 Arbitrage with Power Factor Correction using Energy Storage

Md Umar Hashmi¹, Deepiyo Deka², Ana Bušić¹, Lucas Pereira³, and Scott Backhaus²

The importance of reactive power compensation for power factor (PF) correction will significantly increase with the large-scale integration of distributed generation interfaced via inverters producing only active power. In this work, we focus on co-optimizing energy storage for performing energy arbitrage as well as local power factor corrections. The joint optimization problem is non-convex, but can be solved efficiently using a McCormick relaxation along with penalty-based schemes. Using numerical simulations on real data and realistic storage profiles, we show that energy storage can correct PF locally without reducing arbitrage gains. It is observed that active and reactive power control is largely decoupled in nature for performing arbitrage and PF correction (PFC). Furthermore, we consider a stochastic online formulation of the problem with uncertain load, renewable and pricing profiles. We develop a model predictive control based storage control policy using ARMA forecast for the uncertainty. Using numerical simulations we observe that PFC is primarily governed by the size of the converter and therefore, look-ahead in time in the online setting does not affect PFC noticeably. However, arbitrage gains are more sensitive to uncertainty for batteries with faster ramp rates compared to slow ramping batteries.

I. INTRODUCTION

With the growth of distributed generation (DG) and large-scale renewables, the need to understand their effects on power networks has become crucial. While bulk-renewable generators have well defined rules for performance including that for reactive power, distributed generation owned by small residential consumers have been exempted. This is primarily due to lack of measurement infrastructure and installed DG contributing to a small fraction of total generation. However, in recent years, growing incentives and environmental awareness have resulted in a large number of consumers installing distributed generation. Policies such as Net-Energy Metering in California has lead to more than 913,481 California electricity consumers opting for solar installations by the end of 2018[1]. Understanding the effects, both operational and financial, of growth in distributed energy resources (DERs) is essential for Distribution System Operators (DSOs) to ensure reliable operation. Since DERs in current markets are not financially rewarded for providing reactive power support, small inverters connected to them primarily output active power and almost no reactive power [2]. This is also in compliance with IEEE Standard 1547, which specifies that DG shall not actively regulate the voltage at the point of common coupling [2]. As a result, there has been a degradation of the load power factor (PF) [3].

PF denotes the ratio of active power and the apparent power and is measured as \( \cos(\phi) \), where \( \phi \) denotes the angle between active and reactive power. An alternate definition for PF commonly used in national and ISO level power norm documents is \( \tan(\phi) \) (denoted as \( \text{tg} \phi \)). As distribution grids are primarily designed to operate close to unity power factor, a systematic degradation in PF can lead to high current, excessive thermal losses, aggravated voltage profiles [4], and equipment damage. It has been shown that maintaining a high power factor leads to positive environmental effects due to increased grid efficiency [5]. To this end, several regional transmission organizations and system operators have operational rules for PF as stated in Table I, though primarily for large loads. Note that \( |\cos(\phi)| \) implies symmetric rules for leading and lagging power factor.

However the PF of residential consumers is also a point of concern. For example, the Smart Islands Energy Systems (SMILE) project, initiated by the European Union in 2017 [20], involves data collection at multiple fronts including consumer smart meters in Madeira, Portugal. As a case study, 15 minute averaged household consumption and solar generation data on 18th May, 2018 for a representative residential consumer in the island of Madeira, Portugal is depicted in Fig. 1. Note that while PF at night is close to unity, during the day it degrades significantly due to solar output. Thus low load PF may be subjected to norms and penalties [3]. [1]. Some household smart meters (Eg. Linky smart meters in France) already have reactive power monitoring capability that can implement PF norms [21]. The LV consumers in Uruguay have electricity bills with three different contracts [8] that include penalties for PF degradation. Appendix A in the supplementary material has additional data that detail the effect of solar on PF.

A. Literature Review

While additional infrastructure such as capacitor banks [22] have been proposed to improve power factor, we focus our work on using conventional energy storage/battery for performing power factor correction, in addition to other functions like arbitrage [23], [24]. Note that storage devices generate DC power and hence are connected to the grid through a DC/AC converter/inverter that are often over-sized

different approximation schemes to solve the problem: (a) McCormick relaxation for original non-convex program, (b) receding horizon arbitrage with real-time PFC, and (c) arbitrage with penalty-based PFC. While the McCormick relaxation and real-time PFC policies routinely achieve the optimal solution, the penalty based approach is able to provide best alternatives in scenarios where no feasible solution satisfying PF limits exists. Second, we present a modified penalty-based algorithm that reduces converter usage along with arbitrage and PFC. Third, using realistic pricing, net load (consumption + solar) data and battery parameters, we extensively benchmark the achievable ability of storage devices to maintain PF limits without any significant degradation in arbitrage gains. This implies that household DG can follow PF limits as well if such regulations are created in future distribution grids. Fourth, we consider stochastic extensions of our algorithms for real-time implementation through Model Predictive Control (MPC). We use Auto-Regressive Moving Average (ARMA) processes to model temporally evolving signals in the MPC framework and demonstrate significant benefits from the online algorithms.

The paper is organized in six sections. Section II provides the system description. Section III formulates the co-optimization problem of performing arbitrage and PFC using storage and discusses multiple solution strategies. Section IV presents an online algorithm using ARMA forecasting and MPC in order to mitigate the effect of forecast error. Section V presents the numerical results. Section VI concludes the paper and discusses future directions of research.

II. SYSTEM DESCRIPTION

The system considered in this work consists of an electricity consumer with inelastic demand, renewable generation (rooftop solar) and energy storage battery. The energy storage battery will provide flexibility to deviate consumption in order to make gains by performing arbitrage and correct the power factor to satisfy utility prescribed limits. The block diagram of the system considered is shown in Fig. 2.

We denote time instant as a superscript of the variable. The apparent power of the load shown in Fig. 2 at $i$th time instant is denoted as $S_h^i = P_h^i + jQ_h^i$, where $P_h^i$ and $Q_h^i$ are the active and reactive power consumed. Apparent power of the solar inverter is given as $S_r^i = P_r^i$, where $P_r^i$ is the active power supplied by solar inverter. We assume the solar inverter operates at unity PF. Let us denote the combined load and renewable active and reactive power by $P^i = P_h^i + P_r^i$ and $Q^i = Q_h^i$, respectively. The power factor seen by the grid is the ratio of real power supplied or extracted by the grid over apparent power seen by the grid in the absence of storage it is given by

$$p_{bc}^i = \frac{P^i}{\sqrt{P^i + Q^2}}.$$  \hspace{1cm} (1)

Observe that PF before correction, $p_{bc}^i$, degrades as $P_r^i$ and $Q_h^i$ increases in magnitude. Next we discuss the battery model considered and its effect on PF.

Battery Model: The storage/battery converter can supply active and reactive power. The apparent power output of energy storage (connected through a converter which is an inverter or a rectifier) is given as $S_B^i = P_B^i + jQ_B^i$, where

B. Contribution

We are interested in using energy storage connected through an inverter for the joint task of arbitrage and PFC. In addition to commercial and residential electricity consumers, the formulation is also of interest for renewable integrators, transmission and distribution operators. The first contribution of this work is the development of a non-convex mixed-integer formulation to optimize storage for arbitrage and power factor correction in the presence of DG. While the co-optimization problem is non-convex, we demonstrate three
Let $b^i$ denote active and reactive power outputs respectively. We consider operation over a total duration $T$, with operations divided into $N$ steps indexed by $\{1, \ldots, N\}$. The duration of each step is denoted as $h$. Hence, $T = hN$. We denote the change in the energy level of the battery at $i^{th}$ instant by $x^i$; $x^i > 0$ implies charging and $x^i < 0$ implies discharging. $x^i/h$ denotes the corresponding storage rate with $\delta_{\min} \leq 0$ and $\delta_{\max} \geq 0$ as the minimum and maximum rate limits (kW) respectively. Let the efficiency of charging and discharging of battery be denoted by $\eta_{\text{ch}}, \eta_{\text{dis}} \in (0, 1]$, respectively. The storage active power $P_B^i$ for the $i^{th}$ instant is related to battery energy as $P_B^i = \frac{[x^i]^+}{\eta_{\text{ch}}} - \frac{[x^i]^−}{\eta_{\text{dis}}}$. The active power rate constraint follows as

$$P_B^i \in [P_{B_{\min}}^i, P_{B_{\max}}^i] \quad \text{with} \quad P_{B_{\min}} = \delta_{\min} \eta_{\text{dis}}, \quad P_{B_{\max}} = \delta_{\max} \eta_{\text{ch}},$$

(2)

Though the battery charge level is not affected by the reactive power output $Q_B^i$ of the connected inverter, the amount of active power supplied or consumed is dependent upon it due to the line current limitations [38]. The converter rating is given by the maximum apparent power supplied/consumed, denoted as $S_B^{\max}$ which bounds the instantaneous apparent power $S_B^i$:

$$(S_B^{\max})^2 \geq (S_B^i)^2 = (P_B^i)^2 + (Q_B^i)^2,$$

(3)

Let $b^i$ denote the energy stored in the battery at the $i^{th}$ step with $b^i = b^{i-1} + x^i$. To keep the charge in the battery within prescribed limits, the battery capacity constraint is imposed

$$b^i \in [b_{\min}, b_{\max}],$$

(4)

where $b_{\min} = SoC_{\min} B_{\text{rated}}$ and $b_{\max} = SoC_{\max} B_{\text{rated}}$. $B_{\text{rated}}$ is the rated capacity and $SoC_{\min}$ and $SoC_{\max}$ are the minimum and maximum level of state of charge respectively.

**Energy Arbitrage:** The primary use of the storage device considered here is for ‘Energy arbitrage’ which refers to buying electricity when price is low and selling it when price is high, and in effect making a profit. In this work we assume that buying and selling prices of electricity at each instant $i$ are the same and denote it by $p_{\text{elec}}$. Under this assumption, the arbitrage gains depend on the varying electricity price but not on the inflexible load. As monetary benefits from arbitrage is based only on active power, the operator seeks to minimize

$$\min_{P_B, Q_B} \sum_{i=1}^{N} p_{\text{elec}} P_B^i$$

with additional system constraints. Refer to [37] and Appendix C in the supplementary material for details.

**Power Factor Correction:** Note the power factor formulation in Eq. [1] In the presence of storage, it takes the form

$$p_{\text{pf}}^i = \frac{P_T^i}{\sqrt{(P_T^i)^2 + (Q_T^i)^2}},$$

(5)

where total active power is denoted as $P_T^i = P^i + P_B^i$ and total reactive power is given as $Q_T^i = Q^i + Q_B^i$. It is clear that storage operations can negatively or positively affect the load PF. To ensure that the PF is within the permissible limits,

$$-k \leq \frac{Q_T^i}{|P_T^i|} = \frac{Q^i + Q_B^i}{|P^i + P_B^i|} \leq k,$$

(6)

where $k = \tan(\theta_{\min})$.

We assume that the limits in Eq. [6] are identical for both leading and lagging PF. Note that the feasible region for the PF constraint as shown in Fig. [3a] is non convex. In the next section we will formulate a non-convex storage optimization problem and discuss solution strategies.

**III. ARBITRAGE AND PFC WITH STORAGE**

We formulate the co-optimization problem for performing arbitrage and correcting power factor considering active ($P_B^i$) and reactive power ($Q_B^i$) output from storage connected via an inverter. Following the discussion in the preceding section, the objective function is given as

$$(P_{\text{org}}) \quad \min_{P_B, Q_B} \sum_{i=1}^{N} p_{\text{elec}} P_B^i \quad \text{subject to, Eqs. [2] [3] [4] [6]}$$

Eq. [6] is non-convex but consists of two disjoint convex sets if the active power in the denominator is sign-restricted. This disjoint nature of PF constraint can be formulated as a mixed-integer convex problem by using McCormick relaxation as described in Section III-A. Additional approaches to solve it are discussed in later sections.

**A. McCormick Relaxation based approach**

We reformulate the non-convex PF constraint in ($P_{\text{org}}$) to a bi-linear constraint by introducing binary variables $z$ as $|P_T^i| = (2z - 1) P_T^i$. Here $z$ is equal to 1 when total active power is positive and zero otherwise. Denoting the bi-linear term with variable $y = z P_T^i$, we use McCormick relaxation [38] to convert it to a mixed-integer linear constraint as detailed in
Appendix [B] in the supplementary material. As mentioned in [39], this McCormick relaxation is exact as one of the variables in the bi-linear term is a binary variable. After simplification, we get the following mixed-integer convex problem ($P_{mr}$).

\[
(P_{mr}) \quad \min_{P_B, Q_B} \sum_{i=1}^{N} p_{elec}^i P_B^i
\]

subject to, Eqs. [4] [3] [4]

PF Constraint: 
\[
-2ky + kP_T^i - Q_T^i \leq 0,

-2ky + kP_T^i + Q_T^i \leq 0,
\]

McCormick Constraint:
\[
y \geq P_{lb}^i, \quad y \geq P_{lb}^i + P_{ub}^i z - P_{ub}^i,

y \leq P_{ub}^i, \quad y \leq P_{lb}^i + P_{ub}^i z - P_{lb}^i,
\]

Binary Variable: $z \in \{0, 1\}, \quad 2y - P_T^i \geq 0.$

Here $P_{lb}^i = P_i + P_B^{min}$ is the lower bound of total active power, and $P_{ub}^i = P_i + P_B^{max}$ is the upper bound. Problem ($P_{mr}$) involving mixed-integer linear constraints can be solved by off the shelf solvers like Gurobi or Mosken that can be called by CVX [40]. Note that both ($P_{org}, P_{mr}$) consider arbitrage and PFC at equal footing for all time instances. To study the impact of PFC on arbitrage gains, we propose an approach next where PF of the current instance alone is considered while making optimal arbitrage decisions.

**B. Receding horizon arbitrage with sequential PFC**

We consider a receding horizon approach ($P_{rh}$) that solves two disjoint optimization problems, denoted as ($P_{sub1}$) and ($P_{sub2}$) below, for each time instant $j$ and selects the solution with higher gains and feasibility.

\[
(P_{sub1}) \quad \min_{P_B, Q_B} \sum_{i=1}^{N} p_{elec}^i P_B^i
\]

\[
-k P_T^i \leq Q_T^i \leq k P_T^i, \quad P_T^i \geq 0,
\]

and the second sub problem is given as

\[
(P_{sub2}) \quad \min_{P_B, Q_B} \sum_{i=1}^{N} p_{elec}^i P_B^i
\]

\[
-k P_T^i \geq Q_T^i \geq k P_T^i, \quad P_T^i < 0.
\]

Note that both ($P_{sub1}, P_{sub2}$) are convex and solve a cumulative arbitrage gains problem, but with PFC restricted to the current time-instant $j$ only (no look-ahead PFC). The sub-problems only differ in the sign of the current total active power $P_T^i$. The feasible sub-problem with higher gains sets the storage actions for the current instant $j$, ($P_T^i$) and ($Q_T^i$). The approach then moves to the next instance $j + 1$.

Formulations ($P_{org}$), ($P_{mr}$), ($P_{rh}$) model the PF constraints as hard constraints and ensure their feasibility at every operational point. However, PF violations may be unavoidable and no feasible solution may exist. This may be due to converter limitations as well as storage constraints with regard to capacity and ramping. In such cases, we propose an alternate approach where we correct PF as best as possible.

**C. Arbitrage with penalty based PFC**

We redefine problem ($P_{org}$) using a penalty function $\theta(i)$ for the power factor. The objective of the new formulation ($P_{pla}$) is given by

\[
\min_{P_B, Q_B} \sum_{i=1}^{N} \{p_{elec}^i P_B^i + \theta(i)\},
\]

where we define penalty function $\theta(i)$ as

\[
\theta(i) = \lambda \max(0, |Q_T^i| - k|P_T^i|).
\]

Here $\lambda$ represents the constant associated with the linear cost of violating the PF. The shape of penalty function is shown in Fig. 4. The second term in Eq. 8 represents the amount of PF deviation from preset thresholds. This term will be equal to zero for cases where PF is within permissible limits. The max term can be modelled as two constraints

\[
\theta(i) \geq 0, \quad \theta(i) \leq \lambda(|Q_T^i| - k|P_T^i|)
\]

where absolute value function $|x|$ can further be represented as $(2x - 1)x \geq 0$ with binary variable $z \in \{0, 1\}$. Eq. 9 can now be reformulated as

\[
\theta(i) \geq 0, \quad \theta(i) \leq \lambda(2y_1^i - Q_T^i - 2ky_2^i + kP_T^i),

2y_1^i - Q_T^i \geq 0, \quad 2y_1^i - Q_T^i \geq 0.
\]

Here $y_1^i$ and $y_2^i$ denote bi-linear variables

\[
y_1^i = z_1^i Q_T^i, \quad y_2^i = z_2^i P_T^i
\]

with binary variables $z_1^i$ and $z_2^i$, $z_1^i z_2^i$ is equal to 1 if the total reactive (active) power is greater than zero, and zero otherwise. As before, we use McCormick relaxation (see supplementary material) to convert the bi-linear terms in Eq. 11 to mixed-integer linear constraints

\[
y_1^i \geq Q_{lb}^i z_1^i, \quad y_1^i \leq Q_T^i + Q_{ub}^i z_1^i - Q_{lb}^i

y_1^i \leq Q_{ub}^i z_1^i, \quad y_1^i \leq Q_T^i + Q_{lb}^i z_1^i - Q_{lb}^i

y_2^i \geq Q_{lb}^i z_2^i, \quad y_2^i \geq Q_T^i + P_{ub}^i z_2^i - P_{ub}^i

y_2^i \leq P_T^i z_2^i, \quad y_2^i \leq P_T^i + P_{lb}^i z_2^i - P_{lb}^i.
\]

In these equations, $Q_{lb}^i = Q^i - Q_{B}^{max}$ and $Q_{ub}^i = Q^i + Q_{B}^{max}$ denote the lower and upper bounds respectively for total reactive power.

To summarize, the optimization problem for performing arbitrage and penalization PF violations and its associated constraints are given as

\[
(P_{pla}) \quad \min_{P_B, Q_B} \sum_{i=1}^{N} \{p_{elec}^i P_B^i + \theta(i)\}
\]

Note that while our approach uses linear costs for PF violations, the methodology can be extended to nonlinear penalties in a similar way.
D. Minimizing converter usage with arbitrage and PFC

Power electronic converters degrade with usage [41]. It is in the best interest of energy storage owners to minimize the converter operation, measured in apparent power output, to expand their lifetime. In order to emulate this we propose addition of converter usage component in the objective function of the new optimization problem ($P_{\text{conv}}$). The new objective function consists of three components: (a) increase arbitrage gains, (b) reduce PF penalty and (c) reduce converter usage and is given as

$$
\min_{P_{\text{elec}}, Q_B} \sum_{i=1}^{N} \{p_{\text{elec}} P_B^i + \theta(i) + \beta ((P_B^i)² + (Q_B^i)²) \}
$$

The optimization problem ($P_{\text{conv}}$) is subject to the same constraints as ($P_{\text{plt}}$).

IV. MODELING UNCERTAINTY

The previous section discussed arbitrage and PFC under complete knowledge of future net loads and prices. In this section, we consider the setting where future values may be unknown. To that end, we first develop a forecast model for active and reactive power and electricity price for future times, where the forecast is updated after each time step. We develop the forecasting model for net load with solar generation using AutoRegressive Moving Average (ARMA) model and electricity price forecast using AutoRegressive Integrated Moving Average (ARIMA). The details of modeling are provided in Appendix D in the supplementary material. The forecast values are fed to a Model Predictive Control (MPC) scheme [42] to identify the optimal modes of operation for storage for the current time-instance. Any of the developed schemes from the previous section can be used for the optimization inside MPC. These steps (forecast and MPC) are repeated sequentially and highlighted in online Algorithm 1: ForecastPlusMPC.

Algorithm 1 ForecastPlusMPC

**Global Inputs**: $\eta_h, \eta_m, \delta_{\text{max}}, \delta_{\text{min}}, b_{\text{max}}, b_{\text{min}}, S_B^{\text{max}}, b_0$

**Inputs**: $h, N, T, i = 0$
1. while $i < N$
2. $i = i + 1$
3. Forecast $\hat{P}, \hat{Q}$ from time step $i$ to $N$ using ARMA
4. Forecast $\hat{\eta}_{\text{elec}}$ from time step $i$ to $N$ using ARIMA
5. Co-optimize arbitrage and PFC using inputs $\hat{P}_{\text{elec}}, \hat{P}, \hat{Q}, h, \delta_{\text{max}}, \delta_{\text{min}}, \eta_h, \eta_m, S_B^{\text{max}}$
6. Find out battery output: $P_B$ and $Q_B$
7. $b^{+} = b^{-} + \left[ P_B(i) \right]^{\frac{1}{\eta_h}} - \left[ P_B(i) \right]^{-\frac{1}{\eta_m}}$
8. Update $b_0 = b^{+}$
9. end while

V. NUMERICAL RESULTS

In this section, we demonstrate the performance of our proposed optimization formulations through numerical simulations with real data. As described in Section III we consider multiple storage control policies in the presence of solar, as listed below.

- $P_{\text{arb}}$: Only arbitrage (Appendix C).
- $P_{\text{mr}}$: McCormick relaxation for arbitrage + PFC,
- $P_{\text{rh}}$: Receding horizon arbitrage + sequential PFC,
- $P_{\text{plt}}$: Arbitrage + penalized PFC,
- $P_{\text{conv}}$: Arbitrage + penalized PFC+converter usage.

The price data for our simulations is taken from NYISO [43]. The load and generation data is taken from data collected at Madeira, Portugal. We use the following performance indexes to measure the performance of our simulations:

1) **Arbitrage Gains**: effectiveness in performing arbitrage
2) **Power Factor Correction**: is gauged using 3 indices, using a prescribed PF limit of 0.9: (i) *No. of PF violations* denoted as VLT, (ii) *Mean PF*, and (iii) *Minimum PF*.
3) **Converter Usage Factor (CUF)**: measures usage as

$$
\text{CUF} = \frac{1}{N} \sum_{i=1}^{N} \sqrt{\frac{(P_B^i)^2 + (Q_B^i)^2}{S_B^{\text{max}}}}
$$

As a benchmark for PFC indices, in Table II we list the values over a representative day, for two nominal cases: (a) NSNB (no solar with no battery), and (b) SNB (solar with no battery). It is evident that with addition of solar, the PF seen by the grid deteriorates with number of PF violations increasing by 200% and minimum PF reached decreasing by 80%.

In order to rectify the PF and perform arbitrage we add inverter connected energy storage. In numerical results, we use four batteries with differing converter capacities for comparison. Their parameters are listed in Table III. For fixed battery capacity, we consider four different ramp rates, each of which is described as a ratio of battery capacity over ramp rate. For instance xC-yC ramp rate in Table III will require 1/x hours to fully charge and 1/y hours to fully discharge. By Eq. 2, the ramp rate also fixes the maximum power $P_{\text{max}}$. We define maximum converter capacity $S_B^{\text{max}}$ in terms of $P_{\text{max}}$.

We consider 4 different battery converters: (i) $S_B^{\text{max}} = \frac{P_{\text{max}}}{\eta_h}$, (ii) $S_B^{\text{max}} = 0.9P_{\text{max}}$ (i.e. under-designed), (iii) $S_B^{\text{max}} = 1.25P_{\text{max}}$ (i.e. over-designed), (iv) $S_B^{\text{max}} = 1.5P_{\text{max}}$ (i.e. over-designed). The sampling time $h$ is 15 minutes, time horizon $T$ is 24 hours and the power factor limit set is 0.9.

We compare the arbitrage gains in Table IV and PF violations in Table V respectively for different algorithms and battery settings over a day (96 time instances). Note the arbitrage gains with PFC matches with arbitrage gains for $P_{\text{arb}}$, implying performing PFC does not deteriorated energy storage’s ability to perform arbitrage. For PF violations, as expected, the no. of PF violations for $P_{\text{arb}}$ remain close to SNB. $P_{\text{mr}}$ and $P_{\text{rh}}$ are not feasible (denoted as N.F. in results) for battery with slowest ramp rate and small converter, i.e., PF violations are unavoidable. However, the other schemes
are able to reduce the number of violations drastically. In settings where feasible solution exist, all schemes considered are able to completely avoid any violation. Table VI presents

Table VI: Comparison of mean PF for 1 day

It is clear from the mentioned results that storage devices over multiple settings can be used for PFC without any noticeable loss in arbitrage gains.

Fig. 5 presents the relationship between the PF threshold, mean PF and arbitrage gains for 1C-1C battery. As the effect of PF limit on the maximum possible arbitrage gains is almost non-existent except for PF limit close to 1. This resonates with our claim that PFC and arbitrage are largely decoupled and performing PFC do not degrade energy storage’s ability to perform arbitrage. From Fig. 5 we also observe that the mean PF during the day when solar generation is available drops to 0.81 significantly lower than the mean PF for the whole day in absence of solar generation which is 0.97. Additional numerical results are presented in Appendix E. Next, we discuss results of our developed algorithms in the setting with uncertain knowledge of future variables.

![Fig. 5: Arbitrage gains and mean PF with varying PF limit for 1C-1C](image-url)
future uncertainty does not affect the power factor violations significantly. It is however true that an undersized converter for slow ramping battery have a high CUF compared to other cases.

### VI. Conclusion

In this paper, we propose optimization formulations to operate inverter connected storage devices in distribution grids for co-optimizing arbitrage and power factor correction (PFC), both with or without perfect information. For a majority of cases, we show that the arbitrage gains with PFC converge to the gains achieved when storage performs only arbitrage. The primary reason for PFC being decoupled from arbitrage gains is due to the fact that in most instances, PF can be corrected by adjusting reactive power output. This is primarily governed by converter size and unlike storage active power output, which is constrained by capacity and ramp constraint. We also observe that arbitrage gain of batteries with higher ratio of ramp rate over capacity are more sensitive to uncertainty about future variables as they face capacity constraints more frequently.

It is also noteworthy that increasing the converter size would improve the mean PF without any significant change in arbitrage gains for the same ramping battery. In the current work, we consider a stringent case of maintaining PF for every operational point, though the methodology can be extended to the case with penalties on average PF. Moreover, in future work we will research further selection of optimal converter sizes and use solar and storage converter simultaneously.
Finally we will also research directions to incorporate network power flow constraints pertaining to power and voltage limits into our work on energy storage.

APPENDIX A

DEGRADATION OF PF SEEN FROM THE SUBSTATION

We show the plots of data collected at a LV voltage substation in Madeira, Portugal. The data shows that degradation of power factor seen at the substation. The substation distributes
the single phase distributed generation on each phase such that phases are balanced. However, due to deterioration of active power demand on each phase during the day as evident in Fig. 8. This dip is not observed in the reactive power plot shown as Fig. 9.

![Active Power](image1.png)

**Fig. 8: Active power seen from the sub-station**

![Reactive Power](image2.png)

**Fig. 9: Reactive power seen from the sub-station**

![Power Factor Magnitude](image3.png)

**Fig. 10: Power factor seen from the substation**

Fig. [11] presents the zoomed in plot for Fig. [10]. Fig. [11] shows that during the day when consumers generate part of their consumption using solar PV, leading to deterioration of power factor significantly. The degradation of PF is most prominent for Phase C.

**APPENDIX B**

**MCCORMICK RELAXATIONS**

McCormick envelopes are a type of relaxation used in bi-linear nonlinear programming problems as solving non-convex problems are difficult. The McCormick envelope guarantees convexity but keeps the bounds sufficiently tight [46]. In our setting, we use it to relax bi-linear representation of absolute value operator, say \(|P_T^i| = (2z - 1)(P_T^i)\) where \(z\) denotes a binary variable equal to 1 when \(P_T^i > 0\) and zero otherwise. Let \(y = zP_T^i\) denote the bi-linear variable. We then have

\[
(2z - 1)P_T^i \geq 0 \implies 2y - P_T^i \geq 0.
\]

The McCormick relaxation for the bi-linear term is represented as follows

\[
\begin{align*}
y & \geq z_L P_T^i + P_T^i z - z_L P_L^i, \\
y & \geq z_U P_T^i + P_T^i z - z_U P_U^i, \\
y & \leq z_L P_T^i + P_T^i z - z_L P_U^i, \\
y & \leq z_U P_T^i + P_T^i z - z_U P_L^i,
\end{align*}
\]

where \(z_L, z_U\) and \(P_L^i, P_U^i\) are the lower (upper) bounds for \(z\) and \(P_T^i\) respectively. As \(z_L = 0\) and \(z_U = 1\), the above constraints simplify to

\[
\begin{align*}
y & \geq P_L^i, \quad y \geq P_T^i + P_U^i z - P_U^i, \\
y & \leq P_U^i, \quad y \leq P_T^i + P_L^i z - P_L^i.
\end{align*}
\]

The McCormick relaxation is known to be exact here as one of the variables in the bi-linear term is a binary variable.

**APPENDIX C**

**ENERGY ARBITRAGE**

Energy arbitrage refers to buying energy when the price of electricity is low and selling it when price is high in order to minimize the overall cost of energy. This can be achieved by installing energy storage devices

The price of electricity is denoted as \(p_{elec}^i\). The consumer optimization problem is given as [37]

\[
\min_{i=1}^N p_{elec}^i \left[ P_i + F_B^i \right], \quad \text{subject to: Eqs. [2] [4]}
\]
Since there is no degree of freedom in $P^i$, it is equivalent to

$$(P_{arb}) \quad \min \sum_{i=1}^N p^i_{elec} P^i_B, \quad \text{subject to: Eqs.} \ 24$$

In this problem the uncertainty will be due to variation of electricity price.

**APPENDIX D**

**FORECAST MODEL**

We define the mean behavior of past values of active power at time step $i$ as

$$P^i = \frac{1}{D} \sum_{p=1}^D P_{i-pN} \quad \forall i \in \{k, \ldots, N\}, k \geq 1, \quad (14)$$

where $N$ is the number of points in a time horizon of 1 day, and $D$ is the number of days in the past whose values are considered in calculating $P^i$.

We define the mean behavior of past values of reactive power at time step $i$ as

$$Q^i = \frac{1}{D} \sum_{p=1}^D Q_{i-pN} \quad \forall i \in \{k, \ldots, N\}, k \geq 1, \quad (15)$$

The actual value of active power is given as

$$P^i = \tilde{P}^i + X^i \quad \forall i \in \{k, \ldots, N\}, k \geq 1, \quad (16)$$

where $X^i$ represents the difference from the mean behavior.

The actual value of reactive power is given as

$$Q^i = \tilde{Q}^i + Y^i \quad \forall i \in \{k, \ldots, N\}, k \geq 1, \quad (17)$$

where $Y^i$ represents the actual difference from the mean behavior.

The forecast value of forecast variable $z$ with $\hat{M}^i$ as the difference from mean behavior is given as

$$\hat{z}^i = \hat{z}^i + \hat{M}^i \quad \forall i \in \{k, \ldots, N\}, k \geq 1, \quad (18)$$

We define $\hat{M}^i \ \forall i \in \{k, \ldots, N\}$ as

$$\hat{M}^i = \alpha_1 \hat{M}^i_{k-1} + \alpha_2 \hat{M}^i_{k-2} + \alpha_3 \hat{M}^i_{k-3} + \beta_1 \delta^1_k + \beta_2 \delta^2_k + \beta_3 \delta^3_k, \quad (19)$$

where $\delta^m_k = (z_{k-mN} - \bar{z}_{k-mN})$ and $\alpha^i, \beta^i \forall i \in \{1, 2, 3\}$ are constant. Our forecast model uses the errors in net load without storage for the past three time steps and the error in the same time step for past three days. At time step $i = k - 1$ we calculate $\hat{X}_k$ as shown in Eq. [19]. We also need to calculate $\hat{M}_{k+1}$ till $\hat{M}_N$ in order to update the forecast signal as

$$\hat{M}_N = \alpha_1 \hat{M}_{N-1} + \alpha_2 \hat{M}_{N-2} + \alpha_3 \hat{M}_{N-3} + \sum_{q=1}^3 \beta_q \delta^q_N.$$  

The weights used in ARMA model, $\alpha^i, \beta^i \forall i \in \{1, 2, 3\}$, are tuned by minimizing Eq. [20]

$$\min \sum_i \{||z^i - \hat{z}^i||^2 + ||\text{norm}([\alpha^i, \beta^i])||^1\} \quad (20)$$

We calculate $\hat{z}$ using Eq. [18]. The vector $\hat{z}$ is fed to MPC for calculating optimal energy storage actions for time step $i = k - 1$. At the time step $i = k$, we can calculate $M_k = z_k - \bar{z}_k$.

Similar steps are done for $i \in \{k+1, \ldots, N\}$, till the end of time horizon is reached.

We use AutoRegressive Integrated Moving Average (ARIMA) model of $8^{th}$ lag order and one degree of differencing for forecasting electricity price. The ARIMA model is developed using training data and tested for test dataset. Note that for price forecast the moving average window is set to zero. This model is denoted as

$$\Delta X_{t+1} = \gamma_1 \Delta X_t + \gamma_2 \Delta X_{t-1} + \ldots + \gamma_8 \Delta X_{t-7} \quad (21)$$

where $\Delta X_t = X_t - X_{t-1}$.

**APPENDIX E**

**ADDITIONAL NUMERICAL RESULTS**

We present in Fig. [12] the variation for PF for different ramp rate batteries with same converter size for the same day for $P_{plt}$. The uncorrected PF is shown in Fig. [1].

Fig. [12]: PFC + arbitrage for $S_B^{max} = P_B^{max} = \delta^{max}/\eta_{ch}$

Fig. [13] shows the variation of active power, reactive power and PF variations with and without battery.

Fig. [13]: PFC with arbitrage for four quadrant storage operation

**APPENDIX F**

**POWER FACTOR CORRECTION WITH SOLAR INVERTER**

Traditionally solar inverters in LV distribution network operate at close to unity power factor, primarily due to
no obligations to supply reactive power. This is financially sensible as the DG owner could size their solar inverter based on the maximum active power generation from rooftop solar panels. However, due to large scale DG connection the reactive power responsibilities needs to be shared. In this case study we present a special case of the power factor correction framework presented earlier for energy storage battery, modified for control of a solar inverter. The system considered here consists of a non-elastic consumer with active and reactive power demand and solar inverter with active power output governed by solar generation, thus an uncontrollable variable. The reactive power output of the solar inverter is controlled so as the power factor is corrected as much as possible. Fig. 14 shows the block diagram of the special case where consumer have solar generation interfaced with solar inverter but no storage.

![Residential Customer](image)

**Fig. 14:** Residential consumer with solar generation

The optimization problem for solar inverter for PFC can be obtained by modifying optimization problem $P_{plt}$ described for storage performing arbitrage and PFC. This optimization problem is denoted as $P_{solPFC}$.

$$
\min_{Q_r} \sum_{i=1}^{N} \theta(i),
$$

(22)

where we define penalty function $\theta(i)$ as

$$
\theta(i) = \lambda \max(0, |Q_h^i + Q_r^i| - k|P_h^i - P_r^i|).
$$

(23)

Note $P_{solPFC}$ has only $Q_r$ as the control variable and $P_h^i - P_r^i$ is known at each time instant $i$. Therefore, $|P_h^i - P_r^i|$ is a constant, we denote $M = |P_h^i - P_r^i|$. The $\max$ term can be modeled as two constraints

$$
\theta(i) \geq 0, \quad \theta(i) \geq \lambda(|Q_h^i + Q_r^i| - kM).
$$

(24)

Eq. 24 can now be reformulated as

$$
\theta(i) \geq 0, \quad \theta(i) \geq \lambda(2y_1^i - (Q_h^i + Q_r^i) - kM).
$$

(25)

For cases where penalty is not linear $P_{solPFC}$ could be solved.

Here $y_1^i$ denote bi-linear variable

$$
y_1^i = z_1^i(Q_h^i + Q_r^i),
$$

(26)

with binary variables $z_1^i, z_1^i$ is equal to 1 if the total reactive power is greater than zero, and zero otherwise. We use McCormick relaxation (see supplementary material) to convert the bi-linear term in Eq. 26 to mixed-integer linear constraints

$$
y_1^i \geq Q_h^i z_1^i, \quad y_1^i \geq (Q_h^i + Q_r^i) + Q_{ub}^i z_1^i - Q_{lb}^i
$$

$$
y_1^i \leq Q_h^i z_1^i, \quad y_1^i \leq (Q_h^i + Q_r^i) + Q_{lb}^i z_1^i - Q_{ub}^i
$$

(27)

In these equations, $Q_{lb}^i = Q_h^i - S_B^{max}$ and $Q_{ub}^i = Q_h^i + S_B^{max}$ denote the lower and upper bounds respectively for total reactive power. To summarize, the optimization problem for performing arbitrage and penalization PFC violations and its associated constraints are given as

$$
(P_{solPFC}) \min_{Q_r} \sum_{i=1}^{N} \theta(i),
$$

subject to, Eq. 3, Eq. 25, Eq. 27

The control of solar inverter for PFC has only one decision variable. Furthermore, if we assume that PF violation penalty is linear, i.e., the cost of violating is linearly proportional to the amount of violation then under such a case solar inverter can be controlled with no look-ahead.

We present an algorithm for linear PF violation penalty. In future work we will combine the control of the solar inverter with that of control of the storage inverter to maximize the arbitrage and PFC gains as well as compare it with gains from individual inverter controls.

**Algorithm 2 SolarInverterPFC**

**Inputs:** $Q_h^i, P_r^i, P_h^i, S_B^{max}$

1: Calculate $Js = |Q_h^i| - kM$
2: Calculate Slack = $(S_B^{max})^2 - (P_h^i - P_r^i)^2$.
3: if $Js \leq 0$ then
4: \hspace{1em} No PFC required as PF already within limits
5: \hspace{1em} Set reactive power output of solar inverter $Q_r^i = 0$.
6: else
7: \hspace{1em} if $Q_h^i > 0$ then
8: \hspace{2em} $Q_r^i = \max((-Q_h^i + kM, -\text{Slack})$.
9: \hspace{2em} else
10: \hspace{3em} $Q_r^i = \min(|-Q_h^i - kM|, \text{Slack})$.
11: \hspace{2em} end if
12: \hspace{1em} end if
13: Return $Q_r^i$.
