ABSTRACT

We present a one-pass sparsified Gaussian mixture model (SGMM). Given \( P \)-dimensional datapoints \( \mathcal{X} = \{ \mathbf{x}_i \}_{i=1}^N \), the model fits \( K \) Gaussian distributions to \( \mathcal{X} \) and (softly) classifies each \( \mathbf{x}_i \) to these clusters. After paying an up-front cost of \( O(NP \log P) \) to precondition the data, we subsample \( Q \) entries of each datapoint and discard the full \( P \)-dimensional data. SGMM operates in \( O(KNQ) \) time per iteration for diagonal or spherical covariances, independent of \( P \), while estimating the model parameters \( \theta \) in the full \( P \)-dimensional space, making it one-pass and hence suitable for streaming data. We derive the maximum likelihood estimators for \( \theta \) in the sparsified regime, demonstrate clustering on synthetic and real data, and show that SGMM is faster than GMM while preserving accuracy.

Index Terms—compressive sampling, mixture models, clustering, dimensionality reduction

1. INTRODUCTION

When performing clustering analysis on high-dimensional (\( P \) features), high-volume (\( N \) samples) data, it is common to employ simple clustering schemes like \( k \)-means and \( k \)-nearest-neighbors, particularly during data exploration and feature engineering, because these techniques are fast and return informative results \[1\]. Often each datapoint \( \mathbf{x}_i \in \mathbb{R}^P \) will be seen only once and must then be discarded, necessitating one-pass algorithms. \[2\]. Further, the latent dimension \( P \) may be prohibitively large or the rate of data acquisition may be too high to permit analysis on the full data.

We present a clustering algorithm suitable for this regime: the sparsified Gaussian mixture model (SGMM), building on our previous work in which we developed the sparsification scheme we use here and applied it to \( k \)-means clustering \[3\]. GMM, in particular when using diagonal or spherical covariances, is a natural extension of \( k \)-means: it increases generalizability by taking into account cluster size and covariance and by performing soft clustering, while still being relatively inexpensive to compute \[4\].

SGMM works on compressed data, such that the computation and storage costs are measured in \( Q \ll P \), and yet is one-pass, meaning that the model parameters are estimated in the full \( P \)-dimensional space. These requirements are seemingly orthogonal to each other; we are able to provide both by a careful choice of how we compress the data, which we do using a sketch \( \mathbf{R}_x^T \mathbf{x}_i \) of size \( Q \ll P \). Our sketching scheme is motivated by the Johnson-Lindenstrauss lemma \[5\], which states that certain random projections into lower dimensions preserve pairwise distances to within a small error \( \varepsilon \) with high probability. In particular, these embeddings can be computed efficiently in \( O(NP \log P) \) time \[6\], and the data are recoverable from the embeddings when they are sparse in some basis \[7\]. The idea is to project the data into a lower dimension and perform analyses there, where it is cheap to do so. A variety of approaches have been proposed to this end \[8, 9, 10, 11, 12\], including an application of sketching to Gaussian Mixture models \[13\].

In general, such compressive approaches are two-pass, meaning that access to the full data is required to estimate statistics in the original space, such as the sample mean. The contribution of our method is that it is compressive and one-pass, meaning that we estimate statistics in the full \( P \)-dimensional space using only \( Q \)-dimensional sketches of the data. This is possible because we use a different sampling matrix \( \mathbf{R}_i \) for each datapoint \( \mathbf{x}_i \), so that the \( Q \) features of some dense statistic \( \theta \) informed by \( \mathbf{x}_i \) are in general not the same as the \( Q \) features informed by another datapoint \( \mathbf{x}_j \).

2. THEORY

2.1. Data Preconditioning and Sketching

We will project \( \mathbf{x}_i \) into a lower dimension by keeping \( Q \ll P \) components chosen uniformly at random. Before doing so we precondition the data using a random orthonormal system (ROS):

\[ \mathbf{x}_i = \mathbf{H} \mathbf{D}^{\frac{1}{2}} \mathbf{x}_i^{raw} \quad (1) \]

where \( \mathbf{D} \) is diagonal with entries \( \pm 1 \) chosen uniformly at random and \( \mathbf{H} \) is a discrete cosine transform matrix \[1\]. The ROS

\[^1\text{other choices include Hadamard or Fourier}\]
transformation ensures that, with high probability, the magnitudes of the entries of \( x_i \) are relatively close to each other [14, 6], minimizing the risk of “missing” the information in the vector when subsampling. The ROS can be applied and inverted in \( O(NP \log P) \) time, which is the dominant cost in our algorithm for small enough sketches. A detailed discussion of convergence properties and bounds of the ROS can be found in [3]. Henceforth, when we write \( x_i \), we assume the data have been preconditioned.

Following the preconditioning, we subsample \( Q \ll P \) entries chosen uniformly at random from \( x_i \). This operation can be represented by the product \( R_i^T x_i \), where \( R_i \in \mathbb{R}^{P \times Q} \) is sparse, with \( R_i(p, q) = 1 \) if we are keeping the \( p \)th feature of \( x_i \) and storing it in the \( q \)th dimension of the sparsified vector, and 0 otherwise. Thus \( R_i^T x_i \in \mathbb{R}^Q \) are the entries we preserve from \( x_i \). In practice we store only the \( Q \) entries of \( x_i \) that the subsampling picks out as well as the indices specifying which entries were preserved (the indices of the \( Q \) non-zero rows of \( R_i \)), though it will facilitate our exposition to write quantities like \( R_i^T x_i \), \( R_i \in \mathbb{R}^P \). Crucially, \( R_i \) is resampled for each \( x_i \). This fact is what enables the method to be one-pass.

### 2.2. Mixture Models

We now describe the modeling framework, beginning with a general mixture model [4]. Assume there are \( K \) components and that each datapoint \( x_i \) belongs to one of them, indicated by the hidden variable \( z_i \in \{1, 2, \ldots, K\} \). A mixture model [4] is fully specified by the component distributions \( p_k(x_i \mid \theta_k) = p(x_i \mid z_i = k, \theta_k) \), the component weights \( \pi = \{\pi_k\}_{k=1}^K \) with \( \sum_k \pi_k = 1 \), and the parameters \( \theta = \{\theta_k\}_{k=1}^K \). The distribution for \( x_i \) is given by

\[
p(x_i \mid \theta) = \sum_{k=1}^K \pi_k p_k(x_i \mid \theta_k). \tag{2}
\]

For a mixture of Gaussians, \( \theta_k = \{\mu_k, S_k\} \) where \( \mu_k \in \mathbb{R}^P \) is the mean and \( S_k \in \mathbb{R}^{P \times P} \) is the covariance of the \( k \)th cluster, and \( p(x_i \mid z_i = k, \theta_k) \) is given by

\[
p_k(x_i \mid \theta_k) = \frac{1}{(2\pi)^{P/2} |S_k|^{1/2}} \exp \left( -\frac{1}{2} D_{\theta_k}(x_i) \right) \tag{3}
\]

where

\[
D_{\theta_k}(x_i) = (x_i - \mu_k)^T \Lambda_k (x_i - \mu_k) \tag{4}
\]

is the squared Mahalanobis distance and \( \Lambda_k = S_k^{-1} \) is the \( k \)th precision matrix.

The goal is to simultaneously estimate the parameters \( \theta \), the weights \( \pi \), and the cluster assignments \( z_i \), which we do using the Expectation-Maximization algorithm.

#### 2.3. The EM Algorithm

The log likelihood for data \( \mathcal{X} = \{x_1, x_2, \ldots, x_N\} \) under the mixture distribution given in equation (2) is

\[
\ell(\theta) = \sum_{i=1}^N \log \left( \sum_{k=1}^K p_k(x_i \mid \theta_k) \right). \tag{5}
\]

In the case of GMM’s (as well as in many others) it is intractable to find the maximum likelihood estimators (MLE’s) for \( \theta \) because of the hidden variable \( z_i = \{z_i\}_{i=1}^N \). Expectation-Maximization finds a local optimum by iteratively holding one of the unknown quantities (\( \theta \) or \( z \)) fixed and solving for the other. At each iteration we obtain a new estimate \( \{\theta^t, \pi^t\} \) computed from the previous estimate \( \{\theta^{t-1}, \pi^{t-1}\} \).

Specifically, define the auxiliary function

\[
Q(\theta, \theta^{t-1}) = E \left[ \ell_c(\theta) \mid \mathcal{X}, \theta^{t-1} \right] \tag{6}
\]

where

\[
\ell_c(\theta) = \sum_{i,k} \log p(x_i, z_i = k \mid \theta_k) \tag{7}
\]

is the complete data log likelihood and \( \mathcal{X} \) is the dataset.

The E step is then to compute the expected sufficient statistics in \( Q \) for \( \theta \), which is equivalent to finding the responsibility \( r_{ik} = p(z_i = k \mid x_i, \theta^{t-1}) \) for each datapoint \( x_i \) and component \( k \):

\[
r_{ik} = \frac{\pi_k p_k(x_i \mid \theta_k^{t-1})}{\sum_{j=1}^K \pi_j p_j(x_i \mid \theta_j^{t-1})}. \tag{8}
\]

The auxiliary function in equation (6) can then be expressed in terms of the responsibility as

\[
Q(\theta, \theta^{t-1}) = \sum_{i,k} r_{ik} \log [\pi_k p_k(x_i \mid \theta_k)]. \tag{9}
\]

The M step is to obtain the next iterate \( \{\theta^t, \pi^t\} \) by optimizing \( Q \):

\[
\{\theta^t, \pi^t\} = \arg\max_{\theta, \pi} Q(\theta, \theta^{t-1}). \tag{10}
\]
For a mixture of Gaussians, $Q$ is optimized by the maximum likelihood estimators:

\[
\hat{\pi}_k = \frac{r_k}{N} \quad \text{(11)}
\]

\[
\hat{\mu}_k = \frac{\sum_i r_{ik} x_i}{\sum_i r_{ik}} \quad \text{(12)}
\]

\[
\hat{S}_k = \frac{\sum_i r_{ik} (x_i - \hat{\mu}_k)(x_i - \hat{\mu}_k)^T}{\sum_i r_{ik}} \quad \text{(13)}
\]

The E and M steps are repeated until (guaranteed) convergence to a local maximum or saddle point of $Q$.

2.4. EM for Sparsified Gaussian Mixtures

We now present our main result, the EM algorithm for sparsified Gaussian mixtures; i.e., the equivalent to the responsibility in equation (8) and the parameter MLE’s in equations (11) under sparsification.

The sparsified analog of the squared Mahalanobis distance in equation (4) is

\[
D^R_{\theta_k}(x_i) = (x_i - \mu_k)^T \Lambda^R_{ki} (x_i - \mu_k) \quad \text{(14)}
\]

where

\[
\Lambda^R_{ki} = R_i (R_i^T S_k R_i)^{-1} R_i^T \in \mathbb{R}^{P \times P} \quad \text{(15)}
\]

is the sparsified analog of the precision matrix $\Lambda_k = S_k^{-1}$. The sparsified Gaussian density is:

\[
p^R_{\theta_k}(x_i | \theta_k) = \frac{1}{2^P \pi^{P/2}} \frac{1}{|R_i^T S_k R_i|^{1/2}} \exp \left( -\frac{1}{2} D^R_{\theta_k}(x_i) \right). \quad \text{(16)}
\]

This can be taken to be a $Q$-dimensional Gaussian with mean $R_i \mu_k$ and covariance $R_i^T S_k R_i$ evaluated at $R_i x_i$. Both $p^R_{\theta_k}$ and $D^R_{\theta_k}(x_i)$ are unbiased estimators of their dense counterparts when scaled by $P/Q$ (see Figure 1).

The E-step is to compute the responsibility as given in equation (8). Under sparsification, the responsibility becomes

\[
r_{ik}^R = \frac{\pi_k p^R_{\theta_k}(x_i | \theta_k^{-1})}{\sum_{j=1}^K \pi_j p^R_{\theta_k}(x_i | \theta_k^{-1})} \quad \text{(17)}
\]

and hence the sparsified auxiliary function $Q$ in equation (9) is:

\[
Q^R(\theta, \theta^{-1}) = \sum_{i,k} r_{ik}^R \log \left[ \pi_k p^R_{\theta_k}(x_i | \theta_k) \right]. \quad \text{(18)}
\]

We now derive the maximum likelihood estimators for $\pi_k$ and $\theta_k$ under sparsification.

\textbf{Theorem 1} (Maximum Likelihood Estimators for Sparsified Gaussian Mixtures). The maximum likelihood estimator for $\pi_k$ with respect to $Q^R$ is

\[
\hat{\pi}_k^R = \frac{\sum_i r_{ik}^R}{N}. \quad \text{(19)}
\]

The maximum likelihood estimators for $\mu_k$ and $S_k$ are the solutions to the system

\[
\mu_k^R = \left( \sum_i r_{ik}^R \Lambda_k^{R,i} \right)^T \sum_i r_{ik}^R \Lambda_k^{R,i} x_i \quad \text{(20)}
\]

\[
\sum_i r_{ik}^R \Lambda_k^{R,i} = \sum_i r_{ik}^R \Lambda_k^{R,i} M_{ik} \Lambda_k^{R,i} \quad \text{(21)}
\]

where

\[
M_{ik} = (x_i - \mu_k)(x_i - \mu_k)^T. \quad \text{(22)}
\]

is the scatter matrix.

\textbf{Proof.} The component of $Q^R$ with $\pi_k$-dependence is

\[
\ell^R(\pi_k) = \sum_{i,k} r_{ik}^R \log \pi_k
\]

from which the MLE in equation (19) can be derived by setting $\partial \ell^R / \partial \pi_k = 0$ for each $k$ simultaneously and solving the resulting system. The components of $Q^R$ with $\mu_k$ and $S_k$ dependence are

\[
\ell^R(\mu_k, S_k) = \sum_i r_{ik}^R \left( \log |R_i^T S_k R_i| + D^R_{\theta_k}(x_i) \right). \quad \text{(23)}
\]

To find $\partial \ell^R / \partial \mu_k$ we observe that

\[
\frac{\partial}{\partial \mu_k} D^R_{\theta_k}(x_i) = -2 \Lambda_k^{R,i} (x_i - \mu_k).
\]

Equation (20) then follows by setting $\partial \ell^R / \partial \mu_k = 0$ and re-arranging.

We now find $\partial \ell^R / \partial S_k$. For the first term in the summand of equation (23), we have that

\[
\frac{\partial}{\partial S_k} \log |R_i^T S_k R_i| = \Lambda_k^{R,i} \quad \text{(24)}
\]

which can be obtained element-wise using Jacobi’s formula and the symmetry of $S_k$. For the second term, we apply the “trace trick”:

\[
D^R_{\theta_k}(x_i) = \text{tr} \left[ M_{ik} \Lambda_k^{R,i} \right] \quad \text{(25)}
\]

to find

\[
\frac{\partial}{\partial S_k} D^R_{\theta_k}(x_i) = -\Lambda_k^{R,i} M_{ik} \Lambda_k^{R,i}, \quad \text{(26)}
\]

which can be obtained by direct element-wise differentiation of equation (25). Setting $\partial \ell / \partial S_k = 0$ from equation (23), using equations (24) and (26) we obtain equation (21).
Fig. 2. Accuracy and timing of diagonal SGMM on the subset \( \{0,3,9\} \) of MNIST \((N = 18000)\) as a function of compression. 3 initializations per trial, 20 trials per compression. Shaded regions indicate standard deviation (dark) and extrema (light) taken over the trials.

Evaluating these MLEs does not require access to the full \( x_i \), as in each case such terms are sparsified by the action of \( A_k^{R_k} \). In the case of no sparsification; i.e., \( R_k = I \) for all \( i \), we recover the standard MLEs in equations (11 - 13). Equation [19] has only \( \pi_k^R \) dependence, and hence gives the MLE for this parameter. Equation [20] gives the MLE for \( \mu_k^R \) in terms of the \( A_k^{R_k} \). In the standard case, the \( A_k^{R_k} \) terms cancel and we obtain the MLE for \( \mu_k \), which is then used in place of \( \mu_k \) to find the MLE for \( S_k \); however, in the sparsified case we do not observe this cancelation, and hence must solve equations [20] and [21] simultaneously. This can be done, for example, in an EM-type iterative fashion, but such a procedure further requires the evaluation of \( A_k^{R_k} \), involving a \( Q \times Q \) inverse, of which there are \( KN \) per iteration. These issues can be circumvented by using diagonal or spherical covariances. We give the MLEs for the diagonal case, \( S_k = \text{diag}(s_k) \) where \( s_k \in \mathbb{R}^P \) (proof omitted).

**Corollary 2** (MLEs for diagonal \( S_k \)). When the \( S_k \) are diagonal, the system of equations [20] - [27] yields the MLEs

\[
\hat{\mu}_k = \left( \sum_i r_{ik}^R P_i \right)^{\top} \sum_i r_{ik}^R P_i x_i \tag{27}
\]

\[
\hat{S}_k = \text{diag} \left[ \left( \sum_i r_{ik}^R P_i \right)^{\top} \sum_i r_{ik}^R P_i M_{ik} P_i \right] \tag{28}
\]

where \( P_i \in \mathbb{R}^{P \times P} \) is the sparse projection matrix:

\[
P_i = R_i R_i^T. \tag{29}
\]

In the case of diagonal covariances (as well as in the simpler spherical case in which \( S_k = s_k I \)), the responsibilities

3 via the chain rule and the fact that \( \frac{d}{dt} (A^T A) = (A^T + A^T) \frac{dA}{dt} \)

4 Jacobi’s formula states that \( \frac{d}{dt} \det A = \text{tr} \left[ \text{adj}(A) \frac{dA}{dt} \right] \)
