We propose an experimental setup for the determination of the effective Cooper pair mass \( m^* \) by electrostatic doping of Abrikosov vortices of a superconductor surface. To that end, a superconductor is placed in a constant external magnetic field, perpendicular to the superconducting planes. One of the electrodes is connected to the superconductor, while another one forms a capacitor with the superconductor itself. The nature of the insulator is irrelevant to the experiment. In some sense our experiment aims to measure a new effect. After applying alternating voltage to the capacitor, electrostatic induction leads to oscillations of the magnetic moment. Those oscillations are detected by electromotive force inducted in a detector coil. The electric charges accumulated on the superconducting surface are partially superfluid and contribute to the magnetic field of the vortices. In addition to \( m^* \), this experiment would determine the sign of the Cooper pair charge.

Without the effective Cooper pair mass \( m^* \), the physics of superconductivity is Hamlet without the prince, only with the role of Ophelia performed by onnagata [1]. The purpose of the present work is to suggest a simple method which may lead to developments of Cooper pair mass spectroscopy applicable for type-II superconductors.

To that end, let us consider a superconducting film or slab of \( \text{YBa}_2\text{Cu}_3\text{O}_7 \) or \( \text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_8 \) with thickness \( d_{\text{film}} \), and surface \( S \) in an external electromagnetic field and a superconducting current around a single Abrikosov vortex formed within the film. Using a first level Bohr quantization, the Cooper pairs’ angular momentum around the vortex is given by

\[
m^* rv = h,
\]

where \( m^* \) is the effective Cooper pair mass in the plane of the film, \( r \) is the radial distance from its center and \( v \) is the velocity of circulating fluid of Cooper pairs. Eq. (1) is valid in the range \( \xi \ll r \ll \lambda \), where \( \xi \) is the coherence length and \( \lambda \) is the penetration depth

\[
\frac{1}{\lambda^2(T)} = \frac{e^2 n_{\text{3D}}(T)}{\varepsilon_0 e^2 m^*},
\]

where in Gaussian system \( \varepsilon_0 = 1/4\pi \). The magnetic moment per unit film thickness of this single vortex is then given by cf. [2]

\[
\frac{M_1}{d_{\text{film}}} = \int_\xi^\lambda r^2 j dr = \int_\xi^\lambda r^2 n_{\text{3D}} e^* v dr,
\]

where \( j = n_{\text{3D}} e^* v \). We consider thick films \( d_{\text{film}} > \lambda \) or even slabs of a type-II superconductors. Expressing \( v(r) \) from the Bohr quantization condition Eq. (1) and substituting it in Eq. (3), after integration we obtain the the magnetization of a single vortex per unit film thickness

\[
\frac{M_1}{d_{\text{film}}} = \frac{n_{\text{3D}} \pi \hbar}{2} \left( \frac{e^*}{m^*} \right) (\lambda^2 - \xi^2).
\]

The magnetic moment of a single vortex piercing the superconducting slab is \( M_1 \) and \( M_1/d_{\text{film}} \) has dimension magnetic moment per unit length. We can neglect \( \xi^2 \) in Eq. (1) as \( \xi \) is assumed to be a small quantity, i.e. we suppose type-II superconductor with \( \kappa \equiv \lambda/\xi \gg 1 \). For magnetic fields much smaller than upper critical field \( B < B_{c2} \) the vortices with area density \( B/\Phi_0 \) and total number \( N = BS/\Phi_0 \) are weakly overlapping and the total magnetic moment of the sample is given by the sum of individual magnetic moments

\[
\mathcal{M} = N M_1 = \frac{\Phi}{\Phi_0} M_1 = \left( \frac{M_1}{d_{\text{film}}} \right) \frac{B}{\Phi_0} V,
\]

where we recognize the volume of the film \( V = d_{\text{film}} S \) and the total magnetic flux of the magnetic field (assumed to orthogonal to the film) \( \Phi = BS \). For the magnetic moment per unit area of the sample we have

\[
\frac{M}{S} = \frac{M_1}{\Phi_0} = \frac{1}{4} \left( \frac{e^2}{m^*} \right) n_{\text{3D}} d_{\text{film}} \lambda^2(T) B,
\]

where \( \Phi_0 = 2\pi\hbar/|e^*| \) is the flux quantum and \( e^* \) is the Cooper pair charge \( |e^*| = 2|e| \). One additional speed of light has to be added in the denominator in Gaussian system. The multiplier \( n_{\text{3D}}(T) = d_{\text{film}} n_{\text{3D}}(T) \) is the temperature dependent two dimensional (2D) density of the superfluid charge carriers. As pointed out above, this result for the magnetization is a good approximation when the magnetic field is much smaller than the upper critical field \( B < B_{c2}(T) \). Substituting Eq. (2) in the approximation Eq. (3) and recognizing once again the volume of the film, we arrive at the simpler result for the magnetization

\[
M \equiv \frac{\mathcal{M}}{V} \approx \frac{B}{4\mu_0}, \quad \mu_0 = 1/\epsilon_0 e^2.
\]

This law can be observed field cooling regime. For comparison for Meissner-Ochsenfeld (MO) phase we have \( M_{\text{MO}} = -B/\mu_0 \). In Gaussian system we have to substitute \( \mu_0 = 4\pi \) while in Lorentz–Heaviside units \( \mu_0 = 1 \) and \( \epsilon_0 = 1 \). For a slab in perpendicular field the demagnetizing factor is \( n = 1 \) and for all magnetic fields \( B \) in interval \((0, B_{c2})\) the sample is in vortex state.
The set-up we propose consists of a plane capacitor whose plates are perpendicular to an external magnetic field; see Fig. 1. The Capacitor is placed in a detector coil. One of the plates is the superconductor with an atomically clean surface. The other plate’s properties are not considered additionally. An AC voltage is applied to the plates, resulting in a modulation of the Abrikosov lattice magnetic moment, which can be registered by a detector coil.

![Detector coil](image)

**FIG. 1.** A schematic representation of the proposed setup. A crystal slab of Bi$_2$Sr$_2$CaCu$_2$O$_8$ is connected with an alternating voltage source through a lateral contact. The cleaved surface of the superconductor forms one of the plates of a capacitor. The superconductor surface is covered by an insulator, on which a metal layer is evaporated, acting as the second plate of the capacitor. The system is placed in an external magnetic field which is perpendicular to the capacitor plates. The magnetic moment is detected by a detector coil of a magnetometer. The U-shaped ferrites, permanent magnet, signal generator, preamplifier, and lock-in are not depicted.

The scenario considered has one crucial difference as compared to that leading to Eq. [6], the voltage difference makes the whole film act as a capacitor and there is additional 2D charge density being accumulated due to this field. Recalling the connection between surface charge density $\rho_{2D}$ and the normal component of electric induction $D \cdot dS = \rho_{2D} |dS|$ and simplifying it in the case of our geometry, we see that the additional charge accumulated will be the $z$-components of the electric induction $D_z$ for a temperature tending to 0 (we have assumed the $z$-component to be parallel to the film thickness). In the case of a finite temperature, we can form the dimensionless ratio which coincides with the percent of the superfluid carriers $C(T) = n_{2D}(T)/n_{2D}(0) = \lambda^2(0)/\lambda^2(T)$. Recalling once again the formula for the penetration depth given by Eq. (2), Eq. (6) should be corrected simply by a substitution of the two dimensional (2D) superfluid charge per unit area, which is the modulated electric field

$$e^* n_{2D}(T) = e^* d_{\text{film}} n_{3D}(T) + D_z \frac{\lambda^2(0)}{\lambda^2(T)}.$$  

(8)

Here we can recognize the total electric charge induced on the superconductor surface $Q = S D_z$. Applying alternating current to the superconductor surface, we have $I(t) = \omega Q_0 \cos(\omega t)$ modulating charge oscillations $Q(t) = Q_0 \sin(\omega t)$ and simultaneously measure the time dependent magnetic moment $M(t) = M_0 \sin(\omega t)$, the effective mass of Cooper pairs can be expressed by the ratio of the amplitudes

$$m^* = \frac{e^* B \lambda^2(0)}{4 \left| \frac{dM}{dQ} \right|} = \frac{e B \lambda^2(0) Q_0}{2 \text{sgn}(e^*) M_0},$$  

(9)

where the derivative here is at constant magnetic field and the ratio $M_0/Q_0$ is actually the slope of a linear regression when the electrostatic doping is due to different voltages. The cancellation of the temperature dependent $\lambda^2(T)$ suggests that the parameter determined in this way will have weak temperature dependence. This result allows us to measure the effective Cooper pair mass $m^*$ through the experimental setup presented in Fig. 1 by measuring the change in the magnetic moment of the sample induced by the accumulation of charge due to a voltage generator, all of which happening in the external magnetic field $B$ perpendicular to the film. Since the effective mass is positive, the method simultaneously determines the sign of the Cooper pair charge $\text{sgn}(e^*)$.

From a technological point of view we emphasize that it is not necessary to make contacts on the ab-plane of Bi$_2$Sr$_2$CaCu$_2$O$_8$. This face, which is easily cleaved is one of the plates of the already mentioned plane capacitor and it has to be atomically clean. Contact has to be made on the lateral ac- or bc-plane, which is a relatively simple task. The dielectric material between the plates of the capacitor does not have any specific contribution to the effect, which should be observable even for plain air. In such a way the proposed experiment can be easily performed in every laboratory related to the physics of superconductivity, it is only necessary to have a single Bi$_2$Sr$_2$CaCu$_2$O$_8$ crystal.

The effective mass of a charge carrier is a parameter of a dynamical theory and requires electric field due to the gauge-invariant time derivatives $i\hbar \partial_t - e \varphi$. The electric field should be present on the interface between a superconductor and an insulator and the proposed experiment requires extremely clean interfaces. The proposed experiment utilizes the electrostatic doping of fluxons surface to measure this crucial parameter in the physics of Superconductivity. A carefully prepared structure of Kapton on YBa$_2$Cu$_3$O$_7$ was the system used for the first determination of the effective mass of Cooper pairs [3]. We believe, however, that Bi$_2$Sr$_2$CaCu$_2$O$_8$, which is easily cleaved by adhesive tape surfaces will catalyze the development of Cooper pair mass spectroscopy. Next step would be a systematic investigation of thick films $d_{\text{film}} > \lambda$ of technological superconductor alloys.
