrid formal verification system denoted as FSPVM-E, which combines symbolic execution and higher-order logic theorem proving for verifying the security and reliability of Ethereum-based smart contract services. An analysis of past studies indicates that the current work represents the first hybrid formal verification system implemented in Coq for Ethereum-based smart contracts that is applied at the Solidity source code level. The foundation of FSPVM-E is a general formal memory model that simulates real-world memory operations and provides a basic pointer arithmetic mechanism. The source code of FSPVM-E is Lolisa, which is a large subset of the Solidity programming language. Lolisa is strongly typed according to GADTs, and includes nearly all of the syntax in Solidity. Therefore, the two languages are equivalent, which solves the consistency problem in formalization. The execution engine of FSPVM-E is FEther, which supports static, concyclic, and selective symbolic execution simultaneously. The execution engine is driven by the executable formal semantics of Lolisa, and is able to strictly simulate the service behaviors of smart contracts. In addition, we provide two assistant tools and two assistant libraries to increase the degree of automation in the FSPVM-E verification process. Specifically, the two assistant tools are a translator and a generator, which are respectively applied to automatically translate Solidity into Lolisa, and generate specific formal specifications based on a specified execution environment. The two assistant libraries include a static analysis library and an automation tactic library, which are respectively used to scan for standard vulnerabilities in smart contracts, and provide fully-automatic execution (verification) tactics. In addition, we ensured that FSPVM-E is a trusted verification engine by verifying the self-correctness of the core components of FSPVM-E in Coq. We have also provided simple case studies to demonstrate the novel features of FSPVM-E, which include hybrid analysis functions, consistency, automation, high evaluation efficiency, and modular verification. Finally, the extensibility and universality of FSPVM-E was demonstrated, and a preliminary scheme was proposed to systematically extend FSPVM-E to support the verification of multiple blockchain platforms. As a result, we can now directly verify Ethereum-based service contracts with high automation and evaluation efficiency in Coq directly. In the future, we expect to further develop FSPVM-E until it is sufficiently powerful and friendly for use by general programmers to easily and automatically verify the properties of their smart contract programming. First, we are working to introduce support for other Solidity features, such as inline assembly. Second, we will attempt to implement support for the EOS [46] blockchain platform. Finally, we will design a new functional module in FSPVM-E for assembly and bytecode layers to guarantee security during
compilation.
