We report on muon spin rotation experiments probing the temperature-dependent magnetic penetration depth $\lambda(T)$ in 2H-NbSe$_2$ under high-pressure ($p_{\text{max}} = 2.1$ GPa) and in 4H-NbSe$_2$ at ambient pressure. The current results for ambient pressure along with our earlier findings on 1T'-MoTe$_2$ (Z. Guguchia et. al., Nature Communications 8, 1082 (2017)) demonstrates that the superfluid density $n_s/m^* \propto 1/\lambda^2$ scale linearly with $T_c$ in the three transition metal dichalcogenide superconductors 2H-NbSe$_2$, 4H-NbSe$_2$, and 1T'-MoTe$_2$. Upon increasing pressure, we observe a substantial increase of the superfluid density $n_s/m^* \propto 1/\lambda^2$ in 2H-NbSe$_2$, which we find to correlate with $T_c$. However, the $n_s/m^*$ vs $T_c$ dependence shows a deviation from the Uemura linear relation. A similar deviation from the Uemura line was also observed in previous pressure studies of optimally doped cuprates. The correlation between the superfluid density and the critical temperature is considered a hallmark feature of unconventional superconductivity, especially in high-temperature cuprate superconductors. Here, we show that this correlation is also an intrinsic property of the superconductivity in transition metal dichalcogenides, whereas the ratio $T_c/T_F$ is approximately a factor of 20 lower than the ratio observed in hole-doped cuprates. We, furthermore, find that the values of the superconducting gaps are insensitive to the suppression of the quasi-two-dimensional CDW state, indicating that the CDW ordering and the superconductivity in 2H-NbSe$_2$ are independent of each other.

PACS numbers:

Transition metal dichalcogenides (TMDs) are a class of layered materials, which presently attract great interest because of their versatile physical, chemical, and mechanical properties[1][3]. The TMDs share the MX$_2$ formula, with M being a transition metal (M = Ti, Zr, Hf, V, Nb, Ta, Mo, W or Re) and X being a chalcogen (X = S, Se, or Te). These compounds crystallize in different structural phases resulting from different stacking of the individual MX$_2$ layers, with van der Waals bonding between them.

A variety of novel physical phenomena have been reported in TMDs systems. Most recently topological physics with Dirac-type dispersion, exotic optical and transport behavior originating from valley splitting were predicted and observed[1][4]. Correlated physics has been studied intensively especially in 2H-TaS$_2$, 2H-NbSe$_2$, and more recently in 1T'-MoTe$_2$[5][12][15]. 2H-NbSe$_2$ is a superconductor with a critical temperature $T_c \approx 7.3$ K, and hosts a two-dimensional charge density wave (CDW) with a critical temperature of $T_{\text{CDW}} \approx 33$ K[16][21]. The polymorph 4H-NbSe$_2$ undergoes a CDW transition at $T_{\text{CDW}} \approx 40$ K and becomes superconducting at $T_c \approx 6$ K. The superconducting transition temperature of 2H-NbSe$_2$ is remarkably high in comparison with other TMDs, where commonly transition temperatures below 4 K are observed. Recently, it was found that both the superconducting state, as well as the CDW ordering remain intact even for a single layer of this material[3]. The superconducting transition temperature is thereby lowered in the 2D limit to $T_c \approx 1.1$ K. Previously, the effect of hydrostatic pressure on the CDW ordering and superconductivity were studied in 2H-NbSe$_2$ by means of magnetization and resistivity measurements[22][23]. It was found that upon increasing pressures, CDW ordering is suppressed. The suppression of charge-density wave ordering commonly causes a strong increase of the superconducting transition temperature $T_c$ (see, e.g. references[24][26]). The generic occurrence of a “fragile” SC phase in the systems with competing SC and CDW ground states was reported, recently[27]. In 2H-NbSe$_2$, $T_c$ increases only slightly ($\Delta T_c < 1$ K) with increasing pressure without any anomaly across the critical pressure at which the CDW state disappears. Moreover, both CDW order parameter amplitude as well as its static phase coherence length are unaffected when the superconductivity is suppressed in a high magnetic field[18]. Recent X-ray experiments also suggest that different phonon branches are responsible for SC and CDW orders[29]. These findings suggested that superconductivity is only weakly affected by the suppression of the CDW ordering[18][21][23].

*Electronic address: zurab.guguchia@psi.ch
Layered superconductors, with highly anisotropic electronic properties have been found to be potential hosts for unconventional superconductivity. The most prominent example are the cuprates, consisting of CuO layers and the iron pnictides superconductors, with tetrahedra coordinated FePt layers. Other examples for unconventional superconductivity in layered systems are a monolayer of FeSe on STO and the reported superconductivity in twisted bilayer graphene. Recently, we have reported on muon spin rotation ($\mu$SR) measurements on the TMD superconductor $T_d$-MoTe$_2$, which is considered to be a type-II Weyl semimetal $\text{[10, 11, 30]}$. We had found a linear scaling of superfluid density at $T = 0$ and the transition temperature $T_c$, similar to the relation found earlier in the cuprates $\text{[31]}$ and other Fe-based superconductors $\text{[32, 34]}$.

Here, we report on the substantial increase of the superfluid density $n_s/m^*$ in van der Waals system 2H-NbSe$_2$ (Fig. 1(a)) under hydrostatic pressure, which seems not to be correlated with the suppression of CDW ordered state. We find the superfluid density in 2H-NbSe$_2$, 4H-NbSe$_2$, and 1T’-MoTe$_2$ to scale linearly with $T_c$, which indicates that this linear relation has general validity for transition metal dichalcogenide superconductors. Such relations are considered to be a hallmark feature of unconventional superconductivity $\text{[31, 35, 36]}$ in cuprate and iron-pnictides superconductors. Upon application of pressure on 2H-NbSe$_2$, the $n_s/m^*$ vs $T_c$ dependence shows the deviation from the above mentioned linear behaviour. We find this linear deviation to be very similar to the deviation observed for optimally doped cuprates. Our findings, therefore, pose a challenge for understanding the underlying quantum physics in these layered TMDs and might lead to a better understanding of generic aspects of non-BCS behaviors in unconventional superconductors.

In figure 1(b), we show the schematic phase diagram of the pressure dependence of the CDW transition temperature $T_{\text{CDW}}$ and the superconducting transition temperature $T_c$ for NbSe$_2$, according to reference $\text{[5]}$. The red arrows mark the pressures at which the $T$-dependence of the penetration depth and the superfluid density was measured. As it can be seen, the CDW transition is strongly reduced within the here investigated pressure range between $p = 0$ to 2.2 GPa. In figures 1(c) and (d), two representative the transverse-field (TF) $\mu$SR-time spectra for 2H-NbSe$_2$ at ambient pressure and at the maximum applied pressure of $p = 2.2$ GPa are shown. Both measurements were performed in the pressure cell. For both pressures, the transverse-field (TF) muon time spectra in a field of $\mu_0 H = 70$ mT are shown above ($T = 10$ K) and below ($T = 0.25$ K) the superconducting transition temperature $T_c$. Above $T_c$ the oscillations show a small relaxation due to the random local fields from the nuclear magnetic moments. Below $T_c$ the relaxation rate strongly increases with decreasing temperature due to the presence of a nonuniform local magnetic field distribution as a result of the formation of a flux-line lattice (FLL) in the Shubnikov phase.

From the obtained TF muon time spectra, we have derived the temperature dependence of the muon spin depolarization rate $\sigma_{\text{sc}}$, which is proportional to the second moment of the field distribution (see Method section). In figure 2 we show the temperature dependence of the muon spin depolarization rate $\sigma_{\text{sc}}$ of 4H-NbSe$_2$ at ambient pressure and of 2H-NbSe$_2$ at pressures of $p = 0, 0.4, 0.7, 1.4, \text{and} 2.2$ GPa. Below $T_c$ the relaxation rate $\sigma_{\text{sc}}$ starts to increase from zero with decreasing temperature due to the formation of the FLL. The critical temperatures for 2H-NbSe$_2$ and 4H-NbSe$_2$ are $T_c \sim 6$ K and 7 K, respectively. We find that the low-temperature value of $\sigma_{\text{sc}}$ between 2H-NbSe$_2$ and 4H-NbSe$_2$ increases as much as $T_c$. Upon application of pressure on 2H-NbSe$_2$, the superconducting transition temperature $T_c$ increases which is in good agreement with earlier reports $\text{[22, 23]}$. Furthermore, we observed a substantial increase of the low-temperature value of the muon spin depolarization rate $\sigma_{\text{sc}}$ with increasing pressure. This can be seen most clearly at base temperature, where the muon spin depolarization rate $\sigma_{\text{sc}}(T = 0.25 \text{ K})$ increases by almost $\sim 30\%$ from $p = 0$ GPa to $p = 2.2$ GPa. Interestingly, at all pressures the form of the temperature dependence of $\sigma_{\text{sc}}$, which reflects the topology of the SC gap, shows the saturation at low temperatures, indicating the presence of the isotropic pairing in NbSe$_2$ at all applied pressure.

The second moment of the resulting inhomogeneous field distribution is related to the magnetic penetration depth $\lambda$ as $\langle \Delta B^2 \rangle \propto \sigma_{\text{sc}}^2 \propto \lambda^{-4}$, whereas $\sigma_{\text{sc}}$ is the Gaussian relaxation rate due to the formation of FLL $\text{[37]}$. In order to investigate the symmetry of the superconducting gap, we have therefore derived the temperature-dependent London magnetic penetration depth $\lambda(T)$, which is related to the relaxation rate by:

$$\frac{\sigma_{\text{sc}}(T)}{\gamma_\mu} = 0.0691 \frac{\Phi_0}{\lambda^2(T)} \quad \text{(1)}$$

Here, $\gamma_\mu$ is the gyromagnetic ratio of the muon, and $\Phi_0$ is the magnetic-flux quantum. Thus, the flat $T$-dependence of $\sigma_{\text{sc}}$ observed at various pressures for low temperatures (see Fig. 2) is consistent with a nodeless superconductor, in which $\lambda^{-2}(T)$ reaches its zero-temperature value exponentially.

To proceed with a quantitative analysis, we consider the local (London) approximation ($\lambda \gg \xi$, where $\xi$ is the coherence length) and employ the empirical $\alpha$-model. The model, widely used in previous investigations of the penetration depth of multi-band superconductors $\text{[38–42]}$, assumes that the gaps occurring in different bands, besides a common $T_c$, are independent of each other. The superfluid density is calculated for each component separately $\text{[39]}$ and added together with a weighting factor.
FIG. 1: Schematic Phase Diagram and Transverse-field (TF) μSR time spectra for NbSe$_2$. (a) Crystal structure of 2H-NbSe$_2$. (b) Pressure dependence of $T_c$ and the CDW temperature $T_{CDW}$ (ref. [22]). The red arrows mark the pressures at which the $T$-dependence of the penetration depth was measured. The TF spectra, above and below $T_c$ at pressures of (c) $p = 0$ GPa and (d) $p = 2.2$ GPa are shown. The solid lines in panel (c) and (d) represent fits to the data by means of Eq. 4; The dashed lines are guides to the eyes.

For our purposes, a two-band model suffices, yielding:

$$\lambda^{-2}(T) = \omega_1 \lambda^{-2}(T, \Delta_{0,1}) + \omega_2 \lambda^{-2}(T, \Delta_{0,2})$$

Here $\lambda(0)$ is the London magnetic penetration depth at zero temperature, $\Delta_{0,i}$ is the value of the $i$-th SC gap ($i = 1, 2$) at $T = 0$ K, and $\omega_i$ is the weighting factor, which measures their relative contributions to $\lambda^{-2}$ (i.e. $\omega_1 + \omega_2 = 1$).

The results of this analysis are presented in Fig. 3a, where the temperature dependence of $\lambda^{-2}$ is plotted for 4H-NbSe$_2$ at ambient pressure and for 2H-NbSe$_2$ at pressures of $p = 0, 0.4, 0.7, 1.4,$ and $2.2$ GPa. The dashed and the solid lines for ambient pressure results represent fits for the temperature-dependent London magnetic penetration at ambient pressure using a $s$-wave and a $s + s$-wave model, respectively [30]. As it can be seen, the $s + s$-wave provides a much better description of the data, thereby ruling out a out the simple $s$-wave model as an adequate description of $\lambda^{-2}(T)$ for 2H-NbSe$_2$. The two gap $s + s$-wave scenario with a small gap $\Delta_1 \simeq 0.55(3)$ meV and a large gap $\Delta_2 \simeq 1.25(5)$ meV for $p = 0$ GPa (with the pressure independent weighting factor of $\omega_2 = 0.8(1)$), describes the experimental data remarkably well.

The presence of two isotopic gaps in 2H-NbSe$_2$ and their values are in very good agreement with previous results [13, 17]. According to ARPES data several independent electronic bands (four Nb-derived bands with roughly cylindrical Fermi surfaces, centered at the $\Gamma$ and $K$ points and one Se-derived bands with a small ellipsoid pocket around the $\Gamma$ point) cross the Fermi surface in 2H-NbSe$_2$, two-gap superconductivity can be understood by assuming that the SC gaps open at two distinct types of bands. We find that two gap $s + s$-wave superconductivity is preserved up to the highest applied pressure of $p = 2.2$ GPa. All the $s + s$-wave fits for all pressures are shown in figure 3(c). Furthermore, the pressure dependence of all the parameters extracted from the data analysis within the $\alpha$ model are plotted in Figs. 3(b,c). The critical temperature $T_c$ increases with pressure only by $\sim 0.7$ K at the maximum applied pressure of $p = 2.2$ GPa, as shown in Fig. 3b. We,
however, observe a substantial increase of the superfluid density $\lambda^{-2}$ with increasing pressures, as shown in figure 3(b). At the maximum applied pressure of $p = 2.2$ GPa the increase of $\lambda^{-2}$ is $\Delta \rho \approx 31.4(8)\%$ compared to the value at ambient pressure. The absolute size of the small gap $\Delta_1 \approx 0.5(3)\text{ meV}$ and the large gap $\Delta_2 \approx 1.25(5)\text{ meV}$ remains nearly unchanged by pressure, as shown in figure 3(c). The two gap $s + s$-wave scenario also describes the data for 4H-NbSe$_2$, which was not reported previously. The gap values for 4H-NbSe$_2$ are $\Delta_1 \approx 0.19(3)\text{ meV}$ and $\Delta_2 \approx 0.89(1)\text{ meV}$.

The London magnetic penetration depth $\lambda$ is given as a function of $n_s$, $m^*$, $\xi$ and the mean free path $l$, according to

$$\frac{1}{\lambda^2} = \frac{4\pi n_s e^2}{m^* c^2} \times \frac{1}{1 + \xi/l}.$$ (3)

For systems close to the clean limit, $\xi/l \to 0$, the second term essentially becomes unity, and the simple relation $1/\lambda^2 \propto n_s/m^*$ holds. Considering the upper critical fields $H_{c2}$ of 2H-NbSe$_2$, as reported in detail by Soto et al. [48], we can estimate the in-plane coherence length to be $\xi_{ab} \approx 7.9\text{ nm}$ at ambient pressure $p = 0$ GPa. At ambient pressure, the in-plane mean free path $l$ was estimated to be $l_{ab} \approx 183\text{ nm}$ [48]. No estimates are currently available for $l$ under pressure. However, the in-plane $l$ is most probably independent of pressure, considering the fact that the effect of compression is mostly interlayered, i.e., the intralayer Nb-Se bond length remains nearly unchanged (especially in the here investigated pressure region). [22]

This very small effect of compression can be attributed to the unique anisotropy resulting from the stacking of layers with van der Waals type interactions between them. Thus, in view of the short coherence length and relatively large $l$, we can reliably assume that 2H-NbSe$_2$ lies close to the clean limit [30, 39]. With this assumption, we obtain the ground-state value $n_s/(m^*/\sigma_e) \approx 5.7 \times 10^{27}\text{ m}^{-3}$, and $7.5 \times 10^{27}\text{ m}^{-3}$ for $p = 0$ GPa, and 2.2 GPa respectively.

The strong enhancement of the superfluid density $\lambda^{-2}(0) \propto n_s/(m^*/\sigma_e)$ in 2H-NbSe$_2$ under pressure, as discussed above, is an essential finding of this paper. It should be noted that the impairment of the charge-density wave ordering, and the associated lowering of the charge density wave ordering transition $T_{CDW}$ under pressure may cause the restoring of some electronic density of states at the Fermi surface. However, the electron and hole states that condense into the CDW ordered state comprise only $\approx 1\%$ of the total density of states at the Fermi surface. [22]. This implies that the gap values are insensitive to the suppression of the CDW state. This observation strongly supports the idea that superconducting and CDW orders are somewhat isolated from each other and that the CDW pairing have only a minimal effect on the superconductivity in 2H-NbSe$_2$.

Furthermore, we find the superfluid density in three transition metal dichalcogenide superconductors 2H-NbSe$_2$, 4H-NbSe$_2$ and 1T'-MoTe$_2$ to scale linearly with $T_c$, as shown in figure 1(a) and 4b, which is not expected within BCS theory. This means that the ratio between the superfluid density and the critical temperature $T_c$ in 2H-NbSe$_2$ and 4H-NbSe$_2$ is nearly the same as for the TMD superconductor 1T'-MoTe$_2$ [40], indicating a common mechanism and related electronic origin for the superconductivity. Remarkably, we observed that upon application of pressure on 2H-NbSe$_2$ the dependence between $n_s/m^*$ and $T_c$ deviates from the linear correlation, as shown in Fig. 4b. It is noteworthy that such a deviation was previously found in optimally doped cuprate and Fe-based superconductors under pressure. As an example, inset of Fig. 4b demonstrates the deviation from the Uemura line in the optimally doped La$_{2-x}$Ba$_x$CuO$_4$ ($x = 0.155$) under pressure. It is important to note that in case of 1T'-MoTe$_2$, the linear relation with the right slope holds even under pressure up to the highest investigated pressure of 1.3 GPa. But within this pressure range the maximum $T_c$ of 1T'-MoTe$_2$ is 2.7 K, which is far below from the optimal superconducting region, where $T_c$ is about 8 K. In case
of 2H-NbSe$_2$, the system has a $T_c = 7$ K already at ambient pressure which is still below but quite close to the optimal superconducting region of the phase diagram. Application of pressure pushes the system towards the optimal superconductivity and as can be seen from our data the pressure of 1.7 GPa is enough to reach the maximum $T_c \approx 8$ K in 2H-NbSe$_2$. Since historically the linear increase of $T_c$ with $n_s/(m^*/m_e)$ is observed only in the underdoped region of the phase diagram of unconventional superconductors, the deviation from the linear relationship for 2H-NbSe$_2$ under pressure can be explained by locating the system 2H-NbSe$_2$ within or close to the optimal superconducting region under pressure. The fact that TMDs, studied in this work, exhibit strikingly similar features in the relation between the superfluid density and the critical temperature to those reported in other unconventional superconductors implies that TMDs exhibit unconventional superconducting properties.

The linear relationship between $T_c$ and the superfluid density was originally observed in hole-doped cuprates [31, 35], where the ratio between $T_c$ and their effective Fermi temperature $T_F$ being about $T_c/T_F \sim 0.05$, which means about 4-5 times reduction of $T_c$ from the ideal Bose Condensation temperature for a non-interacting Bose gas. These results were discussed in terms of the crossover from Bose Condensation to BCS-like condensation [33, 54]. Within the picture of BEC to BCS crossover, systems exhibiting small $T_c/T_F$ (large $T_F$) are considered to be in the BCS-like side, while the linear relationship between $T_c$ and $T_F$ is expected only in the BEC-like side. This relationship has in the past been used for the characterization of BCS-like, so-called conventional and BEC-like, so-called unconventional superconductors. The here present results on 2H-NbSe$_2$ and 4H-NbSe$_2$ together with our previously reported results on 1T’-MoTe$_2$ demonstrate that a linear relation between $T_c$ and the superfluid density holds for these TMDs systems, which are in the clean limit. However, we find the ratio $T_c/T_F$ to be reduced further by a factor of $\sim 20$ from the ratio in hole doped cuprates.

In refs [54–56], one of the present authors pointed out that there seem to exist at least two factors which determine $T_c$ in unconventional superconductors: one is the superfluid density and the other is the closeness to the competing state. The second factor can be seen in the energy of the magnetic resonance mode, which represents the difference in free energy between the superconducting state and the competing magnetically ordered state. In the case of hole-doped cuprates, the competing state is characterized by antiferromagnetic order, but frustrated by the introduction of doped holes. In the case of electron-doped cuprates, the competing state develops in antiferromagnetic network diluted by the doped carriers. In the case of present TMDC systems, the competing state comes from charge density waves. These systematic difference of competing states might be related to the three different ratios of $T_c/T_F$ seen in the three different families of superconductors shown in Fig. 4.

In summary, we provide the first microscopic investigation of the superconductivity under hydrostatic pressure in the layered superconductors 2H-NbSe$_2$ and 4H-NbSe$_2$. Specifically, the zero-temperature magnetic penetration depth $\lambda_{eff}(0)$ and the temperature dependence of $\lambda_{eff}^2$ were studied by means of $\mu$SR experiments in 2H-NbSe$_2$ as a function of pressure up to $p \approx 2.2$ GPa and in 4H-NbSe$_2$ at ambient pressure. The superfluid densities in both samples and at all pressures are best described by a two gap $s + s$-wave scenario. Considering the current data on 2H-NbSe$_2$ and 4H-NbSe$_2$ at ambient pressure and our previous observations on 1T’-MoTe$_2$ [30] at ambient as well as at low pressures, we conclude that the superfluid density $n_s/m^* \propto 1/\lambda^2$ scale linearly with $T_c$ in the three transition metal dichalcogenide superconductors 1T’-MoTe$_2$, 2H-NbSe$_2$, and 4H-NbSe$_2$. We also find that the application of pressure on 2H-NbSe$_2$ causes

![FIG. 3: Pressure evolution of various quantities. (a) The temperature dependence of $\lambda^2$ measured at ambient pressure for 4H-NbSe$_2$ and at various applied hydrostatic pressures for 2H-NbSe$_2$. The solid lines correspond to a two-gap $(s + s)$-wave model, the dashed line represent a fit using a single gap $s$-wave model. (b) Pressure dependence of $T_c$ and the zero-temperature value of $\lambda^{-2}(0)$. (c) Pressure dependence of the zero-temperature values of the small superconducting gap $\Delta_1$ and the large superconducting gap $\Delta_2$.](image-url)
Thus show excellent linear scaling between \( n_s/m^* \) and \( T_c \). While 2H-NbSe\(_2\) is pushed into the optimal SC region by pressure, causing the deviation from the Uemura relation between \( n_s/m^* \) and \( T_c \), same as observed for cuprates. Our results demonstrate that a linear relation holds for the above studied transition metal dichalcogenide superconductors, located below the optimal superconducting region of the phase diagram. A ratio \( T_c/T_F \) for TMDs is reduced by a factor of 20 from the ratio in hole doped cuprates. This implies that the superfluid density of TMDs is about an order of magnitude higher than that in the cuprates with respect to their critical temperatures \( T_c \). The fact that TMDs exhibit strikingly similar features in the relation between the superfluid density and the critical temperature to those reported in other unconventional superconductor implies that TMDs exhibit rather unconventional superconducting properties. We also find that the values of the superconducting gaps are insensitive to the suppression of the CDW ordered state, indicating that CDW pairing has only a minimal effect on the superconductivity in 2H-NbSe\(_2\). These results hint towards a common mechanism and electronic origin for superconductivity in TMDs, which might have far reaching consequences for the future development of devices based on these materials.

I. METHODS

Sample preparation: Single-phase polycrystalline samples of 2H-NbSe\(_2\) and 4H-NbSe\(_2\) were prepared by means of high-temperature solid-state synthesis. Stoichiometric amounts of niobium powder (99.99 %) and selenium shots (99.999 %) were mixed (for 4H-NbSe\(_2\) an excess of Selenium was used) and heated in a sealed quartz tube, under an inert atmosphere, at 750 °C (2H-NbSe\(_2\)) and at 900 °C (4H-NbSe\(_2\)) for 3 days.

Pressure cell: A double wall piston-cylinder type of cell made of CuBe material together with Daphne oil was used to generate hydrostatic pressures up to 2.2 GPa \([59–63]\). The small indium plate was placed at the bottom of the sample space. By tracking the superconducting critical temperature of indium using AC susceptibility, we estimated the applied pressure. The fraction of the muons stopping in the sample was \( \sim 40 \% \).

\( \mu \)SR experiment: Positively charged muons \( \mu^+ \) with nearly 100 % spin-polarization act as extremely sensitive magnetic microprobes in a material. We implant these elementary particles into the sample and probe the field distribution in the vortex lattice of a type II superconductor. Such measurements are carried out in a field applied perpendicular to the initial muon spin polarization (so called TF configuration) \([64]\). From these experiments, important length scales of superconductors can be measured, namely the magnetic penetration depth \( \lambda \), its temperature dependence and

![FIG. 4: Superfluid Density versus \( T_c \).](image-url)

(a) Logarithmic plot of \( \lambda_{\text{eff}}^{-2}(0) \) obtained from our \( \mu \)SR experiments in 2H-NbSe\(_2\), 4H-NbSe\(_2\), and MoTe\(_2\). The dashed red line represents the linear fit to the MoTe\(_2\) data. Uemura relation for hole and electron-doped cuprates are shown as solid and dashed lines, respectively. The points for various conventional BCS superconductors are also shown. (b) Linear plot of \( T_c \) against the \( \lambda_{\text{eff}}^{-2}(0) \). Inset shows the \( T_c \) against the \( \lambda_{\text{eff}}^{-2}(0) \) as a function of pressure for optimally doped cuprate superconductor \( \text{La}_2-x\text{Ba}_x\text{CuO}_4 \) \([58]\).
the coherence length $\xi$.

$\mu$SR experiments under pressure were performed at the $\mu$E1 beamline of the Paul Scherrer Institute (Villigen, Switzerland, where an intense high-energy ($p_{\mu} = 100$ MeV/$c$) beam of muons is implanted in the sample through the pressure cell. The low background Dolly instrument was used to study the polycrystalline samples of 2H-NbSe$_2$ and 4H-NbSe$_2$ at ambient pressure.

**Analysis of TF-$\mu$SR data:**

The following function is used to analyze the TF $\mu$SR data:  

$$P(t) = A_s \exp \left[ -\frac{(\sigma_{sc}^2 + \sigma_{nm}^2)t^2}{2} \right] \cos(\gamma_t B_{int},t + \varphi) + A_{pc} \exp \left[ -\frac{\sigma_{pc}^2 t^2}{2} \right] \cos(\gamma_t B_{int,pc} + \varphi),$$  

(4)

Here $A_s$ and $A_{pc}$ denote the initial asymmetries of the sample and the pressure cell, respectively. $\gamma/(2\pi) \approx 335.5$ MHz/T is the muon gyromagnetic ratio and $\varphi$ denotes the initial phase of the muon-spin ensemble. $B_{int}$ represents the internal magnetic field, sensed by the muons. $\sigma_{sc}$ is the relaxation rate, caused by the nuclear magnetic moments. The value of $\sigma_{nm}$ was obtained above $T_c$ and was kept constant over the entire temperature range. The relaxation rate $\sigma_{pc}$ characterize the damping due to the formation of the FLL in the SC state. $\sigma_{pc}$ reflects the depolarization due to the nuclear moments of the pressure cell. The width of the pressure cell signal exhibits the temperature dependence below $T_c$ due to the influence of the diamagnetic moment of the SC sample on the pressure cell [61]. The linear coupling between $\sigma_{pc}$ and the field shift of the internal magnetic field in the SC state was assumed to consider the temperature dependent $\sigma_{pc}$ below $T_c$:

$$\sigma_{pc}(T) = \sigma_{pc}(T > T_c) + C(T)(\mu_0 H_{int,NS} - \mu_0 H_{int,SC}),$$

where $\sigma_{pc}(T > T_c) = 0.25 \text{ } \mu s^{-1}$ is the temperature independent Gaussian relaxation rate. $\mu_0 H_{int,NS}$ and $\mu_0 H_{int,SC}$ are the internal magnetic fields measured in the normal and in the SC state, respectively. As demonstrated by the solid lines in Figs. 2b,c the $\mu$SR data are well described by Eq. (4).

**Analysis of $\lambda(T)$:**

$\lambda(T)$ was calculated considering the London approximation ($\lambda \gg \xi$) using the following function $[39][40]$:

$$\lambda^{-2}(T,\Delta_{0,i}) = 1 + \frac{1}{\pi} \int_0^{2\pi} \int_0^{\infty} \frac{EdEd\varphi}{\sqrt{E^2 - E_t^2}}$$

where $f = [1 + \exp(E/k_B T)]^{-1}$ represents the Fermi function, $\varphi$ is the angle along the Fermi surface, and $\Delta_i(T,\varphi) = \Delta_{0,i} \Gamma(T/T_c)g(\varphi)$ ($\Delta_{0,i}$ is the maximum gap value at $T = 0$). The temperature dependence of the gap is given by the expression $\Gamma(T/T_c) = \tanh \{1.82(1.018(T_c/T_c - 1))^{0.51}\}$ whereas $g(\varphi)$ takes care of the angular dependence of the superconducting gap. Namely, $g(\varphi) = 1$ for both an $s$-wave and an $s$+$s$-wave gap, and $[\cos(2\varphi)]$ for a $d$-wave gap.

**II. ACKNOWLEDGMENTS**

The $\mu$SR experiments were carried out at the Swiss Muon Source (S$\mu$S) Paul Scherrer Institute, Villigen, Switzerland. Z. Guguchia gratefully acknowledges the financial support by the Swiss National Science Foundation (SNF fellowship P300P2-177832). The work at the University of Zurich was supported by the Swiss National Science Foundation under Grant No. PZ00P2_174015. Work at Department of Physics of Columbia University is supported by US NSF DMR-1436095 (DMREF) and NSF DMR-1610633. M.Z.H. is supported by US DOE/BES grant no. DE-FG-02-05ER46200. R.K. acknowledges the Swiss National Science Foundation (grants 200021_149486 and 200021_175935). A.N. acknowledges funding from the European Union’s Horizon 2020 research and innovation programme under the Marie Sklodowska-Curie grant agreement No 701647.

conducting $\text{Ir}_{1-x} (\text{Pt}, \text{Rh})_{x} \text{Te}_2$. Phys. Rev. B 97, 174515 (2018).

[40] The fitting of the $T$-dependence of the penetration depth with $a$ model was performed using the additional library BMW developed by B.M. Wojtek.
