We show that weak measurements can induce a quantum phase transition of interacting many-body systems from an ergodic thermal phase with a large entropy to a nonergonic localized phase with a small entropy, but only if the measurement strength exceeds a critical value. We demonstrate this effect for a one-dimensional quantum circuit evolving under random unitary transformations and generic positive operator-valued measurements of variable strength. As opposed to projective measurements describing a restricted class of open systems, the measuring device is modeled as a continuous Gaussian probe, capturing a large class of environments. By employing data collapse and studying the enhanced fluctuations at the transition, we obtain a consistent phase boundary in the space of the measurement strength and the measurement probability, clearly demonstrating a critical value of the measurement strength below which the system is always ergodic, irrespective of the measurement probability. These findings provide guidance for quantum engineering of many-body systems by controlling their environment.

I. INTRODUCTION

Generic many-body quantum systems obey the eigenstate thermalization hypothesis (ETH), according to which they establish the characteristics of thermal equilibrium in a finite time, leading to ergodic dynamics in local observables. These systems are characterized by highly entangled eigenstates, i.e., states following an extensive scaling of their entanglement entropy, a behavior known as the volume law. However, systems with local interactions can display a transition to a phase in which the entanglement entropy obeys a subextensive area-law scaling, where ETH is violated. A paradigmatic case is that of many-body localization, in which the entanglement transition is driven by the strength of a local disordered potential. The fate of this transition in open quantum systems is the subject of intense current investigations. A promising path to address the entanglement transition in this setting is to consider a randomly driven system on which the external environment acts as a quantum detector. In this scenario, the free unitary evolution of the unobserved system leads to a ballistic temporal growth of entanglement, until it settles into a highly entangled quasi-stationary state that follows the volume law. This tendency is counteracted by local measurements, which induce a stochastic nonunitary backaction. Very recently it has been shown that when local projective measurements are performed frequently enough one encounters an entanglement transition to a quasi-stationary state characterized by an area law.

Projective measurements capture an important but restricted class of environments. A much larger class can be accessed by adopting a more general perspective, according to which quantum measurements are not necessarily characterized by discrete projections in the time evolution, but are generically given by positive operator-valued measurements (POVMs) with a continuous spectrum of outcomes and a corresponding stochastic backaction onto the system. The measurement strength \( \lambda \) can then be controlled to continuously interpolate between the unobserved case and projective measurements. Such weak measurements are also routinely employed in experiments for quantum states readout and quantum feedback protocols, and can be used as a theoretical tool to reproduce Lindblad dynamics of open systems via trajectory averaging. They, therefore, describe a much more versatile framework to model the influence of the environment on an open quantum system. The effect of POVM on entanglement evolution has been addressed for continuous measurements in free fermionic systems, while the existence of an entanglement transition driven by measurement strength for interacting systems has been inferred by the study of mutual information.

In this paper, we systematically study the effect of these weak measurements on the ergodic properties of randomly driven many-body systems, modeled as a quantum circuit with local interactions. By analyzing the entanglement entropy and its variance we show that weak measurements can indeed drive a transition to a nonergodic phase obeying the area law. Similarly to the case of projective measurements, the result resembles that of the Zeno effect in which a transition to frozen dynamics is obtained by sufficiently frequent projective measurements. Importantly, we identify a minimal critical measurement strength below which no localization is possible regardless of the measurement probability \( p \). These results are obtained by mapping out the phase boundary by two different methods, based on the data collapse and scaling of the entropy for different system sizes, as well as the statistical fluctuations of the entropy, which turn out to be maximal at the phase transition. Beyond providing this specific phenomenology, our results open up a broader avenue to study many-body quantum dynamics in open systems, understand their properties in more detail, and guide the implementation of quantum feedback control for technological applications.
II. MODEL

We analyze the entanglement transition in a model consisting of a spatially periodic one-dimensional quantum circuit consisting of a chain of $L$ spins, where $L$ is assumed to be even to allow the partition of the chain into two subsystems of equal length. The chain evolves in time under a sequence of discrete time steps that are action perturbatively small in $\lambda$. The evolution of the random circuit from the measurements is taken at intervals $\delta t \rightarrow 0$ with $\lambda = \lambda_0 \sqrt{\delta t}$, the model generically reproduces a continuous Lindblad equation$^{[10]}$, and for our case reduces to the measurement model used in Ref. [51]

III. VOLUME TO AREA LAW TRANSITION

To discriminate between ergodic and nonergodic many-body phases we utilize the bipartite entanglement entropy

$$S = -\text{tr}(\rho_A \ln \rho_A),$$

where $\rho_A$ is the reduced density matrix of a subchain $A$. This entropy is extensively employed to quantify the entanglement in quantum systems, and its scaling properties with length can be used to determine whether the system is in an ergodic thermal-like phase or a nonergodic localized phase$^{[25][12][10]11[12]}$. Alternative entanglement measures used in the literature include Rényi entropies$^{[15][20][24]}$ and mutual information$^{[20][12][11]}$. We focus on the case where the subchain $A$ is of length $L/2$, which corresponds to cutting the circuit into two halves of equal size. Note that a cut may be commensurate or incommensurate with the unitary operations $U$ in each layer of
The stochastic evolution of the entropy over time is illustrated in Fig. 2. The figure displays a color-coded histogram obtained from 1000 realizations of the stochastic evolution commencing from an unentangled Néel state, and contrasts two cases of different measurement strength while the measurement probability is fixed to $p = 0.9$. For the weaker measurement strength $\lambda/\Delta = 0.2$ [panel (a)] the entropy increases ballistically over $\sim L/2$ time steps and then saturates at a large value, which increases linearly with the system size (see the inset). This is the signature of an extensive entropy scaling according to a volume law. The entropy in the quasistationary regime at long times is close to the value in an unobserved system ($\lambda = 0$ or $p = 0$), where the average entropy is predicted to be given by:

$$\langle S \rangle = \frac{L}{2} \ln 2 - \frac{1}{2}. \quad (4)$$

A qualitatively different behavior is observed for the stronger measurements with $\lambda/\Delta = 0.6$ [panel (b)]. There the entropy saturates quickly, and at a value independent of the system size (see the inset). This corresponds to an area law, as encountered in a localized phase.

The observation of two phases suggests that a phase boundary exists in the parameter space spanned by $p$ and $\lambda/\Delta$. A clear indication of the support of the phases can be obtained from the variance of the entropy, shown in Fig. 3. We again account for 1000 realizations and collect the data from the quasistationary regime (from $\sim L/2$ to a cutoff of 100 time steps, much larger than the range of the transient entropy growth for all systems sizes studied here). As before, the initial state is an unentangled Néel state. We observe that there are two regions where the entropy fluctuations are small, separated by a transition region with a pronounced increase of the fluctuations. The contour of maximal variance (thick lines) is stable for different system sizes, while the critical fluctuations along this contour increase with system size, as we further analyze below. The contour indicates that there exists a critical value $p_{\text{crit}}$ for the measurement probability below which there are too few measurements to localize the system, as previously identified in analogous models based on projective measurements (hence $\lambda/\Delta \to \infty$). Departing from the projective measurement scenario, the measurement probability at the transition becomes dependent on the measurement strength, so that measurements have to occur more frequently when the measurement strength decreases. However, even for permanent measurements ($p = 1$), the transition occurs at a finite measurement strength, which we denote as $(\lambda/\Delta)_{\text{crit}}$. Below this measurement strength, the system is always in the ergodic phase. This is our main result. In the remainder of this paper we characterize these transitions in detail, and in particular, confirm that they become sharp in the limit of a large system size.
IV. CRITICAL BEHAVIOR

In order to determine the two critical parameters, we consider two distinct transition scenarios: (a) the case where the measurement is always performed \( p = 1 \) while the measurement strength \( \lambda / \Delta \) is varied, and (b) the case of almost-projective measurements with \( \lambda / \Delta = 10 \) and varying probability \( p \). Fig. 4 displays the average \( \langle S \rangle \) of the entanglement entropy for both scenarios. For small \( \lambda / \Delta \) or \( p \) the entropy clearly follows a volume law, as can be seen by comparison with the theoretical prediction [4] for an unobserved ergodic system. At large values of these parameters, however, the entropy becomes independent of the system size, so that an area law is observed. That we indeed deal with a well-defined transition follows from the finite-size scaling analysis shown in the insets. For this, we assume that in the critical region the correlation length scales as \( \xi \sim |x - x_{\text{crit}}|^{\nu} \) and the entropy scales as \( \langle S \rangle \sim |x - x_{\text{crit}}|^{\gamma} \), where \( x = p, (\lambda / \Delta) \) is the varied parameter. The scaling ansatz then takes the form

\[
\langle S \rangle L^{-\gamma/\nu} = F \left( L^{1/\nu} (x - x_{\text{crit}}) \right),
\]

where \( F \) is an unknown scaling function. The transition point \( x_{\text{crit}} \) and the critical exponents \( \nu \) and \( \gamma \) can be obtained by means of a data collapse.

The data collapse shown in the insets then gives the values \( (\lambda / \Delta)_{\text{crit}} = 0.30(1) \) and \( p_{\text{crit}} = 0.110(3) \).

Fig. 5 displays analogous results for the entropy fluctuations captured by the variance \( \text{var}(S) \). The main panels present the numerical data, along with a fit utilized to enable reliable extraction of the position and height of the maximal variance. We observe that the positions of the maxima display a remarkably small drift with the
system size, which relieves us from the complications encountered in other cases. Therefore, we can extract the phase transition directly from finite-size scaling of the locations of the maxima, which is again presented in the insets. We observe two scaling curves, one originating from systems of length \( L = 4k \) and another one from systems of length \( L = 4k + 2 \), which, as mentioned before, differ by the commensurability of the bipartition in each layer. Reassuringly, both curves extrapolate to consistent transition points for \( L \to \infty \), giving the values listed in Table I. Combining both transition curves into a simultaneous extrapolation we then obtain the values \( \lambda/\Delta \text{crit} = 0.304(3) \) and \( p \text{crit} = 0.1103(7) \), in excellent agreement with the values found from the average entropy data collapse.

The choice of the scaling function and the corresponding critical exponents are corroborated by the analysis of a different (logarithmic) scaling function and higher Rényi entropies, as reported in Appendix A. The logarithmic scaling does not seem to provide a better fit than the power law in Eq. (5). A power law scaling ansatz for the higher order Rényi entropies is consistent with the results in Table I.

Our results are also supported by the behavior of the mutual information \( I(A : B) \), which is defined as \( I(A : B) = S(A) + S(B) - S(A \cup B) \) for two regions \( A \) and \( B \), and is a measure of correlations between subsystems in the chain. We analyze \( I(A : B) \) for antipodal regions \( A \) and \( B \) on a periodic system of size \( L \) for different \( L \), keeping sizes \( L/6 \) of regions \( A \) and \( B \) constant relative to the system size. Fig. 6 shows that the mutual information exhibits a clear peak near the transition predicted in Table I (dashed lines).

### V. CONCLUSIONS

In conclusion, weak local measurements can drive open many-body systems into a nonergodic low-entropy phase, but only if the measurement strength exceeds a critical value. This means that a continuously observed many-body system can remain ergodic even if the observation strength is finite. We demonstrated our findings for a quantum circuit, evolving under random local unitary operations and local positive operator-value measurements modeled as a Gaussian probe, for which finite-size scaling of the entropy and its fluctuations show that the entanglement phase transition becomes sharp for large systems. Quantum circuits can describe a very large range of dynamics, while weak measurements provide a rather general description of environments, where the variable measurement strength bridges between the fully projective measurements and the fully unitary dynamics of the unsolved system. We, therefore, anticipate that our findings generalize to a large range of settings that deserve further investigation. This includes systems with nonstochastic unitary dynamics as well as different types of interactions, observables, or dimensions, but also practical applications aiming at the control of quantum systems via engineering of their environment.

Appendix A: Further analysis of the scaling of entropy and its variance

In this work we used the power-law scaling ansatz of Eq. (5) to fit the entropy dependence on the measurement probability \( p \) or measurement strength \( \lambda/\Delta \). This choice of the scaling function can be justified based on the general constraints for the volume to area law in many-body localization transition. In random circuits, a logarithmic scaling function has been employed to determine the critical values of the measurement probability for circuits of Clifford algebra operators only. As the use of a logarithmic scaling is justified in Clifford random circuits by the emergence of a conformal symmetry at the transition, we here also report the results of the critical value and exponent from a logarithmic scaling function in our model, even though no conformal symmetry is known to arise.

We used the scaling function

\[
\langle S \rangle - \alpha \ln L = F \left( L^{1/\nu} (x - x_{\text{crit}}) \right),
\]

and collapsed the data by varying \( \nu \) and \( \alpha \) (see Fig. 7). The corresponding critical values are \( (\lambda/\Delta)_{\text{crit}} = 0.30(2) \), \( \nu = 0.80 \), \( \alpha = 1.6 \) for the \( p = 1 \) transition and \( p_{\text{crit}} = 0.14(3) \), \( \nu = 0.96 \), \( \alpha = 1.7 \) for the \( \lambda/\Delta = 10 \) transition. We note that the critical values are different than the ones reported in the caption of Fig. 1 but the fitting of the scaling function is slightly worse across the full range of data. A more detailed comparison would require much larger system sizes, which are not accessible in exact numerics for the Haar model considered here. Furthermore, given the finite system sizes in our study, we cannot rule out a crossover from power-law scaling to logarithmic scaling from the weak-measurement to the strong-measurement transition.

In order to corroborate the results obtained from the scaling of the entropy variance, we have performed similar analysis for the second and third Rényi entanglement entropies, \( S_2 \), \( S_3 \), where

\[
S_\alpha = \frac{1}{1 - \alpha} \ln \text{tr}(\rho_\alpha^2).
\]

For \( \alpha \to 1 \) this becomes the von Neumann entropy. The results are reported in Figs. 5 and 9 and show clear signatures of a phase transition consistent with the picture obtained from the von Neumann entropy. These entropies are of particular experimental interest.
