In this paper we introduce an exactly solvable Kondo lattice model without any fine-tuning local gauge symmetry. This model describes itinerant electrons interplaying with localized moment via only longitude Kondo exchange. Its solvability results from conservation of the localized moment at each site, and it is valid for arbitrary lattice geometry and electron filling. A case study on square lattice shows that the ground state is a Néel antiferromagnetic insulator at half-filling. At finite temperature, paramagnetic phases including Mott insulator and correlated metal are found. The former is a melting antiferromagnetic insulator with strong short-range magnetic fluctuation, while the latter corresponds to a Fermi liquid-like metal. Numerical Monte Carlo simulation and field theoretical analysis confirm that the transition from paramagnetic phases into the antiferromagnetic insulator is a continuous 2D Ising transition. Away from half-filling, patterns of spin stripes (inhomogeneous magnetic order) at weak coupling, and phase separation at strong coupling are predicted. The spin stripe found here may be relevant to novel quantum liquid-crystal order in hidden order compound URu2Si2.

Introduction.– Exactly solvable quantum many-body models play a fundamental role in understanding exotic quantum states in condensed matter physics[1]. In spatial dimension $d > 1$, Kitaev’s toric-code, honeycomb model and certain $Z_2$ lattice gauge field models are prototypical examples [2–5], which shows novel quantum orders like Majorana quantum spin liquid, orthogonal metal, fractionalized Chern insulator, fracton order, Majorana superconductor and many-body localized state [3, 6–12]. Their solvability is due to existence of an infinite number of conserved quantities (for infinite lattice), resulting from intrinsic or emergent local $Z_2$ gauge symmetry. However, because of the designed local gauge symmetry, these models are far from standard ones in condensed matter physics like Hubbard and Kondo lattice models [13, 14]. Thus, it is highly desirable to find out solvable models without any fine-tuning local gauge structure.

In this paper, we introduce an exactly solvable model in any local gauge structure. It is a Kondo lattice model in its anisotropic limit, (also called Ising-Kondo lattice model) which describes itinerant electron interplaying with localized $f$-electron moment via only longitude Kondo exchange [15].

\[
\hat{H} = \sum_{i,j,\sigma} t_{ij} \hat{c}_{i\sigma}^\dagger \hat{c}_{j\sigma} + \frac{J}{2} \sum_{j,\sigma} \hat{S}_{j+\hat{y}}^z \hat{c}_{j+\hat{y}\sigma}^\dagger \hat{c}_{j\sigma}
\]  

(1)

$\hat{c}_{j\sigma}$ is the creation operator of conduction electron while $\hat{S}_{j+\hat{y}}^z$ denotes localized moment of $f$-electron at site $j$. $t_{ij}$ is hopping integral between $i, j$ sites and $J$ is the longitude Kondo coupling, which is usually antiferromagnetic, i.e. $J > 0$. Chemical potential $\mu$ can be added to fix conduction electron’s density.

In literature, this model (with $x$-axis anisotropy) is proposed to account for the anomalously small staggered magnetization and large specific heat jump at hidden order transition in URu2Si2 [15, 16]. It can explain the easy-axis magnetic order and paramagnetic metal or bad metal behaviors in the global phase diagram of heavy fermion compounds [17–20], as well as the emergent Kondo lattice behavior in iron-based and cuprate high-$T_c$ superconductor [21, 22].

Importantly, in Eq. 1, we observe that $f$-electron’s spin/localized moment at each site is conservative since \[\hat{S}_{j}^z, \hat{H} = 0\]. Therefore, when choosing eigenstate of spin $\hat{S}_{j}^z$ as basis, the Hamiltonian is automatically reduced to an effective free fermion model

\[
\hat{H}(q) = \sum_{i,j,\sigma} t_{ij} \hat{c}_{i\sigma}^\dagger \hat{c}_{j\sigma} + \sum_{j,\sigma} \frac{J_{\sigma}}{4} \hat{q}_{\sigma}^j \hat{c}_{j\sigma}^\dagger \hat{c}_{j\sigma}
\]  

(2)

with $q$ emphasizing its $q$ dependence and \[\hat{S}_{j}^z | q_j \rangle = q_j | q_j \rangle, q_j = \pm 1\]. Now, the many-body eigenstate of original model Eq. 1 can be constructed via single-particle state of effective Hamiltonian Eq. 2 under given configuration of effective Ising spin \{ $q_j \}$ . So, Eq. 1 is exactly solvable and can be considered as an effective spin-full Falicov-Kimball (FK) model [23]. Because the procedure of reduction to free fermion model only involving local conservation, the above model is solvable for arbitrary lattice geometry and electron filling, in contrast to isotropic Kondo lattice model [24], where notorious fermion minus-sign problem prevents exact solution/simulation. Including the effect of $z$-axis external magnetic field does not change the solvability.

To illustrate, we consider in this paper a system on square lattice with nearest-neighbor-hopping $-t$. (See also Fig. 1(a)) In terms of analytical arguments and numerically exact lattice Monte Carlo (LMC) simulation[25], we have determined its ground state and its finite temperature phase diagram at half-filling in Fig. 1(b). There exist antiferromagnetic insulator (AI), Mott insulator (MI) and correlated metal (CM). Both AI
and MI have gapful single-particle excitations but CM are gapless metallic state. The transition from AI to CM or MI is a continuous Ising transition. There only exists smooth crossover between CM and MI with the opening of a gap at Fermi energy.

and MI have gapful single-particle excitations but CM are gapless metallic state. The transition from AI to CM or MI is a continuous Ising transition, and a smooth crossover appears between CM and MI with the opening of gap at Fermi energy. The nature of these phases and transitions will be explored in the main text. For other bipartite lattice like honeycomb lattice, its phase diagram is similar to Fig. 1(b) with Dirac semimetal replacing CM. When doping away from half-filling, we have established that various patterns of spin stripes occur at weak coupling and phase separation ultimately dominates at strong coupling. The spin stripe found here may be relevant to electronic liquid crystal phenomena in hidden order compound URu$_2$Si$_2$.[26]

Ground state.— At zero temperature, when our system is half-filled ($\mu = 0$) and on a bipartite lattice (here square lattice), the ground-state configuration of $q_j$ has the two-fold degenerated checkerboard order $q_j = \pm (-1)^j$, according to the theorem proved by Kennedy and Lieb[27]. This can be seen as the Ising antiferromagnetic long-ranged order for localized $f$-electron. For conduction electrons, the single-particle Hamiltonian in the ground state is thus

$$\hat{H} = -t \sum_{<ij>,\sigma} \hat{c}_{i\sigma}^\dagger \hat{c}_{j\sigma} + \sum_{j\sigma} (-1)^j \frac{J\sigma}{4} \hat{c}_{j\sigma}^\dagger \hat{c}_{j\sigma}$$

$$+ \sum_{k\sigma} \left( \hat{c}_{k\sigma} \hat{c}_{k+Q,\sigma} \right) \left( \frac{\varepsilon_k}{4} - \frac{J_{\sigma}}{4} \right) \left( \hat{c}_{k\sigma} + \hat{c}_{k+Q,\sigma} \right)$$

which is just the familiar antiferromagnetic spin-density-wave (SDW) mean-field Hamiltonian with characteristic wavevector $\vec{Q} = (\pi, \pi)$ in Hubbard-like models[28]. But, we have to emphasize that this one is the exact ground state fermion Hamiltonian for $J > 0$. Its quasiparticle dispersion is found to be $E_{k\sigma} = \pm \sqrt{\varepsilon_k^2 + J^2/16}$, which splits the single free conduction electron band into two Hubbard-like bands with direct band gap $\Delta = J/2$.

FIG. 1. (a) The Kondo lattice model in anisotropic limit (Eq. 1) and (b) its finite temperature phase diagram on square lattice from LMC. There exist antiferromagnetic insulator (AI), Mott insulator (MI) and correlated metal (CM). Both AI and MI has single-particle excitation gap but CM are gapless metallic state. The transition from AI to CM or MI is a continuous Ising transition. There only exists smooth crossover between CM and MI with the opening of a gap at Fermi energy.

\[ \varepsilon_k = -2t(\cos k_x + \cos k_y) \] is free conduction electron dispersion.) We conclude that the ground state of half-filled model on the square lattice is an insulating antiferromagnetic state with Néel-like spin order.

Finite-T phase diagram.— At finite temperature, one has to sum over all configurations of effective Ising spin \(\{q_j\}\), which can only be performed via Monte Carlo simulation. (See supplementary materials (SM) for details.) We consider periodic $N_x = L \times L$ lattices with $L$ up to 16. The resulting phase diagram is shown in Fig. 1(b). Here, AI is stable at low-$T$ since discrete Ising symmetry is able to break spontaneously in 2D at finite-$T$, and has a thermodynamic transition into CM in weak coupling or MI in strong coupling. The existence of AI is inferred by its checkerboard order parameter $\phi_c = \frac{1}{N_L^2} \sum_j (-1)^j \langle q_j \rangle$ and SDW structure factor $C_{SDW} = \frac{1}{N_L^2} \sum_{j,k} (-1)^{j+k} \langle \hat{S}_j^z \hat{S}_k^z \rangle$.

\[ \langle \hat{S}_j^z \rangle = \frac{1}{2} (\langle \hat{c}_{j\uparrow}^\dagger \hat{c}_{j\uparrow} - \langle \hat{c}_{j\downarrow}^\dagger \hat{c}_{j\downarrow} \rangle) \] In Fig. 2, both $\phi_c$ and $C_{SDW}$ saturate at low-$T$, which suggests the existence of AI. At high-$T$, $C_{SDW}$ approaches zero and signals a transition to paramagnetic phases. This agrees with the divergence of specific heat $C_v = \frac{\langle H^2 \rangle - \langle H \rangle^2}{N T^2}$ and susceptibility $\chi_q = \frac{\langle \hat{S}_j^z \rangle^2}{T} = \langle S_q \rangle^2 = \frac{1}{N_L^2} \sum_{j,k} (-1)^{j+k} \langle q_j q_k \rangle$ at critical temperature $T_c$. We note that the maximal $T_c$ appears when Kondo coupling is comparable to the band-width of conduction electrons. ($J/t \sim 8$) The qualitative physics in AI can be understood by SDW mean-field theory, but such mean-field approximation underestimates thermal fluctuation and leads to unrealistic $T_c$. This suggests that quantitative predictions from simple SDW mean-field theory cannot be trusted. (See SM for details.)

Mott insulator and correlated metal.—In the high-$T$
paramagnetic regime, based on the behavior of density of state (DOS) \( N(\omega) \) for conduction electrons, magnetization under external magnetic field and conduction electrons’ distribution function \( n_c(k) \), there exist MI and CM. (Fig. 3 and 4)

MI appears at strong coupling and is a melting AI/SDW without long-ranged order but with (fluctuated) short-ranged order. Such short-ranged order gives rise to single-particle gap observed in DOS. (Fig. 3(b)) Intuitively, conduction electrons mediate an antiferromagnetic Ising coupling \( \sim \frac{J}{t^2} \) between localized moments. At strong coupling, only temperature itself prevents the formation of long-ranged magnetic order, but short-ranged order survives. Thus, in short-time regime, conduction electrons feel the short-ranged order just as a true long-ranged order, and an excitation gap appears due to the effective molecular field applied to conduction electrons. It is important to note that the short-ranged order has classical Ising feature, thus it does not involve the resonance-valence-bond physics. So, MI here is irrelevant to quantum spin liquids but more like the featureless MI in Bose-Hubbard or FK models[29–31]. (We have checked that MI has very weak \( T \)-dependence on DOS, contrasting with radical reconstruction around coherent temperature in usual Kondo insulator[32].)

The spectral/single-particle feature of MI can be qualitatively captured by Hubbard-I approximation[13], where two Hubbard-like bands are observed and its DOS is similar to LMC’s results. (See SM for details.) In Hubbard-I approximation, the single-electron Green’s function is

\[
G_\sigma(k, \omega) = \frac{1}{\omega - \mu^\sigma_{\text{loc}} - \varepsilon_k} = \frac{\alpha^2_k}{\omega - \varepsilon_k^\pm} + \frac{1}{\omega - \varepsilon_k^\pm}.
\]

Here, the coherent factor \( \alpha^2_k = \frac{1}{2} \left( 1 + \sqrt{\varepsilon_k^2 + J^2} \right) \) and quasiparticle dispersion is \( \tilde{E}^\pm_k = \frac{1}{2} \left( \varepsilon_k \pm \sqrt{\varepsilon_k^2 + J^2} \right) \). Although no antiferromagnetic order exists in MI, the strong local electron correlation (due to Kondo coupling) splits the band and drives the system into correlated MI. Since MI has a single-particle gap, its thermodynamics and transport properties are insulating and show exponential-\( T \) behavior, \( (C_v \sim \text{finite}) \) and both MI and AI have a spin gap. A strong first-order transition from AI to fully polarized state appears, indicating the absence of field-induced magnetic quantum phase transition. (d) The conduction electrons’ distribution function \( n_c(k) \) along \((0,0)\) to \((\pi, \pi)\) direction. (\(T/t=0.4\))
trons’ distribution function \( n_c(k) = \langle c^\dagger_k \sigma c_k \rangle \). (Fig. 4(d)) In CM, there is a clear jump in \( n_c(k) \) around (underlying) Fermi surface \( k = (\pi/2, \pi/2) \) while only smooth evolution exists in MI.

There is a smooth crossover between CM and MI as inspecting the evolution of energy density \( E = \frac{1}{N} \langle \tilde{H} \rangle \) and double occupation \( d_c = \frac{1}{N} \sum_j \langle c^\dagger_j c_j \rangle \) versus \( J \), where \( E \) and \( d_c \) have nearly linear dependence on \( J \) and no singularity has been observed. (Fig. 5) The transition from MI and CM to AI is continuous as seen from order-parameter \( \phi \) shows one peak structure around \( T \) where \( \phi \) has nearly linear dependence on \( T \) and correlation length critical exponent \( \nu \). This explains why at finite-\( T \) there is first-order transition between metallic states and MI in Hubbard-like models while in our case, only a smooth crossover between metallic states and MI in Hubbard-like models while in our case, only a smooth crossover may be still possible. Assuming a continuous phase transition, the finite-size scaling analysis of checkerboard order parameter \( \phi \) in Fig. 6 suggests that critical behavior of our model belongs to 2D Ising universality class with critical exponent \( \beta = 1/8 \) and correlation length critical exponent \( \nu = 1 \).

**Effective field theory analysis.** In terms of path integral formalism, we have the following action

\[
S = \int d\tau \left[ \sum_{(i,j),\sigma} \bar{c}_{i\sigma}(\partial_\tau \delta_{ij} - t) c_{j\sigma} + \sum_{j,\sigma} \phi_j \bar{c}_{j\sigma} c_{j\sigma} + i\lambda_j (\phi_j^2 - 1) \right]
\]

where \( \bar{c}_{i\sigma}, c_{j\sigma} \) are Grassmann field for conduction electrons, \( \phi_j \) denotes localized moment and \( \lambda_j \) is (dynamic) Lagrangian multiplier. Since above \( T_c \), the localized moment is disordered, it is reasonable to assume \( i\lambda_j = m^2 \) with \( m \) being mass of \( \phi_j \). This is equivalent to the saddle point approximation for constraint \( \phi_j^2 = 1 \). Then, integrating over \( \phi_j \), the action only including conduction electrons reads

\[
S = \int d\tau \sum_{(i,j),\sigma} \bar{c}_{i\sigma}(\partial_\tau \delta_{ij} - t) c_{j\sigma} - \int d\tau \frac{J^2}{16m^2} \sum_{\sigma,\sigma'} \sigma \bar{c}_{j\sigma} c_{j\sigma} \sigma' \bar{c}_{j'\sigma'} c_{j'\sigma'}
\]

Return to Hamiltonian formalism, such action gives rise to a symmetric Hubbard model with effective Hubbard interaction \( U_{eff} = J^2/8m^2 \). Therefore, it seems that the high-\( T \) paramagnetic states could be related to solutions of half-filled symmetric Hubbard model. However, such relation is not strict due to the saddle point approximation. This explains why at finite-\( T \) there is first-order transition between metallic states and MI in Hubbard-like models while in our case, only a smooth crossover appears[33]. Moreover, when approaching \( T_c \), fluctuation effect cannot be neglected, thus it is not reliable to treat our system as an antiferromagnetic Heisenberg model as if \( U_{eff} \rightarrow \infty \) for \( m^2 \rightarrow 0 \).

Alternatively, if we integrate out conduction electrons and set \( \phi_j = (-1)^j \phi_j \) to emphasize the dominating antiferromagnetic correlation, the resulting effective theory is the celebrated Hertz-Millis-Moriya theory with \( \phi \) being antiferromagnetic Ising order parameter field[34–36]. Because of the nesting of Fermi surface on square lattice, antiferromagnetic quantum criticality is avoided and only thermal critical behaviors preserve, (Landau damping due to particle-hole excitation of conduction electrons is subleading and can be neglected away from quantum critical regime) thus the effective theory is replaced by the classic \( \phi^4 \) theory and it corresponds to 2D Ising universality class. This agrees with our LMC simulation.

**Doping away from half-filling.**– Doping the half-filled system leads to inhomogeneous magnetic order or spin
stripe order, as seen in Fig. 7. Here, the ground state configuration of localized $f$-electron moment versus chemical potential $\mu$ is shown, and various patterns of spin stripes occur to minimize the free energy. Conduction electrons have similar spin stripe structure but with opposite direction and small amplitude. When Kondo coupling $J$ is too large compared with band-width of conduction electrons, phase separation ultimately dominates\cite{37}. (See SM for details of phase separation.) These findings are qualitatively consistent with spiral/stripe magnetic phases in isotropic Kondo lattice model\cite{38,39}.

**Conclusion.**—In conclusion, we have provided a solvable lattice fermion Hamiltonian without any local gauge symmetry. Its solvability is due to the conserved localized moment at each lattice site. The case study on square lattice has a Néel antiferromagnetic insulator as its ground state at half-filling. At finite temperature, a 2D Ising-like magnetic-paramagnetic transition into correlated metallic state and Mott insulator is established. The former is a gapless metal with Pauli-like susceptibility under applied magnetic field. The latter is a melting antiferromagnetic insulator with both spin and single-particle gap. In terms of effective field theory, paramagnetic states has been related to counterparts in Hubbard-like models but only smooth crossover, instead of first-order transition, appears in our model. We have also established the existence of spin stripes in this solvable heavy fermion model when doping away from half-filling. Those spin stripe orders may be relevant to novel electronic quantum liquid crystal order in hidden order compound URu$_2$Si$_2$. If frustration is introduced\cite{25}, exotic metallic phase like orthogonal metal can be explored\cite{6,40}. Topological states of matter like topological SDW is also an interesting issue when spin-orbit coupling is added\cite{41}. These will be left for our future work.

**ACKNOWLEDGMENTS**

Y Zhong proposed the project and carried out the calculation. We thank Hantao Lu, Yuehua Su and Yu Liu for helpful discussion on the phase diagram and nature of each phase. Details of Lattice Monte Carlo simulation

When exploring the finite temperature properties, one has to sum over all configurations of effective Ising spin \( \{q_j\} \), which can only be performed via Monte Carlo simulation[25].

Monte Carlo simulation

Firstly, we know that the equilibrium state thermodynamics is controlled by the partition function

\[
\mathcal{Z} = \text{Tr} e^{-\beta \hat{H}} = \text{Tr} e^{-\beta \hat{H}} = \sum_{\{q_j\}} \text{Tr} e^{-\beta \hat{H}(q)}
\]

where \( \hat{H}(q) \) is just Eq. 2 with \( q \) emphasizing its \( q \) dependence.

Here, the trace is split into c-fermion and \( \hat{S}^z \), where the latter is transformed into the summation over all possible configuration \( \{q_j\} \). For each single-particle Hamiltonian \( \hat{H}(q) \), it can be easily diagonalized into

\[
\hat{H}(q) = \sum_n E_n \hat{d}_n^\dagger \hat{d}_n
\]

where \( E_n \) is the single-particle energy level and \( \hat{d}_n \) is the quasi-particle. The fermion \( \hat{d}_n \) is related into \( \hat{c}_j \) via

\[
\hat{c}_j = |0\rangle \langle j| = \sum_n |0\rangle \langle j| n \rangle = \sum_n \langle j| n \rangle = \sum_n \hat{d}_n \phi_n^j.
\]

Now, the trace over c-fermion can be obtained as

\[
\text{Tr} e^{-\beta \hat{H}(q)} = \sum_n \langle n \rangle e^{-\beta \sum_m E_m \hat{d}_m^\dagger \hat{d}_m} |n\rangle = \prod_m \sum_n \langle n \rangle e^{-\beta E_m \hat{d}_m^\dagger \hat{d}_m} |n\rangle
\]

\[
= \prod_m \sum_n \sum_{n_m=0,1} \delta_{n,m}(1 + e^{-\beta E_m})
\]

\[
= \prod_m (1 + e^{-\beta E_m}).
\]

This is the familiar result for free fermion, however one should keep in mind that \( E_n \) actually depends on the effective Ising spin configuration \( \{q_j\} \), thus we write \( E_n(q) \) to emphasize this fact.

So, the partition function reads

\[
\mathcal{Z} = \prod_{\{q_j\}} \sum_n (1 + e^{-\beta E_n(q)}) = \sum_{\{q_j\}} e^{-\beta F(q)}
\]

where we have defined an effective free energy

\[
F(q) = -T \sum_n \ln(1 + e^{-\beta E_n(q)}).
\]

In this situation, we can explain \( e^{-\beta F(q)} \) or \( \rho(q) = \frac{1}{Z} e^{-\beta F(q)} \) as an effective Boltzmann weight for each configuration of \( \{q_j\} \) and this can be used to perform Monte Carlo simulation just like the classic Ising model. Specifically, we start with random or chosen configuration of \( \{q_j\} \), then try to flip each \( q_j \) to \( -q_j \). The relative probability for such flip is determined by effective Boltzmann weight

\[
r = \frac{e^{-\beta F_{\text{new}}(q)}}{e^{-\beta F_{\text{old}}(q)}} = e^{-\beta(F_{\text{new}}(q)-F_{\text{old}}(q))}
\]

where \( F_{\text{old}}(q), F_{\text{new}}(q) \) denotes the effective free energy before and after flip. This is the weight used in the classic Metropolis importance sampling. Alternatively, one can use the so-called bath algorithm, which means

\[
r = \frac{r}{1 + r}
\]

such that the probability is seemingly normalized. Then, we generate a random number \( a \) from uniform distribution \([0, 1]\) and compare this with \( r \). If \( r > a \), the flip of \( q_j \) is accepted and \( F_{\text{old}} \) is updated into \( F_{\text{new}} \), otherwise we reset \( q_j \) to its original value before the flip. By trying to flip \( q_j \) over all sites, this is called a sweep and doing such sweep many times, the system can be equilibrium and the next sweeps are used to calculate physical observable.
To calculate physical quantities, we consider generic operator $\hat{O}$, which can be split into part with only Ising spin $\{q_j\}$ and another part with fermions, 

$$\hat{O} = \hat{O}^c + \hat{O}^q.$$ 

Then, its expectation value in the equilibrium ensemble reads 

$$\langle \hat{O} \rangle = \langle \hat{O}^c \rangle + \langle \hat{O}^q \rangle = \frac{\text{Tr}\hat{O}^c e^{-\beta \hat{H}}}{\text{Tr}e^{-\beta \hat{H}}} + \frac{\text{Tr}\hat{O}^q e^{-\beta \hat{H}}}{\text{Tr}e^{-\beta \hat{H}}}$$

For $\hat{O}^q$, we have 

$$\langle \hat{O}^q \rangle = \frac{\sum_{\{q_j\}} \hat{O}^q(q) e^{\beta \sum_j q_j \text{Tr}_x e^{-\beta \hat{H}(q)}}}{\sum_{\{q_j\}} e^{-\beta F(q)}} = \frac{\sum_{\{q_j\}} \hat{O}^q(q) e^{-\beta F(q)}}{\sum_{\{q_j\}} e^{-\beta F(q)}} = \sum_{\{q_j\}} \hat{O}^q(q) \rho(q).$$

In the Metropolis importance sampling algorithm, the above equation means we can use the simple average to estimate the expectation value like 

$$\langle \hat{O}^q \rangle \approx \frac{1}{N_m} \sum_{\{q_j\}} \hat{O}^q(q)$$ \hspace{1cm} (6) 

where $N_m$ is the number of sampling and the sum is over each configuration. $\hat{O}^q(q)$ is a number since we always work on the basis of $\{q_j\}$.

For $\hat{O}^c$, 

$$\langle \hat{O}^c \rangle = \frac{\sum_{\{q_j\}} e^{\beta \sum_j q_j \text{Tr}_x \hat{O}^c(q) e^{-\beta \hat{H}(q)}}}{\sum_{\{q_j\}} e^{-\beta F(q)}} = \sum_{\{q_j\}} \text{Tr}_x \hat{O}^c(q) e^{-\beta \hat{H}(q)} \sum_{\{q_j\}} e^{-\beta F(q)}$$

and we can insert $\frac{e^{-\beta F(q)}}{e^{-\beta F(q)}}$ in the numerator, which leads to 

$$\langle \hat{O}^c \rangle = \sum_{\{q_j\}} \frac{\text{Tr}_x \hat{O}^c(q) e^{-\beta \hat{H}(q)}}{\text{Tr}_x e^{-\beta \hat{H}(q)}} \frac{e^{-\beta F(q)}}{e^{-\beta F(q)}} = \sum_{\{q_j\}} \frac{\text{Tr}_x \hat{O}^c(q) e^{-\beta \hat{H}(q)}}{\text{Tr}_x e^{-\beta \hat{H}(q)}} \rho(q) = \sum_{\{q_j\}} \langle \langle \hat{O}^c(q) \rangle \rangle \rho(q).$$

This means 

$$\langle \hat{O}^c \rangle \approx \frac{1}{N_m} \sum_{\{q_j\}} \langle \langle \hat{O}^c(q) \rangle \rangle,$$ \hspace{1cm} (7) 

where $\langle \langle \hat{O}^c(q) \rangle \rangle = \frac{\text{Tr}_x \hat{O}^c(q) e^{-\beta \hat{H}(q)}}{\text{Tr}_x e^{-\beta \hat{H}(q)}}$ is calculated based on the Hamiltonian $\hat{H}(q)$. More practically, such statement means if fermions are involved, one can just calculate with $\hat{H}(q)$. Then, average over all sampled configuration gives rise to the wanted results.

The total energy of our system is an essential quantity and can be calculated as 

$$\langle \hat{H} \rangle \approx \frac{1}{N_m} \sum_{\{q_j\}} \left[ \langle \langle \hat{H}(q) \rangle \rangle \right]$$

$$= \frac{1}{N_m} \sum_{\{q_j\}} \left[ \sum_n E_n(q) f(E_n(q)) \right].$$

Here, the $\langle \langle \hat{H}(q) \rangle \rangle$ is just the summation over all quasi-particles for given configuration. Now, the specific heat $C_v$ can be found by $C_v = \frac{\langle \hat{H}^2 \rangle - \langle \hat{H} \rangle^2}{T^2}$, which means 

$$C_v \approx \frac{1}{N_m} \sum_{\{q_j\}} \langle \langle \hat{H}^2(q) \rangle \rangle - \frac{1}{T^2} \langle \hat{H} \rangle^2$$

where 

$$\langle \langle \hat{H}^2(q) \rangle \rangle = \left( \sum_n E_n(q) f(E_n(q)) \right)^2 + \sum_n E_n^2(q) f(E_n(q)) [1 - f(E_n(q))]$$

Next, we consider the spin-spin correlation function $S_{qq}(Q)$, which is defined as 

$$S_{qq}(Q) = \frac{1}{N^2} \sum_{ij} e^{iQ(R_i - R_j)} \langle q_i q_j \rangle.$$ 

This object is designed to detect the static or dynamic (fluctuation) order with the characteristic wave-vector $Q$. If spin orders in certain $Q$, the value of the corresponding $S_{qq}(Q)$ should reach $O(1)$. Now, using Eq. 6, we obtain 

$$S_{qq}(Q) \approx \frac{1}{N_m} \sum_{\{q_j\}} \left[ \frac{1}{N^2} \sum_{ij} e^{iQ(R_i - R_j)} q_i q_j \right].$$

Usually, we may also use its susceptibility 

$$\chi_{qq}(Q) = \frac{\langle S_{qq}(Q)^2 \rangle - \langle S_{qq}(Q) \rangle^2}{T}$$

$$\approx \frac{1}{T} \frac{1}{N_m} \sum_{\{q_j\}} \left[ \frac{1}{N^2} \sum_{ij} e^{iQ(R_i - R_j)} q_i q_j \right]^2$$

$$- \frac{1}{T} \left( \frac{1}{N_m} \sum_{\{q_j\}} \left[ \frac{1}{N^2} \sum_{ij} e^{iQ(R_i - R_j)} q_i q_j \right] \right)^2$$

to locate the position of long-ranged order. Obviously, if orders appear, $\chi_{qq}(Q)$ has to diverge for certain $Q$ at some critical temperature $T_c$. At $T_c$, the specific heat $C_v$ diverges as well.
For total c-fermion density, in terms of Eq. 7, it is easy to show that
\[ n_c = \frac{1}{N_s} \sum_j \langle \hat{c}_j^\dagger \hat{c}_j \rangle \simeq \frac{1}{N_m} \sum_{\{q_i\}} \left[ \frac{1}{N_s} \sum_n f_F(E_n(q)) \right]. \]

Since we work on grand canonical ensemble, if chemical potential is setting to zero, the model is symmetric an c-fermion should be half-filled. So, in this situation, \( n \) is expected to be 1, irrespective of temperature.

If we are interested in the density of state \( N(\omega) \) of c-fermion, we know that for \( \hat{H}(q) \), it is given by
\[ N(\omega, q) = \frac{1}{N_s} \sum_n \delta(\omega - E_n(q)), \]
thus,
\[ N(\omega) \simeq \frac{1}{N_m N_s} \sum_{\{q_i\}} \sum_n \delta(\omega - E_n(q)). \]

Finally, when we calculate fermion’s correlation function like \( \langle \hat{c}_i^\dagger \hat{c}_j \hat{c}_k^\dagger \hat{c}_l \rangle \),
\[ \langle \hat{c}_i^\dagger \hat{c}_j \hat{c}_k^\dagger \hat{c}_l \rangle = \frac{1}{N_m} \sum_{\{q_i\}} \langle \langle \hat{c}_i^\dagger \hat{c}_j \hat{c}_k^\dagger \hat{c}_l \rangle \rangle. \]  
(8)

Then, using the Wick theorem for these free fermions, we get
\[ \langle \langle \hat{c}_i^\dagger \hat{c}_j \hat{c}_k^\dagger \hat{c}_l \rangle \rangle = \langle \langle \hat{c}_i^\dagger \hat{c}_j \rangle \rangle \langle \langle \hat{c}_k^\dagger \hat{c}_l \rangle \rangle + \langle \langle \hat{c}_i^\dagger \hat{c}_k^\dagger \rangle \rangle \langle \langle \hat{c}_j \hat{c}_l \rangle \rangle. \]  
(9)
Next, for each one-body correlation function like \( \langle \langle \hat{c}_i^\dagger \hat{c}_j \rangle \rangle \), one can transform these objects into their quasiparticle basis,
\[ \langle \langle \hat{c}_i^\dagger \hat{c}_j \rangle \rangle = \sum_{m,n} \langle \langle \hat{d}_m^\dagger \hat{d}_n \rangle \rangle \phi_m^\dagger \phi_n \]
\[ = \sum_{m,n} f_F(E_n) \delta_{m,n} \phi_m^\dagger \phi_n \]
\[ = \sum_{\{q_i\}} f_F(E_n) \delta_{\{q_i\}} \phi_m^\dagger \phi_n, \]
then, combining Eq. 9 and inserting this expression into the Eq. 8, we can calculate the fermion’s correlation function.

**Effect of external magnetic field: Magnetization**

If z-axis external magnetic field is included, our model Eq. 1 is changed to
\[ \hat{H} = -t \sum_{\langle i,j \rangle, \sigma} \hat{c}_{i \sigma}^\dagger \hat{c}_{j \sigma} + \frac{J}{2} \sum_{j \sigma} S_j^z \sigma \hat{c}_{j \sigma}^\dagger \hat{c}_{j \sigma} + \frac{e^{-\beta E_n(q)}}{2} \sum_{q_j} \langle \hat{c}_j^\dagger \hat{c}_j \rangle \]
\[ - \hbar \sum_j \left( \hat{S}_j^z + \frac{1}{2} \sum_{\sigma} \sigma \hat{c}_{j \sigma}^\dagger \hat{c}_{j \sigma} \right). \]  
(10)

With choosing eigenstate of spin \( S_j^z \) as basis, the corresponding effective free fermion model reads
\[ \hat{H} = -t \sum_{\langle i,j \rangle, \sigma} \hat{c}_{i \sigma}^\dagger \hat{c}_{j \sigma} + \sum_{j \sigma} \left( \frac{J}{4} q_j - \frac{h}{2} \right) \sigma \hat{c}_{j \sigma}^\dagger \hat{c}_{j \sigma}, \]  
(11)
which is readily to be simulated by LMC with effective free energy \( F(q) = -T \sum_n \ln(1 + e^{-\beta E_n(q)}) - h/2 \sum_q q_j \).

In the main text, by using above formalism, we have calculated the magnetization of conduction electron and localized moment under external field \( h \) in Fig. 4.

**Phase separation**

When doping away from half-filling, the microscopic phase separation is a leading effect for intermediate and large Kondo coupling. An example is given in Fig. 8, where the phase separation is clearly seen with different ferromagnetic droplets.

**Mean-field approximation for SDW state**

For Eq. 1, its SDW mean-field Hamiltonian can be obtained by decoupling the Kondo coupling term via
\[ \sum_{\sigma} S_j^z \sigma \hat{c}_{j \sigma}^\dagger \hat{c}_{j \sigma} + \frac{(-1)^{j+1} \hbar c_s z^2 + \hbar j f_{\text{me}}}{2} \]
where the magnetic order parameters are defined by
\[ \langle S_j^z \rangle = (-1)^{j+1} \hbar c_s \]
\[ \sum_{\sigma} \sigma \hat{c}_{j \sigma}^\dagger \hat{c}_{j \sigma} = (-1)^{j+1} \hbar c_s, \]
(12)
thus, the mean-field Hamiltonian reads

$$\hat{H} = -t \sum_{\langle i,j \rangle, \sigma} \hat{c}_i^{\dagger} \hat{c}_j + \frac{J_m f}{4} \sum_{j} (1)^{j} \sigma \hat{c}_j^{\dagger} \hat{c}_j$$

$$+ \frac{J}{2} (-1)^{j+1} m_c \sum_{j} S_j^z + \frac{J}{2} \sum_{j} m_f m_c$$

$$= \sum_{k \sigma} \left( \hat{c}_{k \sigma} \hat{c}_{k+Q, \sigma} \right) \left( \frac{\varepsilon_k}{J_m f} \right) \left( \hat{c}_{k+Q, \sigma} \right)$$

$$+ \frac{J}{2} m_c \sum_{j} (-1)^{j+1} S_j^z + \frac{J}{2} \sum_{j} m_f m_c.$$

Therefore, its free energy can be found as

$$F = -T \sum_{k \sigma} \left[ \ln(1 + e^{-\beta E_k}) + \ln(1 + e^{-\beta E_{k+Q}}) \right] + N_s \frac{J_m f m_c}{4}$$

$$- T N_s \ln \left( 2 \cosh \frac{\beta J_m f}{4} \right)$$

with $E_{k \pm} = \pm \sqrt{\varepsilon_k^2 + \frac{J^2 m_c^2}{16}}$. So, the mean-field self-consistent equations can be derived by $\frac{\partial F}{\partial m_c} = 0, \frac{\partial F}{\partial m_f} = 0$,

$$m_f = \tanh \frac{J_m f}{4T}$$

$$m_c = \frac{2}{N_s} \sum_{k} \frac{\varepsilon_k}{E_{k+}} \frac{J_m f}{4}.$$  

(13)

From these two equations, one can obtain the equation for SDW critical temperature $T_{cmf}$ in the mean-field approximation,

$$T_{c mf} = \frac{2}{N_s} \sum_{k} \frac{\varepsilon_k}{|\varepsilon_k|} \frac{J^2}{16}.$$  

(14)

In Fig. 9(a), we show the SDW critical temperature $T_{c mf}$ versus $J$, which has linear dependence on $J$. However, since no thermal fluctuation is included, the critical temperature $T_{c mf}$ is rather overestimated compared to the exact critical temperature $T_c$ from LMC.

**Hubbard-I approximation for MI**

In the paramagnetic MI, one can follow the Hubbard-I approximation to give a rough solution for MI itself[13]. To this purpose, we use equation of motion formalism and define the retarded Green’s function as

$$G_{ij, \sigma}(\omega) = \langle \langle \hat{c}_{i \sigma} \rangle \rangle_{\omega}.$$  

(15)

By using the standard equation of motion relation,

$$\omega \langle \hat{A} \hat{B} \rangle_{\omega} = \langle \hat{A} \hat{B} \rangle_{+} + \langle \hat{A} \hat{H} \rangle_{-} \langle \hat{B} \rangle_{\omega}$$

for Eq. 1, it follows that

$$\omega \langle \langle \hat{c}_{i \sigma} \rangle \rangle_{\omega} = \delta_{ij} - t \Delta_{im} \langle \langle \hat{c}_{m \sigma} \rangle \rangle_{\omega} + J \sigma \langle \langle \hat{S}_i^z \hat{c}_{i \sigma} \rangle \rangle_{\omega}.$$  

Here, $\Delta_{im}$ denotes $m$ is the nearest-neighbor site of $i$. For $\langle \langle \hat{S}_i^z \hat{c}_{i \sigma} \rangle \rangle_{\omega}$, we have

$$\omega \langle \langle \hat{S}_i^z \hat{c}_{i \sigma} \rangle \rangle_{\omega} = (S_i^z) \delta_{ij} - t \Delta_{il} \langle \langle \hat{S}_i^z \hat{c}_{l \sigma} \rangle \rangle_{\omega} + \frac{J}{4} \sigma \langle \langle \hat{c}_{i \sigma} \rangle \rangle_{\omega}.$$  

In paramagnetic strong coupling regime, there is no magnetic order, thus $\langle \langle \hat{S}_i^z \rangle \rangle_{\omega} = 0$. Meanwhile, we expect the correlation should be short-ranged, so contribution from $\langle \langle \hat{S}_i^z \hat{c}_{i \sigma} \rangle \rangle_{\omega}$ can be neglected and the above equation has a complete solution.

$$\omega \langle \langle \hat{c}_{i \sigma} \rangle \rangle_{\omega} = \delta_{ij} - t \Delta_{im} \langle \langle \hat{c}_{m \sigma} \rangle \rangle_{\omega},$$  

which can be written as

$$\omega - \frac{J^2}{4\omega} G_{ij, \sigma}(\omega) = \delta_{ij} - t \Delta_{im} G_{mj, \sigma}(\omega).$$  

(16)

Now, performing the Fourier transformation

$$G_{ij, \sigma}(\omega) = \frac{1}{N_s} \sum_k e^{i k (R_i - R_j)} G_\sigma(k, \omega),$$

the single-particle Green’s function in MI reads

$$G_\sigma(k, \omega) = \frac{1}{\omega - \varepsilon_k - \frac{J^2}{4\omega}} = \frac{\alpha_k^2}{\omega - E_k^+} + \frac{1 - \alpha_k^2}{\omega - E_k^-.}$$  

(17)

Here, the coherent factor $\alpha_k^2 = \frac{1}{2} \left( 1 + \sqrt{\varepsilon_k^2 + J^2} \right)$ and

$$\hat{E}_k^\pm = \frac{1}{2} \left[ \varepsilon_k \pm \sqrt{\varepsilon_k^2 + J^2} \right].$$  

(18)

Therefore, although no SDW state appears, the band of conduction electron has been split into two Hubbard-like
bands. This is driven by the local Kondo interaction and the resulting state is MI. Moreover, the DOS in the present Hubbard-I approximation can be obtained by

\[
N(\omega) = \frac{1}{N_s} \sum_{k,\sigma} \left[ -\frac{1}{\pi} \text{Im} G_\sigma(k, \omega + i\Gamma) \right]
\]

where \(\Gamma\) is the damping factor and we give an example in Fig. 9(b).
