The existence and stability of the linear hydrogenic chain $H_3$ and $H^+_3$ in a strong magnetic field is established. Variational calculations for $H_3$ and $H^+_3$ are carried out in magnetic fields in the range $10^{11} \leq B \leq 10^{13}$ G with 17-parametric (13-parametric for $H^+_3$), physically adequate trial function. Protons are assumed infinitely massive, fixed along the magnetic line. States with total spin projection $S_z = -3/2$ and magnetic quantum numbers $M = -3,-4,-5$ are studied. It is shown that for both $H_3$ and $H^+_3$ the lowest energy state corresponds to $M = -3$ in the whole range of magnetic fields studied. As for a magnetic field $B \geq 10^{11}$ G both $H_3$ and $H^+_3$ exist as metastable states, becoming stable for $B \geq 1.9 \times 10^{11}$ G and for $B \geq 2.7 \times 10^{11}$ G, respectively. The excited states \(4(-4)^+, 4(-5)^+\) of $H_3$ and $H^+_3$ appear at magnetic fields $B > 7 \times 10^{11}$ and $10^{12}$ G, respectively.

Surface magnetic fields $B \sim 10^{11} - 10^{14}$ G exist for many neutron stars, while for magnetized white dwarfs the magnetic field can reach $B \sim 10^9$ G (see e.g. [1, 2]). Among these stars there are many which have atmosphere, which is mostly composed from electrons and protons while some heavy nucleus (e.g. $\alpha$, $O$, $Ne$, $C$, $Fe$) can be temperatures of order of $10 \ eV$, electrons and protons can condense into hydrogenic species, forming Hydrogen atoms and Hydrogenic molecular ions.

These enormous magnetic fields modify dramatically the structure of atoms and molecules: as the strength of the magnetic field increases the atoms and molecules become more bound and more compact, their electronic clouds get pronounced cigar-type form and eventually the charged centers are aligned on a magnetic line. Thus, the Coulomb systems become quasi-one-dimensional. Such strong magnetic fields eventually lead to the appearance of exotic charged molecular and atomic systems which do not exist without a strong magnetic field (see e.g. [3] and references therein). In particular, the pioneering studies by Ruderman [4] and, independently, by Kadomtsev-Kudryavtsev [5, 6] predicted qualitatively that finite and supposedly even infinite neutral hydrogenic (linear) chains (and Wigner crystals) could exist if magnetic fields are sufficiently strong. In particular, accurate calculations have shown that in addition to the hydrogen atom $H$ and the $H^+_2$ molecular ion, which exist for any magnetic field, at magnetic fields $B \geq 10^{11}$ G three protons situated along the magnetic line can be bound by single electron (!) forming the exotic molecular ion $H_3^{2+}$ in linear configuration [7]. Furthermore, $H_3^{2+}$ turns out to be the most bound one-electron hydrogenic system for magnetic fields $B \geq 10^{13}$ G [8]. This discovery was used later to construct a model of the atmosphere of the isolated neutron star 1E1207.4-5209 (see [8]) to explain the origin of the absorption lines at $\sim 0.7$ and $1.4 \text{KeV}$ detected by Chandra [9] and confirmed by XMM-Newton [10] X-ray observatories. It predicts the surface magnetic field of $(4 \pm 2) \times 10^{14}$ G.

For systems with two or more electrons it is known that in sufficiently strong magnetic fields the ground state appears in the configuration where all spins of electrons are antiparallel to the magnetic field direction, hence, the total spin takes its maximal value. In field free case the total spin usually does not take the maximal value. It implies that the ground state type can evolve with magnetic field strength. This phenomenon was quantitatively observed for the first time for $H_2$ molecule, where it was shown that the ground state changes from spin-singlet state $^1\Sigma_g$ at zero and weak magnetic fields to triplet unbound (repulsive) state $^3\Pi_u$ for intermediate fields $B \gsim 5 \times 10^8$ G while for larger magnetic fields $B \gsim 3 \times 10^{10}$ G the ground state is the spin-triplet state $^3\Pi_u$ [11] (and references therein). It implies that in this domain $H_2$ molecule is unstable towards dissociation $H + H$. As for the molecular ion $H^+_3$ in a strong magnetic field in linear parallel configuration (aligned with the magnetic field direction) the ground state of $H^+_3$ changes from spin-singlet $^1\Sigma_g$ state to weak magnetic fields $B \gsim 5 \times 10^8$ G (at magnetic fields close to zero the ground state of $H^+_3$ is equilateral triangular configuration in spin-singlet state, it is the most bound hydrogenic specie) to a weakly-bound spin-triplet $^3\Pi_u$ for intermediate fields and, eventually, to spin-triplet state $^3\Pi_u$ for magnetic fields $B \gsim 10^{10}$ G, it is always stable [12]. The list of one-, two-electron hydrogenic systems, which can exist in a strong magnetic field being stable, is given in [3, 13].

In general, it is known very little about atomic-molecular systems with three electrons in a strong magnetic field. In particular, the neutral hydrogenic chain $H_3$ was studied in [14] along with finite hydrogenic chains $H_{3n}, n=2,3,4,...$ in strong magnetic fields $B \geq 10^{11}$ G in sophisticated multiconfigurational Hartree-Fock method. The accuracy obtained was limited, grossly overestimated and in some cases the results were indicated as non-reliable (spurious), the question of the existence and stability was never discussed. We are not aware on any studies of negative hydrogenic molecular ion $H^+_3$.

In present Letter the linear molecular chain $H_3$ and the $H^+_2$ ion are studied in a strong magnetic field being
The main goal of the study is to localize the domain of existence and stability of $H_3$ and $H_2^-$ in strong magnetic fields. We consider two main dissociation channels for both $H_3$: (i) $H_3 \rightarrow H^- + H$, (ii) $H_3 \rightarrow H^+_3 + e$, and $H_2^-$: (iii) $H_2^- \rightarrow H^- + H$, (iv) $H_2^- \rightarrow H^- + e$. Dissociation energies are defined accordingly, $E_{\text{diss}}^{(i)} = E_{T}^{H_2^- + H} - E_{T}^{H_3}$, $E_{\text{diss}}^{(ii)} = E_{T}^{H_3^+ + e} - E_{T}^{H_3}$, and $E_{\text{diss}}^{(iii)} = E_{T}^{H^- + H} - E_{T}^{H_2^-}$, $E_{\text{diss}}^{(iv)} = E_{T}^{H^- + e} - E_{T}^{H_2^-}$. Note that writing about dissociation we ignore the conservation of total angular momentum projection due to possible presence of photon(s) in the final state and assume each of the final products is in the lowest energy state. The energy of a free electron in a magnetic field with $S_z = -1/2$ is zero (see 10 for details). The lowest longitudinal vibrational states around the equilibrium configuration of the ground state are briefly studied.

Atomic units are used throughout ($\hbar = m_e = e = 1$) in making calculations. For the magnetic field $B$ written in a.u. the conversion 1 a.u. = $2.35 \times 10^9$ G is used, as for the energy 1 a.u. = 27.2 eV.

Generalities. The Hamiltonian describing the Coulomb system of three electrons and three aligned (infinitely) massive charged centers $A, B, C$ subject to a constant uniform magnetic field, parallel to the molecular axis $B = B \hat{z}$, is given by

$$H = -\sum_{i=1}^{3} \left( \frac{1}{2} \Delta_i + \sum_{\eta=1}^{3} Z_{\eta} \frac{1}{r_{i\eta}} \right) + \sum_{i<j}^{3} \frac{1}{r_{ij}} + \frac{B^2}{8} \sum_{i=1}^{3} r_i^2 + \frac{B}{2} (L_z + 2S_z) + \frac{Z_A Z_h}{R_{+}} + \frac{Z_A Z_C}{R_{+}} + \frac{Z_C Z_h}{R_{+}} + \frac{Z_h Z_C}{R_{+}},$$

where $\Delta_i$ is Laplacian for the $i$-th electron, $i = 1, 2, 3$. $Z_{A, B, C} = 1$ are the charges of the heavy centers, $\eta = A, B, C$ (protons). The term $-\frac{Z_h}{r_{i\eta}}$ corresponds to the Coulomb attractive potential between the electron $i$ and the nuclei $\eta$ with $r_{i\eta}$ being the electron-nucleus distance. The term $\frac{1}{r_{ij}}$ stands for the inter-electron repulsion between electrons $i$ and $j$, where $r_{ij}$ is the distance between electrons. In turn, $\frac{Z_A Z_h}{R_{+}}$ and $\frac{Z_A Z_C}{R_{+}}$ are the classical Coulomb repulsion energy terms between the (fixed) $A, B, C$ nuclei. The internuclear (classical) distances are $R_{+}$ and $R_{-}$ (see Fig.1). The Hamiltonian (1) includes the Zeeman terms $\frac{1}{2} B \cdot L = \frac{1}{2} B L_z$, and $\frac{3}{2} B \cdot S = B S_z$ (with the g-factor, $g = 2$) and the diamagnetic terms $\frac{B^2}{8} r_i^2$, where $\mu_i^2 = x_i^2 + y_i^2 + z_i^2$, $(i = 1, 2, 3)$ is the transverse distance (squared) between the $i$-th electron and the molecular axis. Putting $Z_h = 0$ the Hamiltonian (1) describes the 3-electron 2-center system in a magnetic field which may correspond to $H_2^-$ molecule.

For the linear $H_3$ molecule the equilibrium configuration was assumed symmetric: $R_+ = R_- \equiv R$, it is confirmed by calculations. In this configuration the Hamiltonian (1) is invariant under transformations $z_1, z_2, z_3 \rightarrow -z_1, z_2, z_3$, and also invariant under rotation around the molecular axis. Thus, the conserved quantities we take into account are: the parity ($\pm$) w.r.t. to $z \rightarrow -z$, see Fig.1, the $z$-component of the total angular momentum $M_z$ (magnetic quantum number), the total electronic spin $S$ and its projection $S_z$ along the $z$-axis. These conserved quantities characterize the state of the system in the standard spectroscopic notation $S_z \pm \frac{1}{2} (M_z)$. The variational method is applied to find the energy of some low-lying states using a trial function based on physics relevance criteria. These trial functions allow us to reproduce both the Coulomb singularities and the correct asymptotic behavior of the potential at large distances (see, e.g. 13).

Trial Function. The orbital (spatial) part of the trial function is proposed as a product of screened lowest Coulomb orbitals, Landau orbitals and exponential correlation factors:

$$\psi(r_1, r_2, r_3) = e^{\alpha_1 z_1 + \alpha_2 z_2 + \alpha_3 z_3 + \alpha_2 r_2} \times \left( \prod_{k=1}^{3} \rho_k \right)^{m_k} e^{i m_k \phi_k - i \alpha_k r_k - i \alpha_2 r_2 - i \alpha_3 r_3} e^{-\frac{i}{2} \beta(k)^2} \phi_k^2,$$

where $\rho_k$, $\phi_k$ are the radial/angular cylindrical coordinates of the $k$-th electron with the magnetic quantum number $m_k$, $k = 1, 2, 3$. In turn, the parameters $\alpha_{k\eta}$, $\alpha_{ij}$ with $i < j = 1, 2, 3$, $\eta = A, B, C$ are screened effective charges, $\beta_{1, 2, 3}$ measure screening of the magnetic field, the classical internuclear distances $R_{\pm}$ are taken as variational parameters. The total number of variational parameters in (2) is 17 (13 as for $H_2^-$).

For states of total spin $S = 3/2$ with projection $S_z = -3/2$, the spin part of the trial function is $\chi = \beta(1) \beta(2) \beta(3)$, where $\beta(k)$, $k = 1, 2, 3$ represents...
the $S = 1/2$ spinor of the $k$-th electron with negative spin projection. Thus, the properly symmetrized total wave function is given by

$$\Psi(r_1, r_2, r_3) = (1 + \sigma_N \hat{P}_{AC})\tilde{A}[\psi(r_1, r_2, r_3)\chi],$$

(3)

where $\hat{P}_{AC}$ is the operator of permutation of the two end nucleus $A$ and $C$ (see Fig.1), and $\sigma_N = \pm 1$ is $z$-parity. The operator $\tilde{A}$ is the three particle antisymmetrizer

$$\tilde{A} = 1 - \hat{P}_{12} - \hat{P}_{13} - \hat{P}_{23} + \hat{P}_{231} + \hat{P}_{312},$$

acting on the coordinates of the electrons. Here $\hat{P}_{ij}$ is the operator of permutation of the electrons $i \leftrightarrow j$, and $\hat{P}_{ijk}$ stands for the permutation of $(123)$ into $(ijk)$.

Numerics for the calculation of the variational energy is described in [16]. Computations were performed in parallel using the cluster Karen (ICN-UNAM) with 120 Intel Xeon processors at $\sim 2.70$ GHz.

**Results.** Variational calculations of the system $(3p, 3e)$ and $(2p, 3e)$ in parallel configuration, see Fig.1, for magnetic fields $10^{11} \lesssim B \lesssim 10^{13}$ G are carried out using the trial function [2] for spin-quartet states with total spin $3/2$ and for total magnetic quantum numbers $M = -2, -3, -4, -5$. For $M = -2$ both systems are unbound: one electron always goes to infinity in $z$-direction. In all other cases we find bound states with a well pronounced minimum in the energy at finite nuclear distances at $R_+ = R_-$ for H$_3$ and for H$_2^-$ systems. It is seen that the total energy and the equilibrium internuclear distances of H$_3$ and H$_2^-$ decrease monotonously with the magnetic field increase, the systems become more bound and compact, see Table IV and VIII respectively. Among the states we study the state with $M = -3$ when the magnetic quantum numbers are $m_1 = 0, m_2 = -1, m_3 = -2$ (being in agreement to the Pauli principle, it guarantees zero Pauli force) realizes the ground state of both H$_3$ and H$_2^-$. Taking different combinations of $m_i$ keeping $M = -3$ in [2] does not improve the energies. States with $M = -4, -5$ always lie above the ground state $^4(-3)^+$. Note that for this state the equilibrium distance is smallest with respect to other states, see Table IV and VIII. Dissociation energies as well as lowest longitudinal vibrational energies are presented in Table VIII and Table XIV. Systematically, the total energies for H$_3$ are smaller than ones calculated in [12], while equilibrium distances are comparable.

For $B \gtrsim 10^{11}$ G the molecule H$_3$ is always stable towards the dissociation channel (i) $^1$H$_2^+ + e$, see Table VIII. However, as for the channel (ii) $^1$H$_3 \rightarrow$ H$_2 + H$ there is a critical magnetic field, where dissociation energy for the ground state vanishes,

$$B_{c}^{H_2}(0) \sim 1.9 \times 10^{11} \text{G},$$

(4)

It indicates that the linear molecular chain H$_3$ always exists, it becomes stable at $B > B_{c}^{H_2}(0)$ being metastable for smaller magnetic fields. The stability of the linear molecule H$_3$ was checked towards longitudinal symmetric vibrations (s), $R_+ = R_-$ and antisymmetric vibrations (a) $R_+ \neq R_-$. The lowest vibrational energy of the symmetric mode $E_{vib}^{(s)}$ are always smaller than those of the antisymmetric mode $E_{vib}^{(a)}$. Both energies increase with the magnetic field growth, see Table VIII. For $B \gtrsim 5 \times 10^{11}$ G the dissociation energies are always larger than the sum of the lowest vibrational energies, hence, the potential energy surface contains, at least, one vibrational state.

As for H$_2^-$ ion the total energies, equilibrium distances and dissociation energies as well as lowest longitudinal vibrational energy are presented in Table VIII. For $B \sim 10^{11}$ G H$_2^-$ is unstable towards both channels (iii) and (iv). However, at the magnetic field $B \sim 2.35 \times 10^{11}$ G the channel (iii) gets forbidden while the channel (iv) is still open. With magnetic field increase at

$$B_{c}^{H_2^-}(0) \sim 2.7 \times 10^{11} \text{G},$$

(5)

this channel gets also forbidden and H$_2^-$ becomes stable, being metastable for smaller magnetic fields. The lowest vibrational energy increases with the magnetic field growth. Potential energy surface contains, at least, one vibrational state in all range of magnetic fields studied.

**Excited States.** The excited states $^4(-4)^+, ^4(-5)^+$ were studied for both H$_3$ and H$_2^-$. For $B \gtrsim 10^{11}$ G both states are bound for both systems. It was checked that minimal energy for H$_3$ always corresponds to symmetric configuration $R_+ = R_-$. The total energy and the equilibrium internuclear distance $R_{eq}$ for H$_3$ and H$_2^-$ are presented in Table XIV and XVI respectively. For both states $^4(-4)^+, ^4(-5)^+$ for each system there exist critical magnetic fields, see below section Conclusions, for which they become stable with respect to dissociation $H_3 \rightarrow H_2 + H$ and $H_2^- \rightarrow H_2 + e$, correspondingly.

**Conclusions.** We have shown that trihydrogen molecule H$_3$ in the form of linear chain exists for $B \gtrsim 10^{11}$ G with the ground state $^1(-3)^+$. It becomes stable towards dissociation for magnetic fields larger than the critical magnetic field $B_{c}^{H_3}(0) \approx 1.9 \times 10^{11} \text{G}$, it also remains stable towards small longitudinal vibrations. Its first excited state $^4(-4)^+$ is always bound and appears stable towards dissociation at $B_{c}^{H_3}(1) \sim 6.9 \times 10^{11} \text{G}$, while the second excited state $^4(-5)^+$ is stable towards dissociation for $B \gtrsim B_{c}^{H_3}(2) \sim 1.2 \times 10^{12}$ G. It excludes a qualitative prediction [3] about existence of infinite hydrogenic chain (and Wigner crystal) for magnetic fields $B < B_{c}^{H_3}(0)$ and, in fact, $\lesssim 10^{12}$ G. For any available strong magnetic field the absorption due dissociation of H$_3$ occurs at less than 100 eV, hence, could not be detected by Chandra or XMM X-ray observatories. As for linear molecular chain H$_4$ one can estimate following the results of [13] for H$_2$, Table VIII for H$_3$ and [14] for H$_4$ that it becomes stable for $B \gtrsim 10^{12}$ G.
