(Dated: March 11, 2019)

We show that any multi-qudit entanglement witness leads to a non-separability indicator for quantum optical fields, which involves intensity correlation measurements and is useful for field states of undefined photon numbers. With the approach we get, e.g., necessary and sufficient conditions for intensity or rate correlations to reveal polarization entanglement and separability conditions for experiments with mutually unbiased multiport interferometers. These entanglement indicators work, for any detection efficiencies, within the standard detector inefficiency model. For specific cases, we show advantages of using local intensity rates rather than intensities. The approach with rates allows a mapping of Bell inequalities for qudits to ones for optical fields. Our results may find applications also in studies of non-classicality of correlations in “macroscopic” many-body quantum systems of undefined or uncontrollable number of constituents.

Non-classicality due to entanglement initially was studied using quantum optical multiphoton interferometry methods, see e.g., [1]. The experiments were constrained to defined total photon number states, e.g., the two photon polarization singlet [2]. This includes GHZ [3] inspired multiphoton interference, with an interpretation that each detection event signals one photon. Higher photon number counts were source of a lower interferometric contrast and were spurious events. However, states of light of undefined photon numbers, e.g., the (bright) squeezed vacuum, can be entangled [4–6]. For specific entanglement conditions for such light see [5–7]. Most importantly a growing part of the experimental effort is now directed at non-classical features of bright (intensive, “macroscopic”) beams of light [8–14]. The other important development is the emergence of integrated optics, allowing to construct stable multiport interferometers [15–22]. To address these developments we present a general theory of mapping multi-qudit entanglement witnesses [23] into entanglement indicators for quantum optical fields which employ intensity correlations or correlations of intensity rates (by intensity rate we mean the ratio of intensity at a given local detector and the sum of intensities at all local detectors). We show also that in some case the second approach leads to a more robust entanglement detection. Potentially this method may find applications in studies of non-classicality of correlations in “macroscopic” many-body quantum systems of undefined or uncontrollable number of constituents, e.g., Bose-Einstein condensates [24], other specific states of cold atoms [25, 26].

First, the essential ideas are presented for polarization measurements by two observers (2 × 2 mode case) and the most simple model of intensity observable: number of photons in the observed beam. Next, we present the general approach, and further on its examples employing specific indicators involving intensity correlations for unbiased multiport interferometers (d × d mode case).

We discuss generalizations to multi-party entanglement indicators. We show that the use of rates leads to a modification of quantum optical Glauber correlation functions, which gives a new tool for studying non-classicality, and that it also gives a handy general method of mapping standard Bell inequalities into ones involving optical fields.

Generalities.—Entanglement is most interesting, and finds quantum informational applications, when it is observed between spatially separated systems. We discuss spatially separated stations (parties), $X = A,B,...$, with interferometers (passive optical devices) with $d_X$ input and output ports. In each output port there is a detector which measures the exit field intensity. One can assume either a pulsed source, sources acting synchronously [27, 28] or that the measurement are performed within a short common time gate. Each time gate (or pulsed emission) is treated as a repetition of the
associate entanglement indicators for polarization measurable state. We will show that with each witness \( \hat{W} \) the following expansion \( \hat{W} \) prove that for any mixed state Stokes parameters.

An alternative approach, normalized Stokes operators introduced by some of us \([29-31]\), puts \( \langle S_j \rangle = \langle \Pi (\hat{a}_j^\dagger \hat{a}_j - \hat{a}_{\perp j}^\dagger \hat{a}_{\perp j}) \Pi \rangle \), where \( \Pi = 1 - |\Omega \rangle \langle \Omega | \) and \( |\Omega \rangle \) is the vacuum state for the considered modes, \( \hat{a}_j |\Omega \rangle = \hat{a}_{\perp j} |\Omega \rangle = 0 \). Operationally, in the \( r \)-th run of an experiment, this requires measurement of photon numbers in the two exits of a polarization analyzer, \( n_r^j \), and \( n_r^{\perp j} \), and dividing their difference by their sum. If the sum is zero, the value is put as zero. The procedure does not require any additional measurements, only the data are differentially processed compared to the standard approach. The zeroth normalized Stokes operator is given by the probability of a non-vacuum event \( \langle S_0 \rangle = \langle \Pi \rangle \). In \([29-31]\), some examples of two-party entanglement conditions and Bell inequalities using such normalized Stokes operators were given. Here we present a different generalized approach, which allows direct extensions to more involved cases.

Homomorphism from two-qubit entanglement witnesses to entanglement indicators for fields involving Stokes parameters.—Pauli operators \( \hat{\sigma} = (\hat{\sigma}_1, \hat{\sigma}_2, \hat{\sigma}_3) \) and \( \hat{\sigma}_0 = 1 \) form a basis in the real space of one-qubit observables. Thus, any two-qubit entanglement witness, \( W \), has the following expansion \( W = \sum_{\mu, \nu} w_{\mu \nu} \hat{\sigma}_\mu \otimes \hat{\sigma}_\nu \), where \( \mu, \nu = 0, 1, 2, 3 \) and \( w_{\mu \nu} \) are real coefficients. We have \( \langle W \rangle_{\text{sep}} \geq 0 \), where \( \langle \cdot \rangle_{\text{sep}} \) denotes an average for a separable state. We will show that with each witness \( W \) one can associate entanglement indicators for polarization measurements involving correlations of Stokes observables for quantum optical fields. The maps are \( \hat{\sigma}_\mu \otimes \hat{\sigma}_\nu \rightarrow \hat{S}_\mu \hat{S}_\nu \), and \( \hat{\sigma}_\mu \otimes \hat{\sigma}_\nu \rightarrow \hat{\Theta}_\mu \hat{\Theta}_\nu \), and they link \( W \) with its quantum optical analogues \( \hat{W}_S = \sum_{\mu, \nu} w_{\mu \nu} \hat{\sigma}_\mu \hat{\sigma}_\nu \), and \( \hat{W}_\Theta = \sum_{\mu, \nu} \mu w_{\mu \nu} \hat{\Theta}_\mu \hat{\Theta}_\nu \), which fulfill \( \langle \hat{W}_S \rangle_{\text{sep}} \geq 0 \) and \( \langle \hat{W}_\Theta \rangle_{\text{sep}} \geq 0 \). The proof goes as follows.

Normalized Stokes operators case.—It is enough to prove that for any mixed state \( \varrho \) of two optical beams underlying correlation measurements of normalized Stokes parameters one can find a \( 4 \times 4 \) density matrix \( \hat{R}_\varrho \) for a pair of qubits, such that the following holds

\[
\langle \hat{W}_S \rangle_\varrho = \text{Tr} \hat{W} \hat{R}_\varrho.
\]

First, we show that (1) holds for any pure state of the two beams \( |\psi AB \rangle \), that is

\[
\frac{\langle \psi AB | \hat{S}_\mu \hat{S}_\nu | \psi AB \rangle}{\langle \psi AB | \Pi^A \Pi^B | \psi AB \rangle} = \text{Tr} \hat{\sigma}_\mu \hat{\sigma}_\nu \hat{R}^{AB}_{\psi}.
\]

Normalized Stokes operators in arbitrary direction can be formulated as \( \hat{m} \cdot \hat{S}_\Omega \), where \( \hat{m} \) is an arbitrary unit real vector, which in the matrix form gives \( \sum_{k,l} \hat{\Pi}^X \hat{S}_\mu |\hat{m} \rangle \langle \hat{s}_k | \Pi^X \hat{\Omega} \), with \( \hat{x}_\mu = \hat{a} \) or \( \hat{b} \) depending on the beam \( X \). In this convention the formula \( \hat{S}_\Omega \) reads \( \sum_{k,l} \hat{\Pi}^X \hat{S}_\mu |\hat{m} \rangle \langle \hat{s}_k | \Pi^X \hat{\Omega} \). The expectation value \( \langle \psi AB | \hat{S}_\mu \hat{S}_\nu | \psi AB \rangle \) can be re-expressed by the following steps. Let us denote the polarization basis \( H \) and \( V \) as \( \hat{x}_H = \hat{x}_1 \) and \( \hat{x}_V = \hat{x}_2 \). We introduce a set of states

\[
|\Psi_{km} \rangle = \hat{a}_k \hat{b}_m \frac{1}{\sqrt{N_A N_B}} \hat{\Pi}^A \hat{\Pi}^B |\psi AB \rangle,
\]

where \( k, m \in \{1, 2\} \). Thus we have

\[
\langle \psi AB | \hat{S}_\mu \hat{S}_\nu | \psi AB \rangle = \sum_{k,l=1}^2 \sum_{m,n=1}^2 \sigma_{\mu \nu}^{k l m n} \langle \Psi_{km} | \Psi_{ln} \rangle^{AB} = \text{Tr} \hat{\sigma}_\mu \otimes \hat{\sigma}_\nu \hat{R}^{AB}_{\psi}.
\]

For mixed states \( \varrho \), i.e., convex combinations of \( |\psi_k^X \rangle \)'s with weights \( p_k \), one gets \( \hat{R}^{AB}_{\varrho} = \sum_k p_k \hat{R}^{AB}_{\psi_k} \) which is positively defined, and its trace is \( \sum_k p_k \text{Tr} \hat{R}^{AB}_{\psi_k} \leq 1 \). Thus after the re-normalization one gets a proper two-qubit density matrix \( \varrho^{AB}_{\psi} \). However, as a purity of a field state \( |\psi^{AB}_{\lambda} \rangle \) does not warrant that the corresponding \( \hat{R}^{AB}_{\lambda} \) is a projector, \( \varrho^{AB}_{\psi} \) does not have to have the same convex expansion coefficients in terms of pure two-qubit states, as \( \varrho \) in terms of \( |\psi^{AB}_{\lambda} \rangle \)'s.

For any separable pure state of two optical beams \( |\psi^{AB}_{\varrho} \rangle \) defined as \( F_A^X F_B^X |\Omega \rangle \), where \( F_A^X \) is a function of creation operators creating a superposition of Fock states for beam (modes) \( X \), and \( |\Omega \rangle \) is the vacuum state of both beams, the matrix \( \hat{R}^{AB} \) factorizes: \( \hat{R}^{AB} = \hat{R}^A \hat{R}^B \). Simply, for each element of \( \hat{R}^{AB} \) we have

\[
\langle \Psi_{km} \rangle^{AB} = \langle \Psi_{k}^X | \Psi_{m}^X \rangle \langle \Psi_{k}^Y | \Psi_{m}^Y \rangle,
\]

where \( \langle \Psi_{k}^X | \Psi_{m}^X \rangle \) are elements of matrix \( \hat{R}^X \) and \( \langle \Psi_{k}^Y | \Psi_{m}^Y \rangle = \hat{x}_1 |\Pi^X F_A^1 |\Omega \rangle^{-1} |\Pi^X F_B^1 |\Omega \rangle \). As \( |\Pi^X F_A^1 |\Pi^X F_B^1 |\Omega \rangle^{-1} |\Pi^X \) can be shown to be a qubit density matrix and \( \langle \hat{W} \rangle_{\text{sep}} \geq 0 \), therefore for pure separable states of the optical beams \( \langle \hat{W} \rangle_{\text{sep}} \geq 0 \) also for all mixed separable states.

Standard Stokes operators case.—Any standard Stokes operator can be put as \( \hat{m} \cdot \hat{\Theta}^X = \sum_{k,l} \eta^X_{kl} |\hat{m} \rangle \langle \hat{s}_k | \hat{\Pi}^X \hat{\Omega} \). As in
the argumentation below (2), we introduce a set of state vectors \( \Phi_{jk}^{AB} = \hat{a}_j \hat{b}_k |\psi^{AB}\rangle \). One has

\[
\langle \psi^{AB} | \hat{\mathcal{O}}_\mu^A \hat{\mathcal{O}}_\nu^B | \psi^{AB}\rangle = \text{Tr} \hat{\mathcal{O}}_\mu^A \hat{\mathcal{O}}_\nu^B \hat{P}^{AB},
\]

where the matrix \( \hat{P}^{AB} \) has entries \( \langle \Phi_{km}^{AB} | \Phi_{in}^{AB}\rangle \). The matrix \( \hat{P}^{AB} \) is positive definite, and its trace is \( \langle \hat{N}_A \hat{N}_B \rangle \). Thus, \( \hat{\mathcal{P}}^{AB} = \hat{P}^{AB} / \langle \hat{N}_A \hat{N}_B \rangle \) is an admissible two-qubit density matrix. Finally, the formula of the homomorphism reads \( \langle \mathcal{W}_\Theta \rangle / \langle \hat{N}_A \hat{N}_B \rangle = \text{Tr} \hat{W} \hat{\mathcal{P}}^{AB} \). All that leads to \( \langle \mathcal{W}_\Theta \rangle_{\text{exp}} \geq 0 \). We stress that for a general state \( \hat{\Omega}_e^{AB} \) does not have to be equal to \( \hat{\mathcal{P}}^{AB} \). Still, \( \hat{\mathcal{R}}^{AB} = \hat{\mathcal{P}}^{AB} \) for states of defined photon numbers in both beams.

**Examples.**—In Appendix A, we show some examples of entanglement indicators which can be derived with the above method. Two of them are in a form of a necessary and sufficient condition for detection of entanglement of two optical beams with correlations of Stokes parameters and sufficient condition for detection of entanglement of above method. Two of them are in a form of a necessary
determination of its spectral projections linked with their respective eigenbases, \( |x^{(j)}_l\rangle \), where \( x = a \) or \( b \) consistently with \( X \) and \( l = 1, \ldots, d_X \). If one fixes a certain pair of bases in \( C^{d_A} \) and \( C^{d_B} \) as “computational ones”, i.e., starting ones, denoted as \( |x\rangle \), one can always find local unitary matrices

**Resistance with respect to losses.**—The entanglement conditions for optical fields, defined by \( \mathcal{W}_S \) and \( \mathcal{W}_\Theta \), are highly resistant to collection-detection losses. We use the usual quantum optical model of losses, which employs a perfect detector in front of which is a beamsplitter of transmissivity amplitude \( \eta \), with the reflection channel describing the losses. One can show that \( \langle \hat{\mathcal{O}}_\mu^A \hat{\mathcal{O}}_\nu^B \rangle \) is always proportional to \( \eta^A \eta^B \) (see Appendix B), where \( \eta^X \) for \( X = A, B \) is Alice’s and Bob’s detector efficiency. Thus, we have a full resistance of entanglement detection with respect to such losses. Of course, a different character of losses may lead to threshold efficiencies.

For conditions based on the normalized Stokes parameters, the analysis of noise resistance runs as follows. First, it is enough to consider only pure states, because mixed ones, as convex combinations of such, cannot introduce anything new in entanglement conditions linear with respect to the density matrix. Any pure state is a superposition of Fock states \( |F\rangle = |n^A_1, n^A_2, n^B_1, n^B_2\rangle \), where \( n^X \) denotes the number of \( i \) polarized photons in beam \( X \). The operators \( \hat{S}_\mu^A \hat{S}_\nu^B \) are diagonal with respect to the Fock basis related with them. Therefore, the dependence on efficiencies of the value of an entanglement indicator in the case of a pure state depends on the behavior of its Fock components. One can show, see Appendix B that for the model of inefficiency as above

\[
\langle F_\eta | \hat{S}_\mu^A \hat{S}_\nu^B | F_\eta \rangle / \langle F | \hat{S}_\mu^A \hat{S}_\nu^B | F \rangle = \langle F_\eta | \hat{S}_0^A \hat{S}_0^B | F_\eta \rangle = \prod_{X=A,B} [1 - (1 - \eta^X)^{m^X}],
\]

where \( |F_\eta\rangle \) is the state \( |F\rangle \) after the above described losses in both channels, and \( \langle F_\eta | \hat{S}_0^A \hat{S}_0^B | F_\eta \rangle = \Pi_{X=A,B} [1 - (1 - \eta^X)^{m^X}] \), where \( m^X \) is the total number of photons in channel \( X \), before the losses. Note that expanding of \( |F\rangle \) in terms of Fock states with respect to different polarizations than \( i, i_1 \) and \( j, j_1 \), does not change the values of \( m^X \), and thus the formula (7) stays put for any indices. The relation (7) implies a strong resistance of the entanglement indicators with respect to losses. Especially for states with high photon numbers, the entanglement conditions based on normalized Stokes parameters, may be more resistant to losses. Simply, whenever \( 0 < \eta < 1 \) one has \( \eta < 1 - (1 - \eta)^n \), and the right hand side with growing \( n \), quickly approaches 1. Generally, the magnitude of violation of the zero threshold would depend on \( \eta \) in a complicated way, dependent on photon number distribution in the original state (before losses).

**Multi-party case.**—Let us consider three parties, and the case of indicators of genuine three beam entanglement. Any genuine three-qubit entanglement witness \( \hat{W}^{(3)} \) has the property that it is positive for all pure product three-qubit states \( |\xi\rangle_{AB,C} = |\psi\rangle_{AB} |\phi\rangle_C \), as well for similar ones with qubits \( A, B, C \) permitted, and of course for all convex combinations of such states. Clearly, with any pure partial product state of the optical beams, e.g. \( |\Xi\rangle_{AB,C} = F_{AB} F_{B2} |\Omega\rangle \), where \( F_{AB} \) is an operator built of creation operators for beams \( A \) and \( B \), etc., one can associate, in a similar way as above, a partially factorisable three-qubit density matrix \( \hat{\mathcal{W}}_{AB} \hat{\mathcal{W}}_{BC} \). Thus, the homomorphism works. Further generalizations are obvious.

**General Theory.**—For a general situation, of beam of \( d_A \) quantum optical modes propagating toward an interferometric measuring station \( A \), and of beam of \( d_B \) modes toward station \( B \), the homomorphism works as follows. We can associate with the situation a \( d_A \times d_B \) dimensional Hilbert Space, tensor factorized into \( C^{d_A} \otimes C^{d_B} \), which contains pure states of a pair of qudits \( A, B \) of dimensions \( d_A \) and \( d_B \). For \( X = A, B \), let \( V^X_i \) be an orthonormal (i.e. satisfying \( \text{Tr} V^X_i V^X_j = \delta_{ij} \)) basis of the space of Hermitian operators acting on \( C^{d_X} \). Therefore, products \( V^A_i \otimes V^B_j \) form an orthonormal basis of the space of Hermitian operators acting on \( C^{d_A} \otimes C^{d_B} \). Thus, any entanglement witness for the pair of qudits, \( \hat{W} \), can be expanded into

\[
\hat{W} = \sum_{j,k=1}^{d_B} \sum_{j,k=1}^{d_A} w_{jk} \hat{V}^A_j \otimes \hat{V}^B_k,
\]

with real \( w_{jk} \). Note that in order to get the optimal expansion (with the minimal number of terms) we can use a Schmidt basis for \( \hat{W} \) (if we assume \( d_A \leq d_B \), we would have only \( d_A^2 \) terms, and thus much less pairs of local measurements to get \( \langle \hat{W} \rangle \)).

In turn, each \( \hat{V}^X_i \) can be decomposed to a linear combination of its spectral projections linked with their respective eigenbases, \( |x^{(j)}_l\rangle \), where \( x = a \) or \( b \) consistently with \( X \) and \( l = 1, \ldots, d_X \). If one fixes a certain pair of bases in \( C^{d_A} \) and \( C^{d_B} \) as “computational ones”, i.e., starting ones, denoted as \( |x\rangle \), one can always find local unitary matrices.
\[ U^X(j) \text{ such that } U^X(j)|l_x = |x^{(j)} \rangle \]. The construction of Reck et al. \cite{32} fixes (phases in) a local multiport interferometer, which performs such a transformation. We shall call such interferometers \( U^X(j) \) ones. In the case of field modes a passive interferometer performs the following mode transformation: \( \sum_k U^X(j) |x^k_l = x^l_j \rangle, \) where \( x^l_j \) is the photon creation operator in the \( l \)-th exit mode of interferometer \( U^X(j) \).

We can construct a two-party entanglement witness \( \hat{W}_R \) for optical fields, which uses correlations of intensity rates behind pairs of \( U^X(j) \) interferometers. For the output \( l_x \) of an interferometer, one can define rate observables as \( \hat{r}_{lx} = \tilde{N}^X_{lx} \tilde{N}^X, \) where \( \tilde{N}^X \) is sum of photon number operators for all outputs of the interferometer. The witness \( \hat{W} \) can be expanded in terms of the computational basis:

\[ \hat{W} = \sum_{x,y} \sum_{m,n} w_{xymn} |a_{m}, b_{n} \rangle \langle m_{a}, n_{b} |. \]  

We form an entanglement witness for optical fields:

\[ \hat{W}_R = \sum_{x,y} \sum_{m,n} w_{xymn} \hat{N}_A \hat{N}_B / \sqrt{N_A N_B} \hat{N}_A \hat{N}_B. \]  

Its average for any pure state of the quantum beams \( |\Psi \rangle \) is given by

\[ \langle \Psi | \hat{W}_R |\Psi \rangle / \langle \Psi | \hat{N}_A \hat{N}_B |\Psi \rangle = \text{Tr} \hat{W} \hat{\mathcal{R}}, \]  

where the matrix \( \hat{\mathcal{R}} \) has elements \( r_{xymn} \)

\[ r_{xymn} = 1 / \langle \Psi | \hat{N}_A \hat{N}_B |\Psi \rangle \langle \Psi | \hat{N}_A \hat{N}_B |\Psi \rangle, \]  

\[ r_{xymn} = \frac{1}{d} \sum_{x,y} \sum_{m,n} w_{xymn} |a_{m}, b_{n} \rangle \langle m_{a}, n_{b} |. \]  

It can be shown via a straightforward generalization of the earlier derivations that \( \hat{\mathcal{R}} \) has all properties of a two-qudit density matrix. Importantly, the actual measurements, in order to be correlations of local ones, should be performed using the suitable sequence of pairs of \( U^X(j) \) interferometers, which enter the expansion of the two-qudit entanglement witness (8). In the entanglement indicator the rates at output \( x^l_j \) of the given local interferometer \( U^X(j) \) must be multiplied by the respective eigenvalue of \( \hat{V}_X^j \) related with the eigenstate \( |x^{(j)}_l \rangle \).

To get an entanglement witness for intensities \( \hat{W}_I \) we take the witness \( \hat{W} \) for a pair of qudits (9) and replace the computational basis kets and bras by suitable creation and annihilation operators:

\[ \hat{W}_I = \sum_{x,y} \sum_{m,n} w_{xynm} a_{m}^+ b_{n}^+ \hat{N}_A \hat{N}_B / \sqrt{N_A N_B} \hat{N}_A \hat{N}_B. \]  

For any pure state of the quantum beams \( |\Psi \rangle \) one has

\[ \frac{\langle \Psi | \hat{W}_I |\Psi \rangle}{\langle \Psi | \hat{N}_A \hat{N}_B |\Psi \rangle} = \text{Tr} \hat{W} \hat{\mathcal{P}}, \]  

where the matrix \( \hat{\mathcal{P}} \) has elements \( \frac{1}{d} \sum_{x,y} \sum_{m,n} w_{xynm} a_{m}^+ b_{n}^+ \hat{N}_A \hat{N}_B / \sqrt{N_A N_B} \hat{N}_A \hat{N}_B \), and has all properties of a two-qudit density matrix.

An example showing further extension to unitary operator bases.—Let \( d \) be a power of a prime number. Consider \( d_A = d_B = d \) beams experiment [see Fig (1)], with families of \( U^X(m) \) interferometers which link the computational basis of a qudit with an unbiased basis \( m \), belonging to the full set of \( d + 1 \) mutually unbiased ones \( \Omega^X \). To get a homomorphic relation between a two-qudit density matrix and matrices \( \hat{\mathcal{R}} \) and \( \hat{\mathcal{P}} \) for the fields we introduce a set of unitary observables for a qudit:

\[ \hat{q}_k(m) = \sum_{j=1}^{d} \omega^{jk} |j(m)\rangle \langle j(m)|, \]  

where \( |j(m)\rangle = U(m)|j\rangle \) and it is the \( j \)-th member of \( m \)-th mutually unbiased basis, and \( \omega = \text{exp}(2\pi i/d) \). Operators \( \hat{q}_k(m)/\sqrt{d} \) with \( k = 1, \ldots, d - 1 \) and \( m = 0, \ldots, d \) and \( \hat{q}_0(0)/\sqrt{d} \) form an orthonormal basis in the Hilbert-Schmidt space of all \( d \times d \) matrices (see appendix C). Thus, we can expand any qudit density matrix as

\[ \begin{align*}
\hat{\varrho} &= \frac{1}{\sqrt{d}} \left[ c_{0,0} \hat{q}_0(0) + \sum_{m=1}^{d} \sum_{k=1}^{d-1} c_{m,k} \hat{q}_k(m) \right],
\end{align*} \]  

where \( c_{m,k} = \text{Tr} \hat{q}_k(0) \hat{\varrho} / \sqrt{d} \) and \( c_{0,0} = 1 / \sqrt{d} \). As the basis observables are unitary, their eigenvalues are complex. The expansion coefficients of an entanglement witness operator in terms of such a basis would be in general complex. This is no problem for theory, but renders useless a direct application of the approach in experiments, as one cannot expect the experimental averages to be real, and thus one has to introduce modifications. Below we present one.

The condition \( \text{Tr} \hat{\varrho}^2 \leq 1 \) can be put as

\[ \frac{1}{d} + \frac{1}{d} \sum_{m=0}^{d-1} \text{Tr} \hat{\varrho} \hat{q}_k(m) \hat{q}_k(m)^\dagger \leq 1. \]  

Thus, applying Cauchy-Schwartz estimate, we get immediately a separability condition for two qudits:

\[ \sum_{m=0}^{d-1} \text{Tr} \hat{\varrho} \hat{q}_k(m) \hat{q}_k(m)^\dagger \leq (d - 1). \]  

With all that was said earlier it is straightforward to establish that a Cauchy-Schwartz-like separability condition homomorphic with (17) is

\[ \sum_{m=0}^{d-1} \text{Tr} \hat{Q}_k^{A} \hat{Q}_k^{B} \leq (d - 1)(\hat{\Pi}_A \hat{\Pi}_B)_{\text{sep}}, \]  

where

\[ \hat{Q}_k(m) = \sum_{j=1}^{d} \hat{P}_X \omega^{jk} \hat{N}_X(m) \hat{P}_X. \]
Here $\hat{n}_j^X(m) = \hat{x}_j^X(m)\hat{x}_j^X(m)$ is a photon number operator
for output mode $j$ of a multiport $m$, at station $X$. For
generalized observables based on intensity, one can
introduce $\hat{Q}_j^X(m) = \sum_{j=1}^d \omega^{jk}\hat{n}_j^X(m)$ to get the following
separability condition

$$\sum_{m=0}^d \sum_{k=1}^{d-1} |\langle \hat{Q}_j^X(m)\hat{Q}_k^B(m) \rangle_{\text{sep}}| \leq (d-1)\langle \hat{N}^A\hat{N}^B \rangle_{\text{sep}}.$$  \hspace{3cm} (20)

In Appendix, one can find other examples which employ
this approach.

Implications for optical coherence theory.—The approach
may be generalized further. Let us take an example Glauber’s correlation functions for optical fields,
say $G^{(4)}$ in the form of $\langle I_A(\vec{x},t)I_B(\vec{x}',t') \rangle$, where the intensity operator has the usual form of $I_X(\vec{x},t) = \hat{F}_X(\vec{x},t)\hat{F}_X(\vec{x},t)$, with normal ordering requiring that operator $\hat{F}_X(\vec{x},t)$ is built out of local annihilation operators. The idea of normalized Stokes operators suggests the following alternative correlation function $\Gamma^4(\vec{x},t;\vec{x}',t')$ given by

$$\langle \hat{I}_A(\vec{x},t)\hat{I}_B(\vec{x}',t') \rangle \frac{\hat{I}_A(\vec{x},t)\hat{I}_B(\vec{x}',t')}{\int a(A)\,d\sigma(\vec{x})\int a(B)\,d\sigma(\vec{x}')\hat{I}_B(\vec{x}',t')} \frac{\Pi_A\Pi_B}{\Pi_A\Pi_B},$$

where $a(X)$ denotes the overall aperture of the detectors in location $X$. Obviously one has $\int a(A)\,d\sigma(\vec{x})\int a(B)\,d\sigma(\vec{x}')\Gamma^4(\vec{x},t;\vec{x}',t') = \langle \Pi_A\Pi_B \rangle$, and for fixed $t$ and $t'$ one can define

$$\langle \Pi_A\Pi_B \rangle^{-1} \times \langle \hat{I}_A(\vec{y},t)\hat{I}_B(\vec{y}',t') \rangle \frac{\hat{I}_A(\vec{y},t)\hat{I}_B(\vec{y}',t')}{\int a(A)\,d\sigma(\vec{x})\int a(B)\,d\sigma(\vec{x}')\hat{I}_B(\vec{x}',t')} \frac{\Pi_A\Pi_B}{\Pi_A\Pi_B},$$

which behaves like a proper two particle density matrix, provided one constrains the range of $\vec{x}, \vec{y}, \vec{x}', \vec{y}'$ to appropriate sets of apertures. As our earlier considerations use simplified forms of (21), it is evident that such correlation functions may help us to unveil non-classicality in situations in which the standard ones fail, see e.g. [35].

Device independent entanglement indicators: Bell inequalities for fields.—The above ideas allow one to introduce a general mapping of qudit Bell inequalities to the ones for quantum optical fields. Any, here two-qudit, Bell inequality for a final number of local measurement settings $\alpha$ and $\beta$ has the following form:

$$\sum_{\alpha\beta} \sum_{i=1}^{d_A} \sum_{j=1}^{d_B} K_{\alpha\beta}^{ij} P_{ij}(\alpha,\beta) + \sum_{i=1}^{d_A} \sum_{\alpha} N_{\alpha}^{i} P_{i}(\alpha) + \sum_{j=1}^{d_B} \sum_{\beta} M_{\beta}^{j} P_{j}(\beta) \leq L_R.$$  \hspace{3cm} (23)

where $P_{ij}(\alpha,\beta)$ denotes the probability of the qudits ending up respectively at detectors $i$ and $j$, when the local setting are as indicated, and $\sum_{j} P_{ij}(\alpha,\beta) = P_{i}(\alpha)$ and $\sum_{j} P_{ij}(\alpha,\beta) = P_{j}(\beta)$. The coefficient matrices $K_{\alpha\beta}^{ij}, N_{\alpha}^{i}, M_{\beta}^{j}$ are real, and $L_R$ is the maximum value allowed by local realism/causality. The bound is reached if one puts $P_{ij}(\alpha,\beta) = D^{i}(\alpha)D^{j}(\beta)$ and $P_{i}(\alpha) = D^{i}(\alpha)$ and $P_{j}(\beta) = D^{j}(\beta)$ with constraints $0 \leq D^{i}(\alpha) \leq 1$, and $\sum_{i=1}^{d_A} D^{i}(\alpha) = 1$.

As for a given run of a quantum optical experiment local measured photon intensity rates $r_i(\alpha)$ and $r_j(\beta)$ satisfy exactly the same constraints, the above general Bell inequality holds for any loaca realistic values of these. We replace $P_{ij}(\alpha,\beta) \rightarrow \langle r_i(\alpha)r_j(\beta) \rangle_{LR}$, and $P_{i}(\alpha) \rightarrow \langle r_i(\alpha) \rangle_{LR}$, etc., where $\langle ... \rangle_{LR}$ is an average in the case of local realism. The bound $L_R$ stays put. To get a Bell operator we further replace the above by rate observables $\hat{r}_i(\alpha)\hat{r}_j(\beta)$, etc. Generalizations to multiparty scenarios are obvious. Thus any Bell inequality, see e.g. [36], can be useful in quantum optical intensity (rates) correlation experiments. Note that one can marry the entanglement witness approach with the one presented above for Bell inequalities to get steering inequalities for quantum optical fields.

Conclusions.—The presented results form tool for a construction of entanglement indicators for optical fields inspired by the vast literature on entanglement witnesses for finite dimensional quantum systems [23]. The indicators allow new methods of data analysis, toward finding non-classicality, for more intense light beams in states of undefined photon numbers. Some of them would be useful in the currently emerging field of integrated optics multi-spatial mode interferometry (see Appendix for examples). One may expect also applications in the case of many-body systems, e.g. a development of methods of analysis of non-classicality of correlations in Bose-Einstein condensates, like in the experiment reported in [42].

Dagomir Kaszlikowski. MW acknowledges NCN grants No. 2015/19/B/ST2/01999 and 2017/26/E/ST2/01008.

APPENDIX

We give here several examples, and more details concerning some derivations.

Appendix A: Necessary and sufficient conditions for intensity and rate correlations to reveal entanglement

Two-qubit states are separable if and only if their partial transposes are positive. Yu et al. derived an equiv-
ent family of conditions for two-qubit states [37] in a form of an inequality, which reads
\[
\langle \hat{S}_1 \hat{S}_1^B + \hat{S}_2 \hat{S}_2^B \rangle^2 + \langle \hat{S}_3 \hat{S}_3^B + \hat{S}_4 \hat{S}_4^B \rangle^2 \leq \langle \hat{S}_0 \hat{S}_0^B + \hat{S}_2 \hat{S}_2^B \rangle^2,
\]
(A1)
where here \(\hat{S}_j^X = \vec{n}_j^X \cdot \vec{\sigma}^X\) for \(X = A, B\), and the unit vectors \(\vec{n}_j^X\) form a right-handed Cartesian basis triad. If a two-qubit state is entangled, then there exists at least one pair of such triads for which the inequality is violated. The conditions can be put in a form of a family of entanglement witnesses:

\[
W(\alpha) = \langle \hat{S}_0 \hat{S}_0^B + \hat{S}_2 \hat{S}_2^B + \sin \alpha(\hat{S}_1 \hat{S}_1^B + \hat{S}_2 \hat{S}_2^B) \rangle + \cos \alpha(\hat{S}_3 \hat{S}_3^B + \hat{S}_0 \hat{S}_0^B),
\]
(A2)

Our homomorphisms can be used to get the following [30]: for normalized Stokes operators
\[
\langle \hat{S}_1 \hat{S}_1^B + \hat{S}_2 \hat{S}_2^B \rangle^2 + \langle \hat{S}_3 \hat{S}_3^B + \hat{P} \hat{P}^B \rangle^2 \leq \langle \hat{P} \hat{P}^B + \hat{S}_3 \hat{S}_3^B \rangle^2,
\]
(A3)
and for standard ones
\[
\langle \Theta_1 \Theta_1^B + \Theta_2 \Theta_2^B \rangle^2 + \langle \Theta_3 \hat{N}^B + \hat{N} \Theta_3^B \rangle^2 \leq \langle \hat{N} \hat{N}^B + \Theta_3 \Theta_3^B \rangle^2.
\]
(A4)
The homomorphisms warrant that the violations of conditions (A3) and (A4) are necessary and sufficient to detect entanglement via measurements of correlations of the Stokes observables. That is, any other condition is sub-optimal.

From the necessary and sufficient condition (A3) one can derive its corollary, which is a necessary condition for separability:

\[
3 \sum_{j=1}^3 |\langle \hat{S}_j^A \hat{S}_j^B \rangle| \leq \langle \hat{P} \hat{P}^B \rangle_{sep}.
\]
(A5)
The condition can be thought as a more tight refinement of the result in [38]. It can be derived using the fact that for two qubits any of the observables \(\sum_k s_k \hat{S}_k \hat{S}_k^B + \sigma_0 \sigma_0^B\), for arbitrary \(s_k = \pm 1\) is non-negative for separable states. This can be reached via an application of the Cauchy inequality for a product pure states of a pair of qubits. Next we apply the homomorphism. One can also see that (A5) is the separability condition (18) for \(d = 2\).

For the standard Stokes operators the associated separability condition (A5) reads

\[
3 \sum_{j=1}^3 |\langle \Theta_j \Theta_j^B \rangle| \leq \langle \hat{N} \hat{N}^B \rangle_{sep}.
\]
(A6)

For states, which locally lead to vanishing averages of local Stokes parameters, here \(\langle \hat{S}_j \hat{P} \rangle = 0\), etc., (e.g., for an ideal four-mode bright squeezed vacuum, see below), the conditions (A5) and (A3) are equivalent. Thus, in such a case the Cauchy inequality based condition is necessary and sufficient for detection of entanglement with normalized Stokes operators. A similar statement can be produced for the analog condition involving traditional Stokes parameters \(\Theta_j\), given by (A6).

Cauchy-like Inequality Condition vs. EPR inspired approach.—Consider four-mode (bright) squeezed vacuum represented by

\[
|\Psi^-\rangle = \frac{1}{\cosh^2 \Gamma} \sum_{n=0}^\infty \sqrt{n+1} \tanh \Gamma |\psi^n\rangle,
\]
(A7)
where \(\Gamma\) describes a gain which is proportional to the pump power, and \(|\psi^n\rangle\) reads

\[
|\psi^n\rangle = \frac{1}{n!}\sqrt{(n+1)} (\hat{a}_+^\dagger \hat{b}_-^\dagger - \hat{a}_-^\dagger \hat{b}_+^\dagger)^n |\Omega\rangle,
\]
(A8)
where \(|\Omega\rangle\) is the vacuum state.

Perfect EPR-type anti-correlations of which are the main trait of the state allow one to formulate the following appealing separability condition, see [5]:

\[
3 \sum_{j=1}^3 \langle \Theta_j^A \Theta_j^B \rangle_{sep}^2 \geq 2 \langle \hat{N} \hat{N}^B \rangle_{sep}.
\]
(A9)
Note, that for \(|\Psi^-\rangle\) and each \(|\psi^n\rangle\) the left-hand side (LHS) of the above is vanishing.

The underlying inequality beyond the condition (A9) can be extracted with the use of well-known operator identity (see e.g. [39]):

\[
3 \sum_{j=1}^3 \Theta_j^2 = \hat{N} (\hat{N} + 2).
\]
(A10)
Using this the (A9) boils down to

\[
- \frac{3}{2} \sum_{j=1}^3 \langle \Theta_j \Theta_j^B \rangle_{sep} \leq \frac{1}{2} \langle \hat{N} \hat{N}^B \rangle_{sep} + \frac{1}{2} \langle \hat{N} \hat{N}^B \rangle_{sep},
\]
(A11)
which by the way can be generalized to

\[
2 \sum_{j=1}^3 |\langle \Theta_j \Theta_j^B \rangle_{sep}| \leq \langle \hat{N} \hat{N}^B \rangle_{sep} + \langle \hat{N} \hat{N}^B \rangle_{sep}.
\]

Condition (A9), or equivalently (A11), cannot be considered as an entanglement indicator for fields \(\mathcal{W}_\alpha\) homomorphic in the way proposed here, with a two-qubit (linear) entanglement witness \(\hat{W}\). The detection of entanglement with (A9) depends on a detector efficiency. The threshold efficiency for entanglement detection is given by \(\eta_{crit} = 1/3\) (see for more details [5]). It does not depend on \(\Gamma\). Obviously, as \(\langle \hat{N} \hat{N}^B \rangle_{sep} \leq \frac{1}{2} \langle \hat{N} \hat{N}^B \rangle + \frac{1}{2} \langle \hat{N} \hat{N}^B \rangle\), the inequality (A11) is not optimal. A more optimal option is to estimate from below the LHS of (A11) using a corollary of the Cauchy-like Inequality \(- \frac{3}{2} \sum_{j=1}^3 \langle \Theta_j \Theta_j^B \rangle_{sep} \leq \langle \hat{N} \hat{N}^B \rangle_{sep}\), which is tighter than (A11). By combining (A6) with (A10) we get

\[
3 \sum_{j=1}^3 \langle \Theta_j \Theta_j^B \rangle_{sep} \geq 2 \langle \hat{N}^A \rangle_{sep} + \langle \hat{N}^A \hat{N}^B \rangle_{sep},
\]
(A12)
The new EPR-like necessary condition for separability, for the considered model of inefficient detection (see the main text, or Appendix B), holds for any efficiency. Note, that (A10) does not contribute anything to the relation (A12), because it is an operator identity. That is, the condition (A12) reduces to (A6).

For normalized Stokes parameters the EPR-like separability condition, which is an analog of (A9), reads

\[
\sum_{j=1}^{3} \left( \hat{S}_j^A + \hat{S}_j^B \right)^2 \geq \left( \hat{\Pi}_A^N \hat{\Pi}_A + \hat{\Pi}_B^N \hat{\Pi}_B \right)_{\text{sep}}.
\]  

For a derivation, see [29] (and see also [40, 41] for its generalizations to d modes). Entanglement detection with (A13) also depends on detector efficiency, but for the considered bright squeezed vacuum state the threshold efficiency \(\eta_{\text{crit}}\) decreases with growing \(\Gamma\). The \(\eta_{\text{crit}}\) is lower than 1/3 for any finite \(\Gamma\).

If one uses the Cauchy-like inequality (A5) and the identity \(\sum_{j=1}^{3} \hat{S}_j^2 = \hat{\Pi} + \hat{\Pi}^2 N \hat{\Pi}\) (see [29]), then the following tighter EPR-like separability condition emerges

\[
\sum_{j=1}^{3} \left( \hat{S}_j^A + \hat{S}_j^B \right)^2 \geq \left( \hat{\Pi}_A^N \hat{\Pi}_A + \hat{\Pi}_B^N \hat{\Pi}_B \right)_{\text{sep}} + \left( \hat{\Pi}_A - \hat{\Pi}_B \right)^2_{\text{sep}}.
\]  

It is equivalent with the much simpler linear condition (A5).

**Appendix B: Resistance with respect to losses**

Here we derive the dependence on a detector efficiency of average values of entanglement indicators for optical fields \(\hat{\mathcal{W}}_{AB}\) and \(\hat{\mathcal{W}}_S\). Our reasoning can be extended to an arbitrary number of quantum optical modes and multi-particle cases.

The loss model (an ideal detector and a beamsplitter of transmission amplitude \(\sqrt{\eta}\) in front of it) is described by a beamsplitter transformation for the creation operators, see e.g. [39], which reads

\[
\hat{a}^\dagger_j(\eta) = \sqrt{\eta} \hat{a}^\dagger_j + \sqrt{1-\eta} \hat{c}^\dagger_j,
\]  

where \(\hat{a}^\dagger_j\) refers to the detection channel in \(j\)-th mode and \(\hat{c}^\dagger_j\) refers to the loss channel linked with the mode.

First, we shall analyze the problem for standard Stokes operators. Let \(\psi^{AB}\) be a pure state of the modes, before the photon losses. The unitary transformation \(\hat{U}(\eta)\) describing losses in all channels leads to \(\hat{U}(\eta|\psi^{AB}) = |\psi^{AB}(\eta)\rangle\), and we have

\[
\langle \psi^{AB}(\eta)|\hat{W}_\Theta|\psi^{AB}(\eta)\rangle = \langle \psi^{AB}|\hat{W}_\Theta(\eta)|\psi^{AB}\rangle,
\]  

where \(\hat{W}_\Theta(\eta)) = \hat{U}(\eta)\hat{W}_\Theta\hat{U}^\dagger(\eta)\). A transformed photon number operator \(\hat{n}_j(\eta) = \hat{a}^\dagger_j(\eta)\hat{a}^\dagger_j(\eta)\) reads

\[
\hat{n}_j(\eta) = (\sqrt{\eta} \hat{a}^\dagger_j + \sqrt{1-\eta} \hat{c}^\dagger_j)(\sqrt{\eta} \hat{a}_j + \sqrt{1-\eta} \hat{c}_j) = \eta \hat{n}_j + \sqrt{\eta(1-\eta)}(\hat{c}^\dagger_j \hat{a}_j + \hat{a}^\dagger_j \hat{c}_j) + (1-\eta) \hat{c}^\dagger \hat{c}_j.
\]  

(B3)

Notice that as the original state \(\psi^{AB}\) does not contain photons in the loss channels, thus in \(\langle \psi^{AB}|\hat{n}_j(\eta)\hat{n}_j(\eta)\rangle\) only the first term of the second line of (B3) survives. For the transmission amplitudes \(\eta^A\) and \(\eta^B\) of beams \(A\) and \(B\), we have

\[
\langle \psi^{AB}|\hat{n}_j(\eta)\hat{n}_j(\eta)\rangle = \eta^A \eta^B \langle \psi^{AB}|\hat{n}^A_\eta \hat{n}^B_\eta \psi^{AB}\rangle.
\]  

(B4)

From this we get the dependence of correlations of Stokes operators on detector efficiency in the form of \(\langle \hat{\Theta}^A_B(\gamma)^A_B(\eta^B)\rangle = \eta^A \eta^B \langle \hat{\Theta}^A_B(\gamma)^A_B(\eta^B)\rangle\).

For normalized Stokes operators, the reasoning is as follows. For Fock states \(|F\rangle = |n_A, n_A, m_B, m_B\rangle\), it is enough to consider only the average value of \(\hat{S}^A_3\) for state \(|F\rangle = |n_A, m_A\rangle\), which we shall denote for simplicity as \(|n,m\rangle\). Obviously for such a state the intensity rate at the detector measuring output \(H\), with the detection efficiency \(\eta\) for each of the detectors in the station, reads

\[
r_1(\eta) = \langle (n, m)|\hat{\Pi}_A \hat{n}_H + \hat{\Pi}_B |(n, m)\eta\rangle
\]

\[= \sum_{k=1}^{n} \sum_{l=0}^{m} \sum_{k=0}^{n} \sum_{l=0}^{m} \frac{n}{k} \frac{m}{l} \frac{1}{k+1} \eta^{k+l} (1-\eta)^{n+1-m-k-l}.
\]  

(B5)

First we notice that \(k{n\choose k} = n{-1\choose k}^{-1}\), and rewrite the first summation as from \(k = 0\) to \(k = n - 1\). Next, let us consider a function \(f(\gamma, \eta)\) of the form

\[
f(\gamma, \eta) = n \sum_{k=0}^{n-1} \sum_{l=0}^{m} \frac{n-1}{k} \frac{m}{l} \frac{1}{k+1+l} \eta^{k+l} (1-\eta)^{n-1+m-k-l},
\]

which for \(\gamma = \eta\) gives \(r_1(\eta)\). Its derivative with respect to \(\gamma\) reads

\[
\frac{d}{d\gamma} f(\gamma, \eta) = n \sum_{k=0}^{n-1} \sum_{l=0}^{m} \frac{n-1}{k} \frac{m}{l} \eta^{k+l} (1-\eta)^{n-1+m-k-l} = n(\gamma + 1) \eta^{n+m-1}.
\]  

(B6)

This upon integration with respect to \(\gamma\), with the initial condition \(f(\gamma = 0, \eta) = 0\), gives for \(\gamma = \eta\) the required result:

\[
r_1(\eta) = \frac{n}{n + m} (1 - (1-\eta)^{n+m}).
\]  

(B7)
It is easy to see that this result has a straightforward generalization to the case of more than two local detectors (e.g., see Fig. 1). To calculate the dependence on \( \eta \) of the rate at detector \( i \), when we have altogether \( d \) detectors at the station, we simply replace in the above formulas \( \hat{n}_H \) by \( \hat{n}_i \) and \( \hat{n}_V \) by \( \sum_{j \neq i} \hat{n}_j \), to get
\[
\hat{n}_i(\eta) = \frac{n}{n_{\text{tot}}} (1 - (1 - \eta)^{n_{\text{tot}}}),
\]
where \( n \) is the number of photons in a Fock state in mode \( i \) and \( n_{\text{tot}} \) is the total number of photons.

**Appendix C: Entanglement experiments involving multipart beamsplitters: homomorphism of single qudit observables and field operators**

**Proof of relation (15) for qudit states.**—We consider a set of unitary qudit observables of the following form (14)
\[
\hat{q}_k(m) = \sum_{j=1}^{d} \omega^{jk} |j(m)\rangle\langle j(m)|,
\]
where \( k = 0, 1, ..., d - 1 \) and \( \omega = \exp(2\pi i/d) \), and \( \hat{U}(m)|j\rangle = |j(m)\rangle \) is a unitary transformation of a computational basis \( (m = 0) \) vector to a vector of a different unbiased basis \( m \). We assume that the bases \( m \neq m' \) are all mutually unbiased, and consider only dimensions in which we have \( d + 1 \) mutually unbiased bases. We show that the operators \( \hat{q}_k(m)/\sqrt{d} \) with \( k = 1, ..., d - 1 \) and \( m = 0, ..., d \), and \( \hat{q}_0(0) = \mathbb{1} \) form an orthonormal basis in the Hilbert-Schmidt space of \( (d \times d) \) matrices.

The orthonormality of the operators can be established as follows. We are to prove that:
\[
\frac{1}{d} \text{Tr} \hat{q}_k(m)\hat{q}_{k'}(m') = \delta_m m' \delta_{kk'}.
\]

- For \( k' = 0 \), this is trivial because all \( k \neq 0 \) operators are traceless (as \( \sum_{j=1}^{d} \omega^{jk} = d \delta_{k0} \)).

- For \( m \neq m' \), with \( k \neq 0 \) and \( k' \neq 0 \), one has
\[
\frac{1}{d} \sum_{l,j,j'} \omega^{-jk+j'k'} \langle l(m)|j(m)\rangle \langle j(m)|j'(m')\rangle \langle j'(m')|l(m)\rangle
\]
\[
= \frac{1}{d} \sum_{l,j,j'} \omega^{-lk+l'k'} \langle l(m)|j'(m')\rangle \langle j'(m')|l(m)\rangle
\]
\[
= \frac{1}{d^2} \sum_{l,j,j'} \omega^{-lk+l'k'} = 0,
\]
where we use the fact that for mutually unbiased bases \( \langle j'(m')|j(m)\rangle^2 = 1/d \).

- For \( m = m' \), in the second line of (C3) we have \( \langle l(m)|j(m)\rangle = \delta_{lj} \), and we get in the last line
\[
\frac{1}{d} \sum_{j,k} \omega^{jk-k'} = \delta_{kk'}.
\]

As we have \( (d-1)(d+1) + 1 = d^2 \) such orthonormal operators, the basis is complete. QED.

**Remarks on the homomorphism.**—We shall now show that for any pure state of a \( d \)-mode optical field \( |\psi\rangle \), one can always find a \( d \times d \) one qudit density matrix \( \mathfrak{M} \) for which the following holds
\[
\frac{\langle \psi|\hat{Q}_k(m)|\psi\rangle}{\langle \psi|\hat{\Pi}|\psi\rangle} = \text{Tr} \hat{q}_k(m)\mathfrak{M},
\]
where \( \hat{Q}_k(m) \) is defined by (19). For the expectation value, which reads
\[
\langle \psi|\hat{Q}_k(m)|\psi\rangle = \langle \psi|\sum_{j=1}^{d} a_j^* a_j (m) \hat{\Pi} \omega^{jk}|\psi\rangle
\]
we introduce a set of states
\[
|\phi_j(m)\rangle = a_j(m) \frac{1}{\sqrt{N}} \hat{\Pi} |\psi\rangle,
\]
which for \( m = 0 \) gives
\[
|\phi_j(0)\rangle = a_j \frac{1}{\sqrt{N}} \hat{\Pi} |\psi\rangle.
\]
Then, one can transform (C5) into
\[
\langle \hat{Q}_k(m) \rangle = \sum_{j=1}^{d} \langle \phi_j(m)|\phi_j(m)\rangle \omega^{jk}.
\]

As it was mentioned in the main text, the unitary transformation of the creation operators between input and output beams is \( \hat{a}_r^\dagger(m) = \sum_s U_{rs} |m\rangle \hat{a}_s^\dagger \), where \( \hat{a}_r^\dagger(m = 0) \) is a reference operator and \( U(m = 0) = 1 \). Thanks to this the state (C6) can be put as
\[
|\phi_j(m)\rangle = \sum_{r=1}^{d} U_{jr}^* |m\rangle a_r \frac{1}{\sqrt{N}} \hat{\Pi} |\psi\rangle
\]
\[
= \sum_r U_{jr}^* |m\rangle |\phi_s(0)\rangle.
\]
Therefore, (C8) can be put as
\[
\langle \hat{Q}_k(m) \rangle = \sum_{j,s,r=1}^{d} \omega^{jk} \langle \phi_r(0)|U_{jr}(m)U_{js}^* |\psi\rangle.
\]
Let us introduce a matrix, denoted by \( M \), whose elements are \( M_{sr} = \langle \phi_r(0)|\phi_s(0)\rangle \). Then
\[
\sum_{r,s=1}^{d} \langle \phi_r(0)|U_{jr}(m)U_{js}^* |\psi\rangle = \sum_{r,s=1}^{d} M_{sr} U_{js}^* (m) |\phi_s(0)\rangle
\]
becomes
\[
\sum_{r,s=1}^{d} U_{jr}(m)M_{sr} U_{js}^* (m) = \left[U(m) M^T U^\dagger(m)\right]_{j1},
\]

\[
(C11)
\]
Finally we arrive at
\[
\langle \hat{Q}_k(m) \rangle = \sum_j \omega^{jk} \left[ U(m) M^T U^\dagger(m) \right]_{jj},
\] (C12)
where \( M \) is a (positive definite) Gramian matrix. Its trace is given by \( \text{Tr} M = (\bar{\Pi}) \leq 1 \). We can normalize it to get \( \mathfrak{M} = M/(\bar{\Pi}) \), which is an admissible qudit density matrix.

Let us now turn back to qudits, and analyze the structure an expectation of the unitary observable \( (C1) \). First, consider a pure state \( |\chi\rangle \). The expectation value reads
\[
\langle \chi|\hat{Q}_k(m)|\chi\rangle = \sum_{j,r,s} \omega^{jk} U_{js}(m) (U^*_{jr}(m)) \langle r|\chi\rangle \langle s|\chi\rangle,
\] (C13)
where we use \( |j(m)\rangle = \sum U_{js}(m) |r\rangle \) and introduce a density matrix \( M^x \) for the state \( |\chi\rangle \) of elements \( M^x_{jk} = \langle j|\chi\rangle \langle k|\chi\rangle \). If we replace \( |\chi\rangle \) by a density matrix given by \( \rho = \sum \chi \rho_{\lambda} \langle \chi\rangle = \chi \rho_{\lambda} \langle \chi\rangle \), then the expectation (C13) becomes
\[
\text{Tr} \rho_{\lambda} \hat{Q}_k(m) = \sum_{j,r,s} \rho_{\lambda} \omega^{jk} \left[ U(m) M^x U^\dagger(m) \right]_{jj},
\] (C14)
where matrix \( M^x \) has elements given by \( M^x_{jk} = \sum \rho_{\lambda} \langle j|\chi\rangle \langle k|\chi\rangle \). Therefore, (C4) holds. Obviously, such reasoning can be generalized to the case of (mixed) states describing correlated beams \( A \) and \( B \), in the way it is done in the main text.

For intensity-based observables, we have a similar relation
\[
\langle \psi|\hat{Q}_k(m)|\psi\rangle = \text{Tr} \hat{Q}_k(m) \mathfrak{M},
\] (C15)
where \( \mathfrak{M} \) is a possible two-qudit density matrix. Note that in general \( \mathfrak{M} \neq \mathfrak{M} \).

**Appendix D: Noise resistance of Cauchy-Schwartz-like separability condition for \( d \times d \)-mode Bright Squeezed Vacuum**

Observables based on rates can in some cases allow a more noise resistant entanglement detection than the ones based directly on intensities.

*Distortion noise.*—We take as our working example a \( d \times d \)-mode bright squeezed vacuum in the presence of a specific type of noise, which can be treated as distortion of the state, which lowers the correlations between the beams.

The bright squeezed vacuum is a state of light of undefined photon number which has, due to entanglement, perfect EPR correlations of numbers of photons between specific modes reaching \( A \) and \( B \). Such an entanglement can be observed in multimode parametric down-conversion emission. The interaction Hamiltonian of the process, for a classical pump, is essentially \( \hat{H} = \gamma \sum_{m=0}^{d-1} \hat{a}_m \hat{b}_m^\dagger + h.c. \) where \( \gamma \) is the coupling constant proportional to a pump power. Thus, \( d \times d \)-mode (bright) squeezed vacuum state is given by
\[
|\Psi_{BSV}\rangle = \frac{1}{\cosh \Gamma} \sum_{n=0}^{\infty} \sqrt{\frac{(n+d-1)!}{n!(d-1)!}} \tan^n \Gamma |\psi\rangle^n,
\] (D1)
where \( \Gamma = \gamma t \) and \( t \) is the interaction time, and
\[
|\psi\rangle^n = \left(\frac{n+d-1}{n!(d-1)!}\right)^{\frac{n}{2}} \left(\sum_{j=1}^{d} a_j b_j^{\dagger}\right)^n |\Omega\rangle.
\] (D2)

The model for a distorted noisy state to be used here is
\[
\hat{g}_{BSV}^{AB} = v |\Psi_{BSV}\rangle \langle \Psi_{BSV}| + (1 - v) \hat{g}_{\text{noise}},
\] (D3)
where \( v \) is a parameter which we call visibility, satisfying \( 0 \leq v \leq 1 \), and \( \hat{g}_{\text{noise}} = \hat{g}^1 \otimes \hat{g}^2 \) with \( \hat{g}^{A(B)} = \text{Tr}_{B(A)} |\Psi_{BSV}\rangle \langle \Psi_{BSV}| \). Note that, on one hand the noise does not carry any correlations between \( A \) and \( B \), and therefore its admixture lower them, but on the other hand it does not change the local statistics (as is does not affect the reduced states).

For the separability condition based on rates (18), the threshold \( v_{\text{rate}}^{\text{crit}} \) to detect entanglement of the state \( \hat{g}_{BSV}^{AB} \) is given by
\[
v_{\text{rate}}^{\text{crit}} = \sqrt{\frac{\langle \Psi|\hat{A}^\dagger \hat{A}\rangle}{\langle \Psi|\hat{A}^\dagger \hat{A}\rangle^2 + d \langle \Psi|\hat{A}^\dagger \hat{A} - \frac{1}{N_A} \hat{A}^\dagger \hat{A}\rangle}}.
\] (D4)
That is, for any \( v > v_{\text{rate}}^{\text{crit}} \) we can verify with (18) that the state \( \hat{g}_{BSV}^{AB} \) is entangled.

To get this formula we use the following:
\[
\sum_{m,k} \text{Tr} \left[ \hat{Q}_k^A(m) \hat{Q}_k^B(m) \hat{g}_{\text{noise}} \right] = 0
\]
and
\[
\text{Tr} \left[ \hat{A}^\dagger \hat{A} \hat{g}_{\text{noise}} \right] = (\text{Tr} \hat{A}^\dagger \hat{A})^2 - \langle \Psi_{BSV}|\hat{A}^\dagger \hat{A}|\Psi_{BSV}\rangle.
\] (D5)
Furthermore, (for a derivation see Appendix E2.)
\[
\sum_{m=0}^{d-1} \sum_{k=1}^{d-1} \left| \langle \Psi_{BSV}|\hat{Q}_k^A(m) \hat{Q}_k^B(m)|\Psi_{BSV}\rangle \right| = (d - 1) \langle \Psi_{BSV}|\hat{A}^\dagger + \hat{A} + \frac{d}{N_A} \hat{A}^\dagger \hat{A}|\Psi_{BSV}\rangle.
\] (D5)
The respective terms of (D4) are given by
\[
\langle \Psi_{BSV}|\hat{A}^\dagger \hat{A}|\Psi_{BSV}\rangle = 1 - \frac{1}{\cosh^2 \Gamma} = 1 - \text{sech}^2 \Gamma.
\] (D6)
and

\[
\langle \Psi_{BSV} | \hat{\Pi}^A | \Psi_{BSV} \rangle = \frac{1}{\cosh^2 \frac{\Gamma}{d}} \sum_{n=0}^{\infty} \frac{1}{n} \frac{(n + d - 1)!}{n!(d - 1)!} \tanh^{2n} \Gamma
\]

\[
= \frac{d \tanh^2 \Gamma}{\cosh^2 \frac{\Gamma}{d}} 3F_2(1, 1, (d + 1); 2, 2; \tanh^2 \Gamma), \tag{D7}
\]

where \( 3F_2(1, 1, (d + 1); 2, 2; \tanh^2 \Gamma) \) is a generalized hypergeometric function of type \( F_q(a_1, \ldots, a_p; b_1, \ldots, b_q; x) \).

Following the similar steps, we derive the threshold visibility \( v_{\text{crit}}^{\text{int}} \) for observables based on intensities:

\[
v_{\text{crit}}^{\text{int}} = \left( \frac{\langle \Psi_{BSV} | \hat{\Pi}^A | \Psi_{BSV} \rangle^2}{\langle \Psi_{BSV} | \hat{\Pi}^A | \Psi_{BSV} \rangle^2 + d \langle \Psi_{BSV} | \hat{\Pi}^B | \Psi_{BSV} \rangle} \right)^{1/2}, \tag{D8}
\]

and as

\[
\langle \Psi_{BSV} | \hat{\Pi}^A | \Psi_{BSV} \rangle = d \sinh^2 \Gamma, \tag{D9}
\]

we have \( v_{\text{crit}}^{\text{int}} = \tanh^2 \Gamma \). Note its independence on \( d \).

Figure 2 shows the threshold visibilities for rates and intensities approaches as functions of the gain \( \Gamma \) for \( d = 2, 3, 5, 7 \).

**Constant noise.**—Consider a noisy state \( (D3) \) with another type of noise that does not depend on gain parameter \( \Gamma \) of the state \( |\Psi_{BSV}\rangle \). The considered noise model is now given by

\[
\vartheta^{AB} = v |\Psi\rangle\langle \Psi| + (1 - v) \vartheta^{\text{noise}}_\Gamma, \tag{D10}
\]

where \( \vartheta^{\text{noise}}_\Gamma = \vartheta^A \otimes \vartheta^B \), with \( \vartheta^{A(B)} = T_{\Gamma(B(A)} |\Psi_{\Gamma'}\rangle\langle \Psi_{\Gamma'}| \), and \( |\Psi_{\Gamma'}\rangle \) denotes the BSV state with a fixed value of \( \Gamma' \).

We emphasize that \( \Gamma' \) is here a fixed parameter of noise while \( \Gamma \) still refers to \( |\Psi_{BSV}\rangle \), and depends on the pumping. Such a model tries to describe situations in which we may have spurious (dark) counts at the detectors, and \( \Gamma' \) is related to an effective temperature of such spurious events.

In this case, the threshold visibilities for observables based on rates and intensities are given by

\[
v_{\text{crit}}^{\text{rate}} = \left( \frac{\langle \Psi_{\Gamma'} | \hat{\Pi}^A | \Psi_{\Gamma'} \rangle^2}{\langle \Psi_{\Gamma'} | \hat{\Pi}^A | \Psi_{\Gamma'} \rangle^2 + d \langle \Psi_{\Gamma'} | \hat{\Pi}^{A(B)} | \Psi_{\Gamma'} \rangle} \right)^{1/2}, \tag{D11}
\]

and

\[
v_{\text{crit}}^{\text{int}} = \left( \frac{\langle \Psi_{\Gamma'} | \hat{\Pi}^B | \Psi_{\Gamma'} \rangle^2}{\langle \Psi_{\Gamma'} | \hat{\Pi}^B | \Psi_{\Gamma'} \rangle^2 + d \langle \Psi_{\Gamma'} | \hat{\Pi}^{A(B)} | \Psi_{\Gamma'} \rangle} \right)^{1/2}, \tag{D12}
\]

which now depends on \( d \). Obviously, \( \langle \Psi_{\Gamma'} | \hat{\Pi}^A | \Psi_{\Gamma'} \rangle \) and \( \langle \Psi_{\Gamma'} | \hat{\Pi}^B | \Psi_{\Gamma'} \rangle \) are constant for chosen \( \Gamma' \). Figure 4 shows the critical visibilities for rates and intensities as a function of the gain \( \Gamma \) for fixed \( \Gamma' = 1 \) in (a) and \( \Gamma' = 2 \) in (b).

**Appendix E: Derivation of some formulas used in Appendix D**, and to obtain the general Cauchy-like separability condition

1. **Formula 1**

We shall show the following:

\[
\sum_{m=0}^{d-1} \sum_{k=1}^{d} |\hat{Q}_k(m)|^2 = (d - 1) \left( \hat{\Pi} + \frac{d}{N} \hat{\pi} \right), \tag{E1}
\]

Note that this is a generalization of the identity \( \sum_{i=1}^{3} \hat{S}_i^2 = \hat{\Pi} + \hat{\Pi} \frac{\hat{\pi}}{d}. \)

The field operators involving the unbiased interferometers, within the approach with rates \( (19) \) can be put as

\[
\hat{Q}_k(m) = \sum_{l,l'=1}^{d} \left( \sum_{j=1}^{d} \omega^{j} U_{jl}(m) U_{jl'}(m) \right) \hat{\Pi}^{\frac{d-1}{2}} \hat{\pi} \hat{\Pi}^{\frac{d-1}{2}}, \tag{E2}
\]

and the formula for \( \hat{Q}_k^\dagger \) is the Hermitian conjugate of the above. The following relations

\[
\sum_{j=1}^{d} U_{jl}(m) U_{jl'}(m) \omega^{jk} = [\hat{q}_k(m)]_{ll'}, \tag{E3}
\]

lead to

\[
\hat{Q}_k(m) = \sum_{l,l'=1}^{d} [\hat{q}_k(m)]_{ll'} \hat{\Pi}^{\frac{d-1}{2}} \hat{\pi} \hat{\Pi}^{\frac{d-1}{2}}, \tag{E4}
\]

where \( \hat{q}_k(m) \) are the qudit operators \( (14) \). Therefore, we have

\[
\sum_{m=0}^{d-1} \sum_{k=1}^{d} |\hat{Q}_k(m)|^2 = \frac{1}{N} \sum_{l,l'=1}^{d} \left( \sum_{m=0}^{d-1} \sum_{k=1}^{d} [\hat{q}_k(m)]_{ll'} [\hat{q}_k(m)]_{ll'} \right) \hat{\Pi}^{\frac{d-1}{2}} \hat{\pi} \hat{\Pi}^{\frac{d-1}{2}}. \tag{E5}
\]

As the operators \( \frac{1}{\sqrt{d}} \hat{q}_k(m) \) and \( \vartheta_0(0) = 1 \) form an orthonormal basis in the Hilbert-Schmidt space of \( d \times d \) matrix, we have

\[
\delta_{ll'} \delta_{nn'} + \sum_{m=0}^{d-1} \sum_{k=1}^{d} [\hat{q}_k(m)]_{ll'} [\hat{q}_k(m)]_{nn'} = d \delta_{ln} \delta_{ll'}. \tag{E5}
\]

All that, and \( [a_i, a_i^\dagger] = \delta_{ij} \), allows one to perform the
FIG. 2. The threshold visibilities as functions of the amplification gain $\Gamma$ for $d \times d$-mode bright squeezed vacuum state $|\Psi\rangle$. Presented results are for $d = 2, 3, 5, 7$. Note that as $d$ increases the results obtained via rates and intensities approaches become similar.

FIG. 3. The ratio between the threshold visibilities for rate and intensity, $v_{\text{crit}}^{\text{rate}} / v_{\text{crit}}^{\text{int}}$ for $d = 2$ as a function of $\Gamma$. Note that the biggest difference between two approaches in favor of rate-observables is for $\Gamma \approx 1$.

Following calculation:

$$\sum_{m=0}^{d} \sum_{k=1}^{d-1} |\hat{Q}_k(m)|^2$$

$$= \hat{\Pi} \frac{1}{N} \sum_{l\ell' n n'=1}^{d} [d\delta_{ll'}\delta_{n n'} - \delta_{ll'}\delta_{nn'}] a_{l}^\dagger a_{n}^\dagger a_{l'} a_{n'} \frac{1}{\hat{N}} \hat{\Pi}$$

$$= \hat{\Pi} \frac{1}{N} \left[ -d \sum_{ln} a_{l}^\dagger a_{l} a_{n} + d \sum_{ll'} a_{l}^\dagger a_{l'} a_{l'} \frac{1}{\hat{N}} \hat{\Pi} \right]$$

$$= \hat{\Pi} \frac{1}{N} \left[ -\hat{N}^2 + d \sum_{ll'} a_{l}^\dagger a_{l} (a_{l} a_{l} + 1) - d \sum_{l} a_{l}^\dagger a_{l} \right] \frac{1}{\hat{N}} \hat{\Pi}$$

$$= \hat{\Pi} \frac{1}{N} \left[ -\hat{N}^2 + d\hat{N}^2 + d^2 \hat{N} - d\hat{N} \right] \frac{1}{\hat{N}} \hat{\Pi}$$

$$= \hat{\Pi} \left[ (d - 1) + \frac{d(d - 1)}{N} \right] \hat{\Pi} \quad (E6)$$

Thus, (E1) holds.

An analogue relation for the observables involving intensities, which reads

$$\sum_{m=0}^{d} \sum_{k=1}^{d-1} |\hat{Q}_k(m)|^2 = (d - 1)\hat{N}(\hat{N} + d) \quad (E7)$$

can be obtained by similar steps. It is a generalization of (A10).
2. Formula 2

We here calculate the expressions which enter of Cauchy-Schwartz-like separability conditions based on rates (18) and intensities (20) for a $d \times d$ mode bright squeezed vacuum. Some of the formulas are also used in the discussion of noise resistance.

Let us consider first the condition (20): its LHS and RHS read

$$LHS = \sum_{m=0}^{d-1} \sum_{k=1}^{d} \langle \Psi_{BSV} | \hat{Q}^B_k(m) \hat{Q}^A_k(m) | \Psi_{BSV} \rangle,$$

$$RHS = (d-1) \langle \Psi_{BSV} | (\hat{N})^2 | \Psi_{BSV} \rangle. \quad (E8)$$

To get the formula for RHS we used

$$\langle \Psi_{BSV} | \hat{N}^A \hat{N}^B | \Psi_{BSV} \rangle = \langle \Psi_{BSV} | (\hat{N}^A)^2 | \Psi_{BSV} \rangle. \quad (E9)$$

The action of $\hat{Q}^B_k(m = 0)$ on an unnormalized $|\psi_n^d\rangle$ of (D2), which we put as $|\phi^n\rangle = \left(\sum_{j=1}^{d} \hat{a}^j_0 \hat{b}^j_0\right)^n |\Omega\rangle$, is as follows

$$\hat{Q}^B_k \left(\sum_{j=1}^{d} \hat{a}^j_0 \hat{b}^j_0\right)^n |\Omega\rangle = \left(\sum_{j=1}^{d} \omega^{jk} \hat{a}^j_k \hat{b}^j_k\right) \left(\sum_{j=1}^{d} \hat{a}^j_0 \hat{b}^j_0\right)^n |\Omega\rangle. \quad (E10)$$

Let us denote as $\hat{X} \equiv \hat{Q}^B_k = \sum_{j=1}^{d} \omega^{jk} \hat{a}^j_k \hat{b}^j_k$ and $\hat{Y} \equiv \sum_{j=1}^{d} \hat{a}^j_0 \hat{b}^j_0$. Then, we have

$$[\hat{X}, \hat{Y}] = \left[\sum_{j=1}^{d} \omega^{jk} \hat{a}^j_k \hat{b}^j_k, \sum_{j=1}^{d} \hat{a}^j_0 \hat{b}^j_0\right] = \sum_{j=1}^{d} \omega^{jk} \hat{a}^j_0 \hat{b}^j_0. \quad (E11)$$

Next, we use the the algebraic fact that if $|[\hat{X}, \hat{Y}]|, \hat{Y} = 0$, then the following holds $[\hat{X}, \hat{Y}^n] = n[\hat{X}, \hat{Y}] \hat{Y}^{n-1}$ and $\hat{X} \hat{Y}^n = \hat{Y}^n \hat{X} + n[\hat{X}, \hat{Y}] \hat{Y}^{n-1}$. Applying this relation to

$$\hat{Q}^B_k \left(\sum_{j=1}^{d} \hat{a}^j_0 \hat{b}^j_0\right)^n |\Omega\rangle = \left(\sum_{j=1}^{d} \omega^{jk} \hat{a}^j_k \hat{b}^j_k\right) \left(\sum_{j=1}^{d} \hat{a}^j_0 \hat{b}^j_0\right)^{n-1} |\Omega\rangle, \quad (E12)$$

where we use $\sum_{j=1}^{d} \omega^{jk} \hat{a}^j_0 \hat{b}^j_0 |\Omega\rangle = 0$. We have the same relation if we replace $\hat{Q}^B_k$ by $\hat{Q}^A_k$ in (E12), i.e.,

$$\hat{Q}^A_k \left(\sum_{j=1}^{d} \hat{a}^j_0 \hat{b}^j_0\right)^n |\Omega\rangle = \hat{Q}^B_k \left(\sum_{j=1}^{d} \hat{a}^j_0 \hat{b}^j_0\right)^n |\Omega\rangle. \quad (E13)$$

The identity (E13) holds for all $m = 0, 1, \ldots, d$. In the case of $m \neq 0$ the formulas look the same if one employs creation and annihilation operators related with the interferometers $U(m)$ for $A$ and $U^+(m)$ for $B$, and the fact that $\sum_{j=1}^{d} \hat{a}^j_0 \hat{b}^j_0 = \sum_{j=1}^{d} \hat{a}^j_0 \hat{b}^j_0 = \hat{N}^A(m) \hat{N}^A(m)$, which is at the root of EPR correlations of the state. All that, and the identity (E7), lead to

$$LHS = \sum_{m=0}^{d-1} \sum_{k=1}^{d} \langle \Psi | \hat{Q}^A_k(m) | \Psi \rangle = (d-1) \langle \Psi | \hat{N}^A + \hat{N}^A | \Psi \rangle. \quad (E14)$$

Thus, we get

$$LHS = \langle \Psi | \hat{N}^A + \hat{N}^A | \Psi \rangle > \langle \Psi | (\hat{N}^A)^2 | \Psi \rangle = RHS, \quad (E15)$$

for every $\Gamma$.

A reasoning following similar steps leads to a violation of the Cauchy-Schwartz-like separability condition (18) for observables involving rates, as for the bright squeezed vacuum.
vacuum we have in this case:

\[
\text{LHS} = \langle \Psi | (\hat{\Pi}^A + \hat{\Pi}^A \frac{d}{N^A} \hat{\Pi}^A) | \Psi \rangle
\]

\[
\text{> } \langle \Psi | \hat{\Pi}^A | \Psi \rangle = \text{RHS},
\]

(E16)

where \( \hat{\Pi}^A = (\hat{\Pi}^A)^2 \) was used.
