Abstract
We present a variant of the quantum relational Hoare logic from (Unruh, POPL 2019) that allows us to use “expectations” in pre- and postconditions. That is, when reasoning about pairs of programs, our logic allows us to quantitatively reason about how much certain pre-/postconditions are satisfied that refer to the relationship between the programs inputs/outputs.

1 Introduction
Relational Hoare logics (RHL) are logics that allow us to reason about the relationship between two programs. Roughly speaking, they can express facts like “if the variable \( x \) in program \( c \) is equal to \( x \) in program \( d \), then after executing \( c \) and \( d \), respectively, the content of variable \( y \) in program \( c \) is greater than that of \( y \) in \( d \).” RHL was introduced in the deterministic case by [Ben04], and generalized to probabilistic programs by [BGZ09] (pRHL) and to quantum programs by [Unr19] (qRHL). RHLs have proven especially useful in the context of verification of cryptographic schemes. For example, the CertiCrypt tool [BGZ09, Cer] and its successor EasyCrypt [Bar+11, Bar+14] use pRHL to create formally verified cryptographic proofs. And [Unr18] implements a tool for verifying quantum cryptographic proofs based on qRHL.

*Presented at ICALP 2021 [LU21]
On the other hand, “normal” (i.e., not relational) quantum Hoare logics have been developed in the quantum setting, starting with the predicate transformers from [DP06], see [Fen+07; Yin12; CMS06; Kak09]. Out of these, [DP06; Fen+07; Yin12] use “expectations” instead of “predicates” for the pre- and postconditions of the Hoare judgments. To understand the difference, consider the case of classical probabilistic programs. Here, a predicate is (logically equivalent to) a set of program states (and a program state is a function from variables to values). In contrast, an expectation is a function from program states to real numbers, basically assigning a value to each program state. Probabilistic Hoare logic with expectations, implicit in [Koz83], uses expectations as the pre- and postconditions of a Hoare judgment. Then, roughly speaking, the preexpectation tells us what the expected value of the postexpectation is after running the program. This can be used to express much more fine-grained properties of probabilistic programs, giving quantitative guarantees about their probabilistic behavior, instead of just qualitative (a certain final state can or cannot occur). As [DP06] showed, the same approach can be used for quantum programs. Here, an expectation is modeled by a self-adjoint operator $A$ on the space of all program states. The “value” of a given program state $\rho$ is then computed as the trace $\text{tr} A \rho$. While at the first glance not as obvious as the meaning of classical expectations, this formalism has nice mathematical properties and is also equivalent to taking the expectation value of the outcome of a real-valued measurement. By using this approach, [DP06; Fen+07; Yin12] can express more fine-grained judgments about quantum programs, by not just expressing which final states are possible, but also with what probabilities.

Yet, qRHL [Unr19] did not follow this approach (only mentioning it as possible future work). As a consequence, qRHL does not enable as fine-grained reasoning about probabilities as the non-relational quantum Hoare logics. On the other hand, the non-relational quantum Hoare logics do not allow us to reason about the relationship between programs.

In this work, we combine the best of two worlds. We present a variant of qRHL, expectation-qRHL, that reasons about pairs of programs, and at the same time supports expectations as the pre- and postconditions, thus being as expressive as the calculi from [DP06; Fen+07; Yin12] when it comes to the probabilistic behavior of the programs.

Related work. The relevant prior work has already been discussed above. Concurrently and independently, [Bar+19] presented a different formalization of expectation-qRHL. (The first versions on arXiv appeared within two months of each other.) The biggest difference is the definition of couplings which in our setting are separable quantum states, and in their setting nonseparable quantum states. Therefore, the soundness proofs are totally different in [Bar+19] and in the present paper, even for the same rules. As a consequence, we can avoid having to reason about judgments with side-conditions, making compositional reasoning about more complex programs much easier (see Appendix A). A unique contribution of the present paper is that relational properties between non-terminating programs can be proved in our logic, while the logic in [Bar+19] is mainly designed for terminating programs. We give a detailed technical comparison with [Bar+19] in Appendix A.

Organization. In Section 2 we introduce notation and preliminaries, including the concept of expectations. In Section 3 we give syntax and semantics of the imperative quantum programming language that we study. In Section 4 we give the definition of expectation-qRHL. In Section 6, we give the soundness proofs of all our rules. In Section 5, we present sound rules for reasoning about expectation-qRHL judgments. And in Section 7, we analyze the quantum Zeno effect as an example of using our logic.

In Appendix A, we give a detailed comparison of our logic with [Bar+19].
2 Preliminaries: Variables, Memories, and Predicates

In this section, we introduce some fundamental concepts and notations needed for this paper, and recap some of the needed quantum background as we go along. When introducing some notation $X$, the place of definition is marked like this: $\llbracket X \rrbracket$. All symbols are listed in the symbol index. For further mathematical background we recommend [Con97; Con00], and for an introduction to quantum mechanics [NC10].

Variables. Before we introduce the syntax and semantics of programs, we first need to introduce some basic concepts. A \textit{variable} is described by a variable name $x, y, z$ that identifies the variable, and a nonempty type $T$. The \textit{type} of $x$ is simply the nonempty set of all (classical) values the variable can take. E.g., a variable might have type $\{0, 1\}$, or $\mathbb{N}_1$. Lists or sets of variables will be denoted $X, Y, Z$. Given a list $X = x_1 \ldots x_n$ of variables, we say its \textit{type} is $T_1 \times \cdots \times T_n$ if $T_i$ is the type of $x_i$. We write $\llbracket XY \rrbracket$ for the concatenation/disjoint union of lists/sets of variables $X, Y$.

Memories and quantum states. An \textit{assignment} assigns to each variable a classical value. Formally, for a set $X$, the \textit{assignments over} $X$ are all functions $m$ with domain $X$ such that: for all $x \in X$ with type $T_x$, $m(x) \in T_x$. That is, assignments can represent the content of classical memories.

To model quantum memories, we simply consider superpositions of assignments: A (pure) \textit{quantum memory} is a superposition of assignments. Formally, $\ell^2[X]$, the set of all quantum memories over $X$, is the Hilbert space with basis $\{\ket{m}\}_m$ where $m$ ranges over all assignments over $X$. Here $\ket{m}$ simply denotes the basis vector labeled $m$. We often write $\ket{m}_X$ to stress which space we are talking about. We call a quantum memory $\psi$ \textit{normalized} iff $\|\psi\| = 1$. Intuitively, a normalized quantum memory over $X$ represents a state a quantum computer with variables $X$ could be in. We also consider quantum states over arbitrary sets $X$ (as opposed to sets of assignments). Namely, $\ell^2(X)$ denotes the Hilbert space with orthonormal basis $\{\ket{x}\}_{x \in X}$. (In that notation, $\ell^2[X]$ is simply $\ell^2(A)$ where $A$ is the set of all assignments on $X$.) Normalized elements of $\ell^2[X]$ represent quantum states.

We often treat elements of $\ell^2(T)$ and $\ell^2[X]$ interchangeably if $T$ is the type of $X$ since there is a natural isomorphism between those spaces.

In many situations, we additionally need an additional symbol $\bot$ that denotes that a memory is not available because the program did not terminate. A \textit{quantum $\bot$-memory over} $X$ is an element of $\ell^2[X] \bot := \ell^2(A \cup \{\bot\})$ where $A$ is the set of all assignments on $X$. That is, a quantum $\bot$-memory is a superposition between a quantum memory and $\ket{\bot}$.

The tensor product $\otimes$ combines two quantum states $\psi \in \ell^2(X), \phi \in \ell^2(Y)$ into a joint system $\psi \otimes \phi \in \ell^2(X \times Y)$. In the case of quantum memories $\psi, \phi$ over $X, Y$, respectively, $\psi \otimes \phi \in \ell^2[XY]$. (And in this case, $\psi \otimes \phi = \phi \otimes \psi$ since we are composing “named” systems.)

We will need to consider entangled pairs of memories. Specifically, a \textit{quantum bimemory over} $X_1, X_2$ is an element of $\ell^2[X_1] \otimes \ell^2[X_2] = \ell^2[X_1X_2]$. Similarly, a \textit{quantum $\bot$-bimemory} is an element of $\ell^2[X_1]^\bot \otimes \ell^2[X_2]^\bot$, i.e., a tensor product of two quantum $\bot$-memories. (Note: “one-sided-$\bot$” states such as $\ket{m} \otimes \ket{\bot}$ are included in this.) For clarity, we often write $\ket{\bot_1}, \ket{\bot_2}$ instead of $\bot$ to emphasize whether we are talking about elements of $\ell^2[X_1]^\bot$ or $\ell^2[X_2]^\bot$.

For a vector (or operator) $a$, we write $a^*$ for its adjoint. (In the finite dimensional case, the adjoint is simply the conjugate transpose of a vector/matrix. The literature also knows the

\footnote{We stress that we do not assume that the type is a finite or even a countable set. Consequently, the Hilbert spaces considered in this paper are not necessarily finite dimensional or even separable. However, all results can be informally understood by thinking of all sets as finite and hence of all Hilbert spaces as $\mathbb{C}^N$ for suitable $N \in \mathbb{N}$.

\footnote{When we say “basis”, we always mean an orthonormal Hilbert-space basis.}
Mixed quantum memories. In many situations, we need to model probabilistic quantum states (e.g., a quantum state that is |0⟩ with probability 1/2 and |1⟩ with probability 1/2). This is modeled using mixed states (a.k.a. density operators). Having normalized state ψi with probability pi is represented by the operator ρ := ∑i pi proj(ψi). In particular, proj(ψ) is the density operator of a pure quantum state ψ. Then ρ encodes all observable information about the distribution of the quantum state (that is, two distributions of quantum states have the same ρ iff they cannot be distinguished by any physical process). And tr ρ is the total probability ∑i pi. Note that we do not formally impose the condition tr ρ = 1 or tr ρ ≤ 1 unless explicitly specified. We call a mixed state normalized iff tr ρ = 1. We will often need to consider mixed states of quantum memories (i.e., mixed states with underlying Hilbert space ℓ²(𝑋)). We call them mixed (quantum) memories over 𝑋. Analogously, we define mixed bimemories and mixed ⊥-bimemories as mixed states of quantum (⊥-)bimemories.

Let $P_\perp := \text{proj}(⊥)$ and $P_\perp^\perp := \text{id} - P_\perp$. We can easily access the terminating and nonterminating part of a mixed ⊥-memory: $\downarrow_\perp(\rho) := P_\perp \rho P_\perp$ and $\downarrow_\perp'(\rho) := P_\perp^\perp \rho P_\perp^\perp$ are the memory ρ after measuring that we have termination or do not have termination, respectively.

For a mixed (⊥-)bimemory ρ over $𝑋_1 𝑋_2$ the partial trace $\text{tr}_i(\rho)$ (𝑖 = 1, 2) is the result of throwing away the left/right memory (i.e., it is a mixed memory over $𝑋_𝑖$). Formally, $\text{tr}_i$ is defined as the continuous linear function satisfying $\text{tr}_1(\sigma ⊗ \tau) := \tau \cdot \text{tr} \sigma$, $\text{tr}_2(\sigma ⊗ \tau) := \sigma \cdot \text{tr} \tau$.

A mixed memory ρ is $(𝑋, 𝑌)$-separable (i.e., not entangled between 𝑋 and 𝑌) iff it can be written as $ρ = ∑_i p_i ⊗ ρ'_i$ for mixed memories $p_i, ρ'_i$ over $𝑋, 𝑌$, respectively. (Potentially infinite sum.) When 𝑋, 𝑌 are clear from the context, we simply say separable.⁵ In this paper, when we write infinite sums of operators, convergence is always with respect to the trace norm: $‖𝐴‖_\text{tr} := \text{tr} \sqrt{𝐴 † 𝐴}$. (In the finite-dimensional case, the choice of norm is irrelevant since all norms are equivalent then.)

Operations on quantum states. An operation in a closed quantum system is modeled by an isometry $𝑈$ on $ℓ²(𝑋)$.⁶ If we apply such an operation on a mixed state $ρ$, the result is $𝑈 ρ 𝑈^*$. In particular, denote by $\text{id}$ the identity operation, i.e. $\text{id} ψ = ψ$ for all pure states ψ in this space.

An operator $𝐴$ on $ℓ²(𝑋)$ can be interpreted as an operator on $ℓ²(𝑋) ⊗ ℓ²(𝑋)$ by setting $𝐴 ⊥ := 0$. To avoid confusion, we often write $𝐴 ⊗ 0_⊥$ for the operator on $ℓ²(𝑋) ⊗ ℓ²(𝑋)$. Similarly, an operator $𝐴$ on $ℓ²(𝑋_1) ⊗ ℓ²(𝑋_2)$ can be seen as an operator on $ℓ²(𝑋_1) ⊗ ℓ²(𝑋_2)$, we write $𝐴 ⊗ 0_{⊥⊥}$ for the operator on $ℓ²(𝑋_1) ⊗ ℓ²(𝑋_2) ⊗ ℓ²(𝑋_3) ⊗ ℓ²(𝑋_4)$.

Most often, isometries will occur in the context of operations that are performed on a single variable or list of variables, i.e., an isometry $𝑈$ on $ℓ²(𝑋)$. Then $𝑈$ can also be applied to $ℓ²(قاری)$

---

3 Mathematically, density operators are positive Hermitian trace-class operators on $ℓ²(𝑋)$. The requirement “trace-class” ensures that the trace exists and can be ignored in the finite-dimensional case.

4 Sums without index set are always assumed to have an arbitrary (not necessarily finite or even countable) index set. In the case of sums of vectors in a Hilbert space, convergence is with respect to the Hilbert space norm, and in the case of sums of positive operators, the convergence is with respect to the Loewner order.

5 Note that this is not the only possible definition of separability. (And maybe, from a physics point of view, not even the most natural one.) For example, [HSW05] show that the set of separable states as defined here is not closed w.r.t. the trace-norm. Instead, they define the set of separable states as the closure of the set we consider. (This is, roughly speaking, equivalent to taking an integral instead of the sum in $∑_i p_i ⊗ ρ'_i$.) However, our definition of separability works well in our setting. We do not know whether the definition from [HSW05] would give us the same set of reasoning rules.

6 That is, a norm-preserving linear operation. Often, one models quantum operations as unitaries instead because in the finite-dimensional case an isometry is automatically unitary. However, in the infinite-dimensional case, unitaries are unnecessarily restrictive. Consider, e.g., the isometry $|𝑖⟩ → |𝑖 + 1⟩$ with $𝑖 ∈ ℤ$ which is a perfectly valid quantum operation but not a unitary.
with $Y \supseteq X$: we identify $U$ with $U \otimes \text{id}_{Y \setminus X}$. Furthermore, if $X$ has type $T$, then an isometry $U$ on $\ell^2(T)$ can be seen as an isometry on $\ell^2[X]$ since we identify $\ell^2(T)$ and $\ell^2[X]$. If we want to make $X$ explicit, we write $U_{\otimes X}$ for the isometry $U$ on $\ell^2[Y]$. For example, if $U$ is a $2 \times 2$-matrix and $x$ has type bit, then $U_{\otimes X}$ can be applied to quantum memories over $xy$, acting on $x$ only. This notation is not limited to isometries, of course, but applies to other operators, too. (By operator we always mean a bounded linear operator in this paper.)

In slight overloading of notation, we also write $U_{\otimes X}$ for $U$ acting on $\bot$-memories, where $(U_{\otimes X})|\bot\rangle = 0$. (That is, $U_{\otimes X}$ is short for the more precise $(U_{\otimes X}) \oplus 0_{\bot}$.) We also write $U_{\otimes X_1}$ for $U$ acting on $\bot$-bimemories. In this case, we simply have $U_{\otimes X_1} := (U_{\otimes X_1}) \otimes \text{id}$. In particular, $(U_{\otimes X_1}(|m\rangle \otimes |\bot\rangle)) = (U_{\otimes X_1}(|m\rangle \otimes |\bot\rangle) = (U_{\otimes X_1}(|\bot\rangle \otimes |m\rangle)) = 0$. Analogously for $U_{\otimes X_2}$.

We will use only binary measurements in this paper. A binary measurement $M$ on $\ell^2[X]$ has outcomes $\text{true}, \text{false}$ and is described by two bounded operators $M_{\text{true}}, M_{\text{false}}$ on $\ell^2[X]$ that satisfy $M_{\text{true}}^* M_{\text{true}} + M_{\text{false}}^* M_{\text{false}} = \text{id}$, its Kraus operators. Given a mixed memory $\rho$, the probability of measurement outcome $t$ is $p_t := \text{tr} M_t \rho M_t^*$, and the post-measurement state is $M_t \rho M_t^*/p_t$.

**Expectations.** In this work, we will use expectations as pre- and postconditions in Hoare judgments. The idea of using expectations originated in [Koz83] for reasoning about (classical) probabilistic programs. Intuitively, an expectation is a quantitative predicate, that is for any memory (or bimemory, in our case), it does not tell us whether the memory satisfies the predicate but how much it satisfies the predicate. Thus, classically, an expectation is simply a function from assignments to reals. By analogy, in the quantum setting, one might want to define expectations, e.g., as functions $f$ from quantum bimemories to reals (i.e., an expectation would be a function $\ell^2[X] \rightarrow \mathbb{R}_{\geq 0}$). However, such expectations might behave badly, for example, it is not clear how to compute the expected value $f(\psi)$ for a random $\psi$ if the distribution of $\psi$ is given in terms of a density operator. A better approach was introduced by [DP06]. Following their approach, we define an expectation as a positive operator $A$ on quantum bimemories.

We use letters $A, B, C, \ldots$ for expectations in this paper. This expectation then assigns the value $\psi^* A \psi$ to the quantum memory $\psi$ (equivalently, $\text{tr} A \text{proj}(\psi)$). To understand this, it is best to first look at the special case where $A$ is a projector. Then $\psi^* A \psi = 1$ iff $\psi$ is in the image of $A$, and $\psi^* A \psi = 0$ iff $\psi$ is orthogonal to the image of $A$. Such an $A$ is basically a predicate (by outputting 1 for states that satisfy the predicate). Of course, states that neither satisfy the predicate nor are orthogonal to it will output a value between 0 and 1. Any expectation $A$ can be written as $\sum_i p_i A_i$ with projectors $A_i$. Thus, $A$ would give $p_i$ “points” for satisfying the predicate $A_i$. In this respect, expectations in the quantum setting are similar to classical ones: classical expectations give a certain amount of “points” for each possible classical input.

The nice thing about this formalism is that, given a density operator $\rho = \sum_i p_i \text{proj}(\psi_i)$, we can easily compute the expected value of the expectation $A$. More precisely, the expected value of $\psi^* A \psi = \text{tr} A \text{proj}(\psi)$ with $\psi := \psi_i$ with probability $p_i$. That expected value is $\sum_i p_i \text{tr} A \text{proj}(\psi_i) = \text{tr} A(\sum_i p_i \text{proj}(\psi_i)) = \text{tr} A \rho$. This shows that we can evaluate how much a density operator satisfies the expectation $A$ by just computing $\text{tr} A \rho$. This formula will be the basis for our definitions!

(A note for physicists: an expectation $A$ in our setting is nothing else but an observable, and $\text{tr} A \rho$ is the expected value of the outcome of measuring the observable $A$ when the system is in state $\rho$.)

Analogously, we define $\bot$-expectations on quantum $\bot$-bimemories. However, we add one restriction: The value of a $\bot$-expectation should not change if we measure whether the $\bot$-bimemory is in $|\bot\rangle$ or not. Formally, a $\bot$-expectation is a positive operator on quantum $\bot$-

---

\footnote{Recall from page 5 that operators are always bounded in our context. This means that $A$ is bounded, too. This means that the values that an expectation $A$ can assign to states are between 0 and $B$ for some finite $B$.}
bimemories that is invariant under $\mathcal{E}_\perp \otimes \mathcal{E}_\perp$ where $\mathcal{E}_\perp (\rho) := P_\perp \rho P_\perp + P_\perp P_X$. ($\mathcal{E}_\perp$ corresponds to measuring and forgetting whether a given mixed $\perp$-memory is $\perp$ or not.) Note that for an expectation $A$, the operator $A \otimes 0_{\perp \perp}$ is a $\perp$-expectation. We can thus see expectations as special cases of $\perp$-expectations.

A very simple example of an expectation would be the matrix $A := \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}$ that assigns 1 to $|0\rangle$, and $\frac{1}{2}$ to $|1\rangle$. And given the density operator $\rho = \frac{1}{2} \text{id}$ (representing a uniform qubit), $\text{tr} A \rho = \frac{1}{2}$ are intuitively expected.

**Free variables.** Given an expectation $A$, we will often wish to indicate which variables it talks about, i.e., what are its *free variables*. Since our definition of expectations is semantic (i.e., we are not limited to expectations expressed using a particular syntax) we cannot simply speak about the variables occurring in the expression describing $A$. Instead, we say $A$ contains only variables from $Y$ (written: $\text{fv}(A) \subseteq Y$) iff there exists an expectation $A'$ over $Y$ such that $A = A' \otimes \text{id}$. Note that there is a certain abuse of notation here: We formally defined “$\text{fv}(A) \subseteq Y$”, but we do not define $\text{fv}(A)$. $\text{fv}(A) \subseteq Y$ should formally just be seen as an abbreviation for “there exists $A$ over $Y$ such that $A = A' \otimes \text{id}$.”

**Quantum equality.** In [Unr19], a specific predicate $X_1 \equiv_q X_2$ was introduced to describe the fact that two quantum variables (or list of quantum variables) have the same state. Formally, $X_1 \equiv_q X_2$ is the subspace consisting of all quantum memories in $\ell^2[X_1X_2]$ that are invariant under $\text{SWAP}_{X_1X_2}$, the unitary that swaps variables $X_1$ and $X_2$. Or equivalently, $X_1 \equiv_q X_2$ denotes the subspace spanned by all quantum memories of the form $\phi \otimes \phi$ with $\phi \in \ell^2[X_1] = \ell^2[X_2]$. We write $\textbf{EQUAL on } X_1X_2$ for the projector onto $X_1 \equiv_q X_2$.

### 3 Quantum programs

**Syntax.** We will now define a small imperative quantum language. The set of all programs is described by the following syntax:

$$c,d ::= \text{apply U to X} | X \leftarrow \psi | \text{if M[X] then c else d} | \text{while M[X] do c} | c:d | \text{skip} | \text{abort}$$

Here $X$ is a list of variables and $U$ an isometry on $\ell^2[X]$, $\psi \in \ell^2[X]$ a normalized state, and $M$ is a binary measurement on $\ell^2[X]$. (There are no fixed sets of allowed $U$ and $\psi$, any isometry/state that we can describe can be used here.)

Intuitively, $\text{apply U to X}$ means that the operation $U$ is applied to the quantum variables $X$. E.g., $\text{apply H to x}$ would apply the Hadamard gate to the variable $x$ (we assume that $H$ denote the Hadamard matrix). It is important that we can apply $U$ to several variables $X$ simultaneously, otherwise no entanglement between variables can ever be produced. The program $X \leftarrow \psi$ initializes the variables $X$ with the quantum state $\psi$. The program $\text{if M[X] then c else d}$ will measure the variables $X$ with the measurement $M$, and, if the outcome is true, execute $c$, otherwise execute $d$.

---

8In fact, defining $\text{fv}(A)$ is possible only if there is a smallest set $Y$ such that $\exists A'$. $A = A' \otimes \text{id}$. This is not necessarily the case. For example: Let $x_\bullet$ denote an arbitrary element of the type of $x$ for all variables $x$. For a set $X$ of variables, let $AX[m] := [m]$ for all assignments $m$ over $X$ where $m(x) \neq x_\bullet$ only for finitely many $x$. Let $AX[m] := 0$ otherwise. Then $AX = A_Y \otimes \text{id}$ for all co-finite $Y \subseteq X$. But for any non-co-finite $Y \subseteq X$, $AX \neq B \otimes \text{id}$ for all $B$ over $Y$. So $\text{fv}(AX)$ would have to be the smallest co-finite subset of $X$. But if $X$ is infinite, there is no smallest co-finite subset of $X$.

9That is, $\text{SWAP}_{X_1X_2}(\psi \otimes \phi) = \phi \otimes \psi$ for $\psi \in \ell^2[X_1]$, $\phi \in \ell^2[X_2]$.

10Very similar to [Yin12], except that we replace their case-statement by an if-statement and allow initialization with arbitrary states instead of just $|0\rangle$.

11We will assume throughout the paper that all programs satisfy those well-typedness constraints. In particular, rules may implicitly impose type constraints on the variables and constants occurring in them by this assumption.
The program \texttt{while }$M \mathbf{[}X \mathbf{]} \texttt{ do } c$ measures $X$, and if the outcome is \texttt{true}, it executes $c$. This is repeated until the outcome is \texttt{false}.

Finally, $c; \texttt{do}$ executes $c$ and then $\texttt{do}$. And \texttt{skip} does nothing. We will always implicitly treat “;” as associative and \texttt{skip} as its neutral element. \texttt{abort} never terminates.

**Semantics.** The denotational semantics of our programs $c$ are represented as completely positive trace-reducing maps $\llbracket c \rrbracket$ on the mixed memories over $X^{\text{all}}$, defined by recursion on the structure of the programs. Here $X^{\text{all}}$ is a fixed set of program variables, and we will assume that all variables under consideration are contained in this set.\footnote{We fix some set $X^{\text{all}}$ in order to avoid a more cumbersome notation $\llbracket c \rrbracket^X$ where we explicitly indicate the set $X$ of program variables with respect to which the semantics is defined.} The obvious cases are $\llbracket \texttt{skip} \rrbracket := \text{id}$ and $\llbracket c; \texttt{do} \rrbracket := \llbracket \texttt{do} \rrbracket \circ \llbracket c \rrbracket$ and $\llbracket \texttt{abort} \rrbracket (\rho) := 0$. And application of an isometry $U$ is also fairly straightforward given the syntactic sugar introduced above: $\llbracket \texttt{apply } U \texttt{ to } X \rrbracket (\rho) := (U \llbracket X \rrbracket \rho)(U \llbracket X \rrbracket)^*$. (The notation $U \llbracket X \rrbracket$ was introduced on page 5.)

Initialization of quantum variables is slightly more complicated: $X \leftarrow \psi$ initializes the variables $X$ with $\psi$, which is the same as removing $X$, and then creating a new variable $X$ with content $\psi$. Removing $X$ is done by the operation $\text{tr}_X$ (partial trace, see page 4). And creating new variables $X$ in state $\psi$ is done by the operation $\otimes \text{proj}(\psi)$. Thus we define $\llbracket X \leftarrow \psi \rrbracket (\rho) := \text{tr}_X \rho \otimes \text{proj}(\psi)$.

The if-command first performs a measurement and then branches depending on the outcome. We then have that the state after measurement (without renormalization) is $(M_t \llbracket X \rrbracket \rho)(M_f \llbracket X \rrbracket)^*$ for outcome $t = \texttt{true}, \texttt{false}$. Then $c$ or $\texttt{do}$ is applied to that state and the resulting states are added together to get the final mixed state. Altogether:

\[
\llbracket \texttt{if } M \llbracket X \rrbracket \texttt{ then } c \texttt{ else } \texttt{do} \rrbracket (\rho) := \llbracket c \rrbracket (\downarrow_{\texttt{true}}(\rho)) + \llbracket \texttt{do} \rrbracket (\downarrow_{\texttt{false}}(\rho))
\]

where $\downarrow_t := (M_t \llbracket X \rrbracket \rho)(M_f \llbracket X \rrbracket)^*$.

While-commands are modeled similarly: In an execution of a while statement, we have $n$ iterations of “measure with outcome $\texttt{true}$ and run $c$” (which applies $\llbracket c \rrbracket \circ \downarrow_{\texttt{true}}$ to the state), followed by “measure with outcome $\texttt{false}$” (which applies $\downarrow_{\texttt{false}}$ to the state). Adding all those branches up, we get the definition:

\[
\llbracket \texttt{while } M \llbracket X \rrbracket \texttt{ do } c \rrbracket (\rho) := \sum_{n=0}^{\infty} \downarrow_{\texttt{false}}((\llbracket c \rrbracket \circ \downarrow_{\texttt{true}})^n(\rho))
\]

We call a program $c$ terminating iff $\text{tr} \llbracket c \rrbracket (\rho) = \text{tr} \rho$ for all $\rho$.

**Semantics with explicit non-termination.** $\llbracket c \rrbracket$ is not trace-preserving if $c$ is not terminating. For technical reasons, we will need a variant of this function that is trace-preserving. This can be achieved by outputting a mixed state that has an explicit state $\text{proj}(\downarrow_{\bot})$ to denote non-termination. This semantic function $\llbracket c \rrbracket^\bot$ takes mixed $\bot$-memories to mixed $\bot$-memories and can be easily derived from $\llbracket c \rrbracket$:

\[
\llbracket c \rrbracket^\bot (\rho) := \llbracket c \rrbracket (\downarrow_\bot(\rho)) + (\text{tr} \rho - \text{tr} \llbracket c \rrbracket (\downarrow_\bot(\rho))) \text{proj}(\downarrow_{\bot}).
\]

$(P_\bot, P_\bot)$ are defined on page 4.) Operationally, $\llbracket c \rrbracket^\bot$ first measures if the state is $\bot$. If so, nothing happens. Otherwise, $c$ is applied. If $c$ does not terminate, the final output memory is set to

\footnote{It may not be immediately obvious that $\llbracket c \rrbracket^\bot$ is completely positive. Complete positivity is shown as follows: $f(\rho) := \text{tr} \rho - \text{tr} \llbracket c \rrbracket (\rho)$ is a linear functional. For $\rho \geq 0$, $f(\rho) \in [0, \text{tr} \rho]$ since $\llbracket c \rrbracket$ is trace-reducing. Hence $f$ is positive. Every positive linear functional is completely positive [Con00, Lemma 34.5]. The function $g(c) := c \cdot \text{proj}(\downarrow_{\bot})$ is completely positive. Thus $g \circ f$ is completely positive. Also $\llbracket c \rrbracket \circ \downarrow_{\bot}$ is completely positive as a composition of two completely positive functions. Thus $\llbracket c \rrbracket^\bot = \llbracket c \rrbracket \circ \downarrow_{\bot} + g \circ f$ is completely positive.}
be \( \perp \). \([\mathcal{C}]\) is easily seen to be trace-preserving. Moreover, we have the composition property \([\mathcal{C} \otimes \mathcal{D}] = [\mathcal{D}] \circ [\mathcal{C}]\), since

\[
[\mathcal{D}]([\mathcal{C}]^\perp (\rho)) = [\mathcal{D}] [\mathcal{C}] (\rho_{\mathcal{L}}) + (\text{tr} \rho - \text{tr}[\mathcal{C}] (\rho_{\mathcal{L}})) \text{proj}(\perp))
\]

\[
= [\mathcal{D}][\mathcal{C}] (\rho_{\mathcal{L}}) + (\text{tr}[\mathcal{C}]^\perp (\rho) - \text{tr}[\mathcal{D}][\mathcal{C}] (\rho_{\mathcal{L}})) \text{proj}(\perp))
\]

\[
= [\mathcal{C} \otimes \mathcal{D}] (\rho_{\mathcal{L}}) + (\text{tr} \rho - \text{tr}[\mathcal{C} \otimes \mathcal{D}] (\rho_{\mathcal{L}})) \text{proj}(\perp)) = [\mathcal{C} \otimes \mathcal{D}]^\perp (\rho).
\]

4 qRHL with expectations

**Defining the logic.** We now present our definition of expectation-qRHL. We follow the approach from [Unr19] to use separable couplings to describe the relationship between programs. A **coupling** between two mixed states \(\rho_1\) and \(\rho_2\) is a mixed state \(\rho\) that has \(\rho_1\) and \(\rho_2\) as marginals. (That is, \(\text{tr}_{\mathcal{X}_2} \rho = \rho_1\) and \(\text{tr}_{\mathcal{X}_1} \rho = \rho_2\) if \(\rho_1, \rho_2\) are states over \(\mathcal{X}_1, \mathcal{X}_2\), respectively.) This is analogous to probabilistic couplings: a coupling of distributions \(\mu_1, \mu_2\) is a distribution \(\mu\) with marginals \(\mu_1, \mu_2\). Note that couplings trivially always exist if \(\rho_1\) and \(\rho_2\) have the same trace (namely, \(\rho := \rho_1 \otimes \rho_2 / \text{tr} \rho_1\)). Couplings become interesting when we put additional constraints on the state \(\rho\). For example, if we require the support of \(\rho\) to be in the subspace \(C := \text{span}\{[00], [11]\},\) then \(\rho_1 = \text{proj}([00])\) and \(\rho_2 = \text{proj}([00])\) have a coupling (namely, \(\rho = \text{proj}([00])\)), as do \(\rho_1 = \text{proj}([11])\) and \(\rho_2 = \text{proj}([11])\) (namely, \(\rho = \text{proj}([11])\)), but not \(\rho_1 = \text{proj}([01])\) and \(\rho_2 = \text{proj}([11])\). Things become particularly interesting when \(\rho_1, \rho_2\) are not pure states. E.g., \(\rho_1 = \frac{1}{2} \text{proj}([00]) + \frac{\sqrt{3}}{2} \text{proj}([11])\) and \(\rho_2 = \frac{1}{2} \text{proj}([00]) + \frac{\sqrt{3}}{2} \text{proj}([11])\) have such a coupling as well (namely, \(\rho = \frac{1}{2} \text{proj}([00]) + \frac{\sqrt{3}}{2} \text{proj}([11])\)) but \(\rho := \rho_1 \otimes \rho_2\) is not a coupling with support in \(C\).

Thus, a subspace such as \(C\) can be seen as a predicate describing the relationship of \(\rho_1, \rho_2\). The states \(\rho_1, \rho_2\) satisfy \(C\) iff there is a coupling with support in \(C\). This idea leads to the following tentative definition of qRHL:

**Definition 1 (qRHL, tentative, without expectations)** For subspaces \(A, B\) (i.e., spaces of quantum memories over \(\mathcal{X}_1, \mathcal{X}_2\)), \(\{A\} \mathcal{C} \sim \mathcal{D} \{B\}\) holds iff for any \(\rho_1, \rho_2\) that have a coupling with support in \(A\), the final states \([\mathcal{C}] (\rho_1), [\mathcal{D}] (\rho_2)\) have a coupling with support in \(B\).

However, it was noticed in [Unr19] that the definition becomes easier to handle if we impose another condition on the couplings. Namely, the coupling should be separable, i.e., there should be no entanglement between the two systems corresponding to \(\rho_1, \rho_2\). That is, the definition of qRHL used in [Unr19] is Definition 1 with ‘coupling’ replaced by ‘separable coupling’. We will also adopt the separability condition in our definition of expectation-qRHL.\(^{14}\)

So far, we have basically recapped the definition from [Unr19]. However, that definition only allows us to express Hoare judgments that do not involve expectations since \(A\) and \(B\) in Definition 1 are subspaces (predicates), not expectations. To define expectation-qRHL, we follow the same idea, but instead of quantifying over only the initial states satisfying the precondition, we quantify over all initial states, and merely require that (the coupling of) the final states satisfies the postexpectation at least as much as (the coupling of the) initial states satisfy the preexpectation. That is:

**Definition 2 (Expectation-qRHL (eqRHL), first attempt)** For expectations \(A, B, \{A\} \mathcal{C} \sim \mathcal{D} \{B\}\) holds iff for any \(\rho_1, \rho_2\) with separable coupling \(\rho\), the final states \([\mathcal{C}] (\rho_1), [\mathcal{D}] (\rho_2)\) have a separable coupling \(\rho'\) such that \(\text{tr} A \rho \leq \text{tr} B \rho'\). (Recall that \(\text{tr} A \rho\) indicates how much \(\rho\) satisfies \(A\), and analogously \(\text{tr} B \rho'\), cf. Section 2.)

\(^{14}\)Unr19 was not able to prove the Frame rule without adding this separability condition. Our reasons for adopting the separability condition are slightly different: we do not have a Frame rule anyway, but for other elementary rules such as the rule Equal in [Unr19] with quantum expectations and quantum variables, it is unclear how to prove them without the separability condition.
For terminating programs \( c, \bar{c} \), this definition already works well. Unfortunately, if \( c, \bar{c} \) do not terminate with probability 1, we have some undesired effects: For example, assume that \( c = \text{skip} \), and \( \bar{c} \) is a program that with probability \( 1 - \varepsilon \) does nothing (\text{skip}) and but with probability \( \varepsilon \) does not terminate (\text{abort}). Then \( \{A \} c \sim \bar{c} \{B \} \) does not hold for any \( A,B \). Why?

The final states \( [c](\rho_1), [\bar{c}](\rho_2) \) have trace 1 and \( 1 - \varepsilon \), respectively. Therefore there exists no coupling \( \rho' \) of \( [c](\rho_1), [\bar{c}](\rho_2) \). (It follows from the definition of couplings that the coupling must have the same trace as its marginals.) Hence \( \{A \} c \sim \bar{c} \{B \} \) does not hold. Similarly, \( \{A \} c \sim \bar{c} \{B \} \) does not hold whenever there are two input states \( \rho_1, \rho_2 \) such that \( c, \bar{c} \) terminate with different probabilities. (Even if this nontermination only occurs for input states for which \( A \) evaluates to 0!) This makes it near impossible to reason about non-terminating programs.\(^{15}\)

There are a number of approaches how one can circumvent this problem. E.g., one could allow \( \rho' \) to be a “subcoupling” instead of a coupling (i.e., its marginals do not have to equal \( [c](\rho_1), [\bar{c}](\rho_2) \) but only lower bound them).\(^{16}\) The subcoupling always exists, even if the traces are not equal. However, we find that adding such “hacks” to the definition makes it more difficult to understand what the definition exactly does in case of non-terminating programs.

Instead, we choose an approach that makes non-termination explicit. That is, when a program does not terminate, we assign a specific state \( |\bot\rangle \) to its output, and we allow expectation to explicitly refer to it (e.g., an expectation could assign value 1 to nontermination, and value 0 to termination). The denotation \( [c]^+ \) defined on page 7 does exactly that. And expectations that live on a space that has an explicit nontermination-state \( |\bot\rangle \) were introduced as \( \bot \)-expectations on page 5. This leads to the following definition:

**Definition 3 (Expectation-qRHL, informal)** For \( \bot \)-expectations \( A,B \), \( \{A \} c \sim \bar{c} \{B \} \) holds iff for any \( \rho_1, \rho_2 \) with separable coupling \( \rho \), the final states \( [c]^+(\rho_1), [\bar{c}]^+(\rho_2) \) have a separable coupling \( \rho' \) such that \( \text{tr} A \rho \leq \text{tr} B \rho' \).

Note that a coupling of \( [c]^+(\rho_1), [\bar{c}]^+(\rho_2) \) always exists since \( [\cdot]^+ \) is trace-preserving. (Below, we will derive certain specific variants of eqRHL such as eqRHL with total correctness as specific cases of this definition. Also, we will see that subcoupling-based definitions can be recovered as special cases in Lemma 2.) By plugging in the definition of couplings into Definition 3, we get the following precise definition:

**Definition 4 (Expectation-qRHL, generic)** Let \( A,B \) be \( \bot \)-expectations and \( c, \bar{c} \) programs. Then \( \{A \} c \sim \bar{c} \{B \} \) holds iff for any separable mixed \( \bot \)-bimemory \( \rho \) over \( X_1^{\text{all}}, X_2^{\text{all}} \), there is a separable mixed \( \bot \)-bimemory \( \rho' \) over \( X_1^{\text{all}}, X_2^{\text{all}} \) such that

- \( \text{tr}_1 \rho' = [c]^+ (\text{tr}_1 \rho) \).
- \( \text{tr}_2 \rho' = [\bar{c}]^+ (\text{tr}_2 \rho) \).
- \( \text{tr} A \rho \leq \text{tr} B \rho' \).

In this definition, \( X_1^{\text{all}}, X_2^{\text{all}} \) are isomorphic copies of the set \( X^{\text{all}} \) of variables. That is, while strictly speaking, \( [c]^+ \) maps mixed \( \bot \)-memories over \( X^{\text{all}} \) to mixed \( \bot \)-memories over \( X^{\text{all}} \), we can also see it as mapping mixed \( \bot \)-memories over \( X^{\text{all}} \) to mixed \( \bot \)-memories over \( X^{\text{all}} \). Analogously for \( \bar{c} \) and \( X_2^{\text{all}} \). We make use of this in the preceding definition when we apply \( [c]^+, [\bar{c}]^+ \) to \( \rho_1, \rho_2 \), respectively. In the rest of the paper, we simply call a mixed state \( (\rho_1, \rho_2) \)-coupling if it is separable and has marginals \( \rho_1 \) and \( \rho_2 \).

Note that we defined \( \bot \)-expectations to be invariant under \( \mathcal{E}_L \otimes \mathcal{E}_L \) (page 5), i.e., that they implicitly measure first whether the quantum memories are \( |\bot\rangle \). Otherwise, we would not even...\(^{15}\) Even if we are interested in a Hoare logic with total correctness, this behavior is undesired. Instead, we want that a nontermination with small probability simply introduces some small penalty in the expectations. For example, in the case of non-relational Hoare with total correctness, \( \{(1 - \varepsilon) \text{id} \} A \{ \text{id} \} \) means that \( A \) is nonterminating with probability \( \leq \varepsilon \).

\(^{16}\) This is explored further in Section 4 for special cases of our definition.
have \{A\} \textsf{skip} \simproj \textsf{skip} \{A\} (rule \textsf{Skip} below), for example if \(A := \text{proj}(\frac{1}{\sqrt{2}}|0\rangle + \frac{1}{\sqrt{2}}|\perp\rangle)\). This is because even the program \textsf{skip} measures whether the memory is \(|\perp\rangle\) (by definition of \([|\perp\rangle]\)), so it may change the state if the memory is in a superposition between \(|\perp\rangle\) and something else.

**Partial/total correctness.** The generic definition of eqRHL (Definition 4) allows us to explicitly express in our pre-/postexpectations how nontermination should be treated. While this allows for maximal generality, in practice it might be cumbersome to always have to specify explicitly how the expectations behave on \(|\perp\rangle\). Instead, we define below three special cases of eqRHL that hardcode the treatment of \(|\perp\rangle\).

The simplest case is eqRHL with total correctness: Here, nontermination is “forbidden”, i.e., we assign value \(0\) to it. Recall from page 4 that for an expectation \(A, A \oplus 0_{\perp\perp}\) is the corresponding \(\perp\)-expectation. It assigns \(0\) to a state that has \(|\perp\rangle\) in the left or right memory. Hence, eqRHL with total correctness simply means that all pre/postconditions are of the form \(A \oplus 0_{\perp\perp}\). The following definition specifies convenient syntax for this special case:

**Definition 5 (Expectation-qRHL, total)** Let \(A, B\) be expectations and \(c, \varnothing\) programs. Then \(\{A\} c \simproj \varnothing \{B\}\) iff \(\{A \oplus 0_{\perp\perp}\} c \simproj \varnothing \{B \oplus 0_{\perp\perp}\}\).

A second common variant of Hoare logic is “partial correctness”. Here we allow nontermination, i.e., if a program does not terminate, we assign the value \(1\). That is, we use pre/postexpectations of the form \((A \oplus 0_{\perp\perp}) + T\) where \(T\) assigns value \(1\) when the left or right memory is in state \(|\perp\rangle\):

**Definition 6 (Expectation-qRHL, partial)** Let \(A, B\) be expectations and \(c, \varnothing\) programs. Then \(\{A\} c \simproj \varnothing \{B\}\) iff \(\{(A \oplus 0_{\perp\perp}) + T\} c \simproj \varnothing \{(B \oplus 0_{\perp\perp}) + T\}\) where \(T := (\text{proj}(|\perp\rangle) \otimes P_L) + (P_L \otimes \text{proj}(|\perp\rangle)) + \text{proj}(|\perp\rangle) \otimes |\perp\rangle\).

Unfortunately, this definition does not necessarily behave as we would like. E.g., if both \(c\) and \(\varnothing\) terminate with probability \(\leq \frac{1}{2}\) on all inputs, then \(\{A\} c \simproj \varnothing \{B\}\) holds for any \(A \leq \text{id}\) and any \(B\). That is, any property holds with probability \(1\) for those programs which is not what we would expect! Why does this happen? Since \(\left[\text{id}_c\right]^+(\rho_1), \left[\text{id}_\varnothing\right]^+(\rho_2)\) are 50\% nontermination, we can “match up” the nonterminating part of \(\left[c\right]^+(\rho_1)\) with the terminating part of \(\left[\varnothing\right]^+(\rho_2)\) and vice versa in the coupling \(\rho\) of the output states. Then \(\text{tr} T \rho^\prime = 1\) and thus \(\{A\} c \simproj \varnothing \{B\}\) holds.

The problem here is that we treat nontermination as a “wildcard” that is allowed to match any behavior of the other program. While there may be valid use cases for such a notation, we believe that in most cases this is not what we want.

Instead, we define a notion we call “semipartial”. In this eqRHL-variant, we allow nontermination, but only when it occurs in the two programs “in sync”. I.e., we consider pre/postexpectations that assign 1 to \(|\perp\rangle \otimes |\perp\rangle\), but 0 to a state where one program has nonterminated and the other has terminated. Formally:

**Definition 7 (Expectation-qRHL, semipartial)** Let \(A, B\) be expectations and \(c, \varnothing\) programs. Then \(\{A\} c \simproj \varnothing \{B\}\) iff \(\left\{\left(A \oplus 0_{\perp\perp}\right) + \text{proj}(|\perp\rangle \otimes |\perp\rangle)\right\} c \simproj \varnothing \left\{(B \oplus 0_{\perp\perp}) + \text{proj}(|\perp\rangle \otimes |\perp\rangle)\right\} \).

**Pure initial states.** In many cases, it is much easier to work with the definition of eqRHL correctness if one can assume that the initial states of \(c, \varnothing\) are pure states, and that the initial coupling is the tensor product of those states. (No nontrivial correlations.) The following lemma shows that we can do so without loss of generality:

10
Figure 1: In these rules, “any” can be any of “tot”, ”semi”, “par”. For any = par, the termination condition in WHILE1 can be replaced by \( A \leq id \), and for any = semi the termination condition in JOINTWHILE can be replaced by \( A \leq id \). We refer to the symmetric rules of **APPLY1**, **INIT1**, **IF1**, and **WHILE1** (obtained by applying **SYM**) as **APPLY2**, **INIT2**, **IF2**, and **WHILE2**.
Lemma 1 Let $A, B$ be $\perp$-expectations and $\mathfrak{c}, \mathfrak{d}$ programs. Then $\{A\} \subseteq \mathfrak{d} \{B\}$ holds iff

- for all unit quantum memories $\psi_1, \psi_2$ over $X_1, X_2$, respectively, there is a separable $\perp$-mixed binemory $\rho'$ over $X_1, X_2$ such that
  - $\text{tr}_2 \rho' = [\mathfrak{c}]^\perp(\text{proj}(\psi_1))$,
  - $\text{tr}_1 \rho' = [\mathfrak{d}]^\perp(\text{proj}(\psi_2))$,
  - $\text{tr} A \text{proj}(\psi_1 \otimes \psi_2) \leq \text{tr} B \rho'$. 17

- for all unit quantum memories $\psi_1$ over $X_1$, we have $\text{tr} A \text{proj}(\psi_1 \otimes |\perp\rangle) \leq \text{tr} B ([\mathfrak{c}]^\perp(\text{proj}(\psi_1)) \otimes \text{proj}(|\perp\rangle))$.

- for all unit quantum memories $\psi_2$ over $X_2$, we have $\text{tr} A \text{proj}(|\perp\rangle \otimes \psi_2) \leq \text{tr} B (\text{proj}(|\perp\rangle) \otimes [\mathfrak{d}]^\perp(\text{proj}(\psi_2)))$.

- $\text{tr} A \text{proj}(|\perp\rangle \otimes |\perp\rangle) \leq \text{tr} B \text{proj}(|\perp\rangle \otimes |\perp\rangle)$.

Proof. Let $P(\psi_1, \psi_2)$ mean that there exists a separable $\perp$-mixed binemory $\rho'$ such that $\text{tr}_2 \rho' = [\mathfrak{c}]^\perp(\text{proj}(\psi_1))$, and $\text{tr}_1 \rho' = [\mathfrak{d}]^\perp(\text{proj}(\psi_2))$, and $\text{tr} A \text{proj}(\psi_1 \otimes \psi_2) \leq \text{tr} B \rho'$.

Notice that $P(\psi_1, |\perp\rangle)$ holds iff there exists a separable $\perp$-mixed binemory $\rho'$ such that (i) $\text{tr}_2 \rho' = [\mathfrak{c}]^\perp(\text{proj}(\psi_1))$, and (ii) $\text{tr}_1 \rho' = [\mathfrak{d}]^\perp(\text{proj}(|\perp\rangle)) = \text{proj}(|\perp\rangle)$, and (iii) $\text{tr} A \text{proj}(\psi_1 \otimes |\perp\rangle) \leq \text{tr} B \rho'$. The conditions (i),(ii) are equivalent to $\rho' = [\mathfrak{c}]^\perp(\text{proj}(\psi_1)) \otimes \text{proj}(|\perp\rangle)$, and in this case (iii) becomes $\text{tr} A \text{proj}(\psi_1 \otimes |\perp\rangle) \leq \text{tr} B ([\mathfrak{c}]^\perp(\text{proj}(\psi_1)) \otimes \text{proj}(|\perp\rangle))$.

Thus $P(\psi_1, |\perp\rangle)$ holds iff $\text{tr} A \text{proj}(\psi_1 \otimes |\perp\rangle) \leq \text{tr} B ([\mathfrak{c}]^\perp(\text{proj}(\psi_1)) \otimes \text{proj}(|\perp\rangle))$. Analogously, $P(|\perp\rangle, \psi_2)$ holds iff $\text{tr} A \text{proj}(|\perp\rangle \otimes \psi_2) \leq \text{tr} B (\text{proj}(|\perp\rangle) \otimes [\mathfrak{d}]^\perp(\text{proj}(\psi_2)))$, and $P(|\perp\rangle, |\perp\rangle)$ holds iff $\text{tr} A \text{proj}(|\perp\rangle \otimes |\perp\rangle) \leq \text{tr} B \text{proj}(|\perp\rangle \otimes |\perp\rangle)$.

Thus the statement of the lemma is equivalent to:

$$\{A\} \subseteq \mathfrak{d} \{B\} \iff \forall \psi_1 \in \ell^2[X_1] \cup \{|\perp\rangle\}, \psi_2 \in \ell^2[X_2] \cup \{|\perp\rangle\}, P(\psi_1, \psi_2).$$ (1)

The $\Rightarrow$-direction is immediate from Definition 4.

We show the $\Leftarrow$-direction. Fix some separable $\perp$-mixed binemory $\rho$ over $X_1 X_2$. To prove that $\{A\} \subseteq \mathfrak{d} \{B\}$ holds, we need to construct a separable $\rho'$ such that:

(i) $\text{tr}_2 \rho' = [\mathfrak{c}]^\perp(\text{tr}_2 \rho)$.

(ii) $\text{tr}_1 \rho' = [\mathfrak{d}]^\perp(\text{tr}_1 \rho)$.

(iii) $\text{tr} A \rho \leq \text{tr} B \rho'$.

Recall the definition of $E_\perp$ from page 6. Let $\rho^\perp := (E_\perp \otimes E_\perp)(\rho)$. Then $\rho^\perp$ is also a separable mixed $\perp$-binemory, thus we can write $\rho^\perp$ as $\rho^\perp = \sum_j p_j \text{proj}(\psi_{1j} \otimes \psi_{2j})$ for unit quantum memories $\psi_{1j}, \psi_{2j}$ over $X_1, X_2$ and $p_j \geq 0$. By definition of $E_\perp$, we can choose the $\psi_{1j}, \psi_{2j}$ as $\psi_{1j} \in \ell^2[X_1] \cup \{|\perp\rangle\}$ and $\psi_{2j} \in \ell^2[X_2] \cup \{|\perp\rangle\}$. (I.e., $\psi_{1j}$ is never a superposition between $|\perp\rangle$ and something else. Same for $\psi_{2j}$.)

By assumption (rhs of (1)), for all $j$, we have $P(\psi_{1j}, \psi_{2j})$. Thus, there exists a separable mixed $\perp$-binemory $\rho_j'$ over $X_1 X_2$ such that

- $\text{tr}_2 \rho_j' = [\mathfrak{c}]^\perp(\text{proj}(\psi_{1j}))$.

- $\text{tr}_1 \rho_j' = [\mathfrak{d}]^\perp(\text{proj}(\psi_{2j}))$.

- $\text{tr} A \text{proj}(\psi_{1j} \otimes \psi_{2j}) \leq \text{tr} B \rho_j'$.

Then let $\rho' := \sum_j p_j \rho_j'$. Since all $\rho_j'$ have trace 1, and $\sum_j p_j = \text{tr} \rho \leq \infty$, $\rho'$ exists.

We have (i) since

$$\text{tr}_2 \rho' = \sum_j p_j \text{tr}_2 \rho_j' = \sum_j p_j [\mathfrak{c}]^\perp(\text{proj}(\psi_{1j})) = [\mathfrak{c}]^\perp(\sum_j p_j \text{proj}(\psi_{1j})) = [\mathfrak{c}]^\perp(\text{tr}_2 \rho^\perp) = [\mathfrak{c}]^\perp(\text{tr}_2 \rho).$$

Here $(*)$ holds since $[\mathfrak{c}]^\perp \circ E_\perp = [\mathfrak{c}]^\perp$ by construction of $[\mathfrak{c}]^\perp$ and $E_\perp$.

\[17\text{Or equivalently, } \|\sqrt{A}(\psi_1 \otimes \psi_2)\| \leq \text{tr} B \rho'. \text{ Or } (\psi_1 \otimes \psi_2)^\ast A(\psi_1 \otimes \psi_2) \leq \text{tr} B \rho'.\]
mixed bimemory. However, we do not know such an equivalent reformulation for semipartial couplings instead of couplings.

To circumvent the problem that Definition 2 does handle nonte-terminating programs well is to use Equivalent reformulations.

As discussed after Definition 2, an alternative means of trying to circumvent the problem that Definition 2 does handle nonterminating programs well is to use subcouplings instead of couplings.

Here, we show that the notions of eqRHL with partial and total correctness can be equivalently restated in terms of subcouplings (instead of the extended semantics $\llbracket \cdot \rrbracket^+$ over $\perp$-memories). However, we do not know such an equivalent reformulation for semipartial correctness.

**Lemma 2** Let $A, B$ be expectations and $c, d$ programs. Then $\{A\} c \sim d \{B\}$ iff for any separable mixed bimemory $\rho$ over $X_1^a, X_2^a$, there is a separable mixed bimemory $\rho'$ over $X_1^a, X_2^a$ such that

- $\tr_2 \rho' \leq [c](\tr_2 \rho)$.
- $\tr_1 \rho' \leq [d](\tr_1 \rho)$.
- $\tr A\rho \leq \tr B\rho'$.

**Proof.** We first prove the “only if” part, namely, we need to construct $\rho'$ for any given $\rho$ such that the three conditions hold. Let $p_1$ and $p_2$ be the marginals of $\rho$. Consider the $\perp$-mixed bimemory $\rho \oplus 0_{\perp\perp}$ as the input coupling, then $\{A\} c \sim d \{B\}$ implies that the output states $\llbracket c \rrbracket (p_1 \oplus 0_{\perp\perp}) = \llbracket c \rrbracket (\rho) + (\tr (p_1 - \llbracket c \rrbracket (p_1)) \proj(\perp))$ and $\llbracket d \rrbracket (p_2 \oplus 0_{\perp\perp}) = \llbracket d \rrbracket (p_2) + (\tr (\rho - \llbracket d \rrbracket (p_2)) \proj(\perp))$ have a separable coupling $\rho'$ such that

$$\tr A\rho = \tr (A \oplus 0_{\perp\perp})(\rho \oplus 0_{\perp\perp}) \leq \tr (B \oplus 0_{\perp\perp})(P_L \otimes P_L) \leq \tr (B \oplus 0_{\perp\perp})(P_L \otimes P_L) \leq \tr (B \oplus 0_{\perp\perp})(P_L \otimes P_L).$$

Now let $(P_L \otimes P_L) \hat{\rho}(P_L \otimes P_L) = \rho' \oplus 0_{\perp\perp}$, then $\rho'$ is separable and $\tr A\rho \leq \tr B\rho'$. In order to show that $\rho'$ is exactly the bimemory we need to construct, it remains to prove that $\rho'$ is a subcoupling of the output state $\llbracket c \rrbracket (p_1)$ and $\llbracket d \rrbracket (p_2)$, which is achieved by

$$\llbracket c \rrbracket (p_1) = P_L(\tr_2 \hat{\rho})P_L = \tr_2 \rho' + \tr_2 (P_L \otimes P_L) \hat{\rho}(P_L \otimes P_L)$$

$$\llbracket d \rrbracket (p_2) = P_L(\tr_1 \hat{\rho})P_L = \tr_1 \rho' + \tr_1 (P_L \otimes P_L) \hat{\rho}(P_L \otimes P_L).$$

Then we prove the “if” part. We derive $\{A \oplus 0_{\perp\perp}\} c \sim d \{B \oplus 0_{\perp\perp}\}$ by Lemma 1. It suffices to construct for any normalized quantum memories $\psi_1, \psi_2$ over $X_1^a, X_2^a$, a separable coupling $\rho$ of the output $\perp$-memories $\llbracket c \rrbracket (\proj(\psi_1))$ and $\llbracket d \rrbracket (\proj(\psi_2))$ such that $\tr \proj(\psi_1 \otimes \psi_2) \leq \tr (B \oplus 0_{\perp\perp}) \rho$, noting that the other three conditions for input bimemories $\psi_1 \otimes \perp\perp$, $\perp\perp \otimes \psi_2$, and $\perp\perp \otimes \perp\perp$ have naturally been satisfied for $\perp$-expectations $A \oplus 0_{\perp\perp}$ and $B \oplus 0_{\perp\perp}$. The three premises here allow us to find memories $\sigma_1$ and $\sigma_2$ with separable coupling $\sigma$ such that $\sigma_1 \leq \llbracket c \rrbracket (\proj(\psi_1))$, $\sigma_2 \leq \llbracket d \rrbracket (\proj(\psi_2))$ and $\tr \proj(\psi_1 \otimes \psi_2) \leq \tr \proj(\psi_1) \otimes \psi_2) \leq \tr B\sigma$. Without loss of generality, we assume that $\tr \llbracket c \rrbracket (\proj(\psi_1)) \geq \tr \llbracket d \rrbracket (\proj(\psi_2))$. If $\tr \llbracket c \rrbracket (\proj(\psi_1)) = \tr \sigma$, it is easy to verify that
\(\sigma\) is actually a coupling of the output memories and it suffices to choose \(\rho = \sigma \oplus 0_{11}\). For 
\[\text{tr}[c](\text{proj}(\psi_1)) > \text{tr} \sigma = \text{tr} \sigma_1,\]
let
\[
\rho = \sigma + \frac{\text{tr}[c](\text{proj}(\psi_1)) - \text{tr}[d](\text{proj}(\psi_2))}{\text{tr}[c](\text{proj}(\psi_1)) - \text{tr} \sigma} (\|c\|\text{proj}(\psi_1) - \sigma_1) \otimes \text{proj}(11) \\
+ \frac{(\|c\|\text{proj}(\psi_1) - \sigma_1) \otimes (\|d\|\text{proj}(\psi_2) - \sigma_2)}{\text{tr}[c](\text{proj}(\psi_1)) - \text{tr} \sigma} (1 - \text{tr}[c](\text{proj}(\psi_1)))\text{proj}(11) \otimes |1\rangle.
\]
Then it is easy to verify that \(\rho\) is a separable coupling of \(\|c\|^\dagger(\text{proj}(\psi_1)) = \|c\|\text{proj}(\psi_1) + (1 - \text{tr}[c](\text{proj}(\psi_1)))\text{proj}(11)\) and \(\|d\|^\dagger(\text{proj}(\psi_2)) = \|d\|\text{proj}(\psi_2) + (1 - \text{tr}[d](\text{proj}(\psi_2)))\text{proj}(11)\), and \(\text{tr} A\text{proj}(\psi_1 \otimes \psi_2) \leq \text{tr} B\sigma \leq \text{tr}(B \oplus 0_{11})\rho\).

**Lemma 3** Let \(A, B\) be expectations and \(c, d\) programs. Then \(\{A\} \leq P\{B\}\) holds iff for any separable mixed bimemory \(\rho\) over \(X_1^{\text{all}}, X_2^{\text{all}}\), there is a separable mixed bimemory \(\rho'\) over \(X_1^{\text{all}}, X_2^{\text{all}}\) such that
- \(\text{tr}_2 \rho' \leq \|c\|(\text{tr}_2 \rho)\).
- \(\text{tr}_1 \rho' \leq \|d\|(\text{tr}_1 \rho)\).
- \(\text{tr} \rho' \geq \text{tr}[c](\text{tr}_2 \rho) + \text{tr}[d](\text{tr}_1 \rho) - \text{tr} \rho\).
- \(\text{tr} A\rho \leq \text{tr} B\rho' + \text{tr} \rho - \text{tr} \rho'\).

**Proof.** We first prove the “only if” part. We construct \(\rho'\) for input bimemories \(\rho_1\) and \(\rho_2\) with coupling \(\rho\) in a similar way to the proof of **Lemma 2**. Consider the 1-mixed quantum memory \(\rho \oplus 0_{11}\) as the input coupling, then \(\{A\} \leq P\{B\}\) implies that the output states \(\|c\|^\dagger(\rho_1 \oplus 0_{11}) = \|c\|(\rho_1) + (\text{tr}_1 \rho_1 - \text{tr}[c](\rho_1))\text{proj}(11)\) and \(\|d\|^\dagger(\rho_2 \oplus 0_{11}) = \|d\|(\rho_2) + (\text{tr}_2 \rho_2 - \text{tr}[d](\rho_2))\text{proj}(11)\) have a separable coupling \(\hat{\rho}\) such that
\[
\text{tr} A\rho = \text{tr}(A \oplus 0_{11} + T)(\rho \oplus 0_{11}) \leq \text{tr}(B \oplus 0_{11} + T)\hat{\rho} \\
= \text{tr}(B \oplus 0_{11})(P_L \otimes P_L)\hat{\rho}(P_L \otimes P_L) + \text{tr} \rho - \text{tr}(P_L \otimes P_L)\hat{\rho},
\]
where \(T := (\text{proj}(11) \otimes P_L) + (P_L \otimes \text{proj}(11) \otimes |1\rangle \langle 1|)\). Now let \((P_L \otimes P_L)\hat{\rho}(P_L \otimes P_L) = \rho' \oplus 0_{11}\), then \(\rho'\) is separable, \(\text{tr} A\rho \leq \text{tr} B\rho' + \text{tr} \rho - \text{tr} \rho'\). Moreover, it follows from Equation 2 that \(\rho'\) is subcoupling of the output memories \(\|c\|(\rho_1)\) and \(\|d\|(\rho_2)\), and
\[
\text{tr} \rho' + \text{tr} \rho' - \text{tr} [c](\text{tr}_2 \rho) - \text{tr} [d](\text{tr}_1 \rho) = \text{tr} \rho' + \text{tr} \hat{\rho} - \text{tr} \rho' - \text{tr}(P_L \otimes P_L)\hat{\rho} - \text{tr}(P_L \otimes P_L)\rho' = \text{tr}(P_L \otimes P_L)\hat{\rho \ominus \rho} \geq 0.
\]
Then we prove the “if” part. We derive \(\{A \oplus 0_{11} + T\} \leq P\{B \oplus 0_{11} + T\}\) by **Lemma 1**. It suffices to construct for any normalized quantum memories \(\psi_1, \psi_2\) over \(X_1^{\text{all}}, X_2^{\text{all}}\), a separable coupling \(\rho\) of the output 1-memories \(\|c\|^\dagger(\text{proj}(\psi_1))\) and \(\|d\|^\dagger(\text{proj}(\psi_2))\) such that \(\text{tr} A\text{proj}(\psi_1 \otimes \psi_2) \leq \text{tr}(B \oplus 0_{11} + T)\rho\), noting that the other three conditions for input bimemories \(\psi_1 \otimes |1\rangle \otimes \psi_2\), and \(|1\rangle \otimes \psi_2\) have naturally been satisfied for 1-expectations \(A \oplus 0_{11} + T\) and \(B \oplus 0_{11} + T\). The three premises here allow us to find memories \(\sigma_1\) and \(\sigma_2\) with separable coupling \(\sigma\) such that \(\sigma_1 \leq \|c\|(\text{proj}(\psi_1)), \sigma_2 \leq \|d\|(\text{proj}(\psi_2))\), \(1 + \text{tr} \sigma - \text{tr}[c](\text{proj}(\psi_1)) - \text{tr}[d](\text{proj}(\psi_2)) \geq 0\), and \(\text{tr} A\text{proj}(\psi_1 \otimes \psi_2) \leq \text{tr} \sigma + 1 - \text{tr} \sigma\). Let
\[
\rho = \sigma + (\|c\|(\text{proj}(\psi_1)) - \sigma_1) \otimes P_L + P_L \otimes (\|d\|(\text{proj}(\psi_2)) - \sigma_2) \\
+ (\text{tr} \sigma + \text{tr} \rho - \text{tr}[c](\text{proj}(\psi_1)) - \text{tr}[d](\text{proj}(\psi_2)))P_L \otimes P_L.
\]
Then it is easy to verify that \(\rho\) is the mixed 1-bimemory we need.

In this definition, \(\text{tr} \rho - \text{tr} \rho' \geq 0\) describes the nontermination probability. **Lemma 2** and
Lemma 3 mean that total and partial correctness can be alternatively defined using the concept of subcouplings, without considering the \( \perp \)-extension of the expectations and programs.

Lemma 4 Let \( A, B \) be expectations and \( c, d \) programs. Then \( \{A\} c \sim d \{B\} \) (resp. \( \{A\} c \approx d \{B\} \)) holds iff for all unit quantum memories \( \psi_1, \psi_2 \) over \( X_1^{\text{all}}, X_2^{\text{all}} \), respectively, there is a separable bimemory \( \rho \) over \( X_1X_2 \) such that

\[
\begin{align*}
\text{tr}_2 \rho &\leq [c](\text{proj}(\psi_1)), \\
\text{tr}_1 \rho &\leq [d](\text{proj}(\psi_2)), \\
\text{tr} \text{Aproj}(\psi_1 \otimes \psi_2) &\leq \text{tr} B \rho^{18} \quad (\text{resp. } \text{tr} \text{Aproj}(\psi_1 \otimes \psi_2) \leq \text{tr} B \rho + 1 - \text{tr} \rho \text{ and } 1 + \text{tr} \rho \geq \text{tr} [c](\text{proj}(\psi_1)) + \text{tr} [d](\text{proj}(\psi_2)).)
\end{align*}
\]

Proof. We prove by using Lemma 2 (resp. Lemma 3). For any mixed separable bimemory \( \rho \) as input, let \( \rho = \sum_i p_i \psi_i \otimes \phi_i \) where \( p_i \in [0,1] \), \( \psi_i \) and \( \phi_i \) are normalized pure quantum memories. Then from the premises, let \( \rho_i \) be the output bimemories corresponding to input \( \psi_i \otimes \phi_i \). It is easy to verify that \( \rho' = \sum_i p_i \rho_i \) is the output bimemory corresponding to \( \rho \).

\[ \square \]

5 Description of the rules

We describe the rules of our logic one by one. Recall that we essentially have four different logics: partial, semipartial, total, and the general case from which the former three are derived. To keep things readable, we only describe the rules for the partial, semipartial, and total case here. (Listed in Figure 1.) In Section 6, we state and prove the rules in the general case. The rules in Figure 1 are then simple consequences of the rules in the general case. The sole exception are rules related to while-loops: here not all of the partial, semipartial, total case follow directly from the general while rule. Those cases that do not follow are proved separately.

5.1 Structural rules

First, we mention the “structural” rules, i.e., rules that are not related to a specific language construct. There is \( \text{SYM} \) for exchanging the two programs. (In this rule, \( \text{SWAP} : \ell^2[X_1^{\text{all}}] \otimes \ell^2[X_2^{\text{all}}] \rightarrow \ell^2[X_1^{\text{all}}] \otimes \ell^2[X_2^{\text{all}}] \) is the unitary operator \( \text{SWAP}_\bot : \psi \otimes \phi \mapsto \phi \otimes \psi. \) \( \text{EXFALSO} \) allows us to show anything from an impossible preexpectation. \( \text{SEQ} \) allows us to analyze the sequential composition of programs. \( \text{CONSEQ} \) allows us to weaken a judgment. (The preexpectation can be replaced by a smaller preexpectation, and the postexpectation can be replaced by a larger preexpectation. \( \leq \) is the Loewner order). And finally, \( \text{SCALE} \) allows us to scale pre- and postexpectations by a scalar factor.

5.2 One-sided rules

Conceptually simplest are the one-sided rules, i.e., rules that have \( \text{skip} \) on the right (or left) hand side. By combining them with \( \text{SEQ} \), we can prove facts about pairs of programs one statement at the time. Here, we only describe the rules with \( \text{skip} \) on the right side, the other case is analogous.

Apply: First, consider the \( \text{APPLY}_1 \) rule. It is stated (like all our rules), in a backward reasoning style, i.e., for any postexpectation \( A \), the tells us the corresponding preexpectation, here \( (U \text{ on } X_1)^* A (U \text{ on } X_1) \). (Recall that \( U \text{ on } X_1 \) denotes \( U \) applied to \( X_1 \).) This is quite intuitive: the left program applies \( U \text{ on } X_1 \), so the preexpectation corresponding to the postexpectation \( A \) is what we get if we apply \( U \text{ on } X_1 \) and then compute the preexpectation, i.e.,

\[ \text{18} \text{Or equivalently, } \| \sqrt{A}(\psi_1 \otimes \psi_2) \| \leq \text{tr} B \rho. \text{ Or } (\psi_1 \otimes \psi_2)^* A(\psi_1 \otimes \psi_2) \leq \text{tr} B \rho. \]
\((U \text{ on } X_1)^*A(U \text{ on } X_1)\). (And it is \((U \text{ on } X_1)^*A(U \text{ on } X_1)\) and not \(A(U \text{ on } X_1)\) because the latter is not Hermitian and thus not a valid expectation.)

A toy example how to apply this rule: we want to know what the probability is to measure \(x\) has to be so that it will be \(|0\rangle\) after applying a Hadamard \(H\). Thus our postexpectation is \(\text{proj}(|0\rangle)\text{ on } x_1\). Applying \texttt{rule APPLY1}, we get that \(\{B\} \text{ apply } H \text{ to } x \xrightarrow{\text{any}} \text{skip } \{\text{proj}(|0\rangle)\text{ on } x_1\}\) for \(B := (H \text{ on } x_1)^*(\text{proj}(|0\rangle)\text{ on } x_1)(H \text{ on } x_1)\). (Here \(\sim \approx\) can be any of \(\sim, \sim_{\text{semi}}, \sim_{\text{par}}\).) A simple calculation reveals: \(B = (H^*\text{proj}(|0\rangle)H) \text{ on } x_1 = \text{proj}(|+)\text{ on } x_1\). Thus we learned (unsurprisingly) that to get \(|0\rangle\), we need to start out with \(|+\rangle\).

\textbf{Init:} The \texttt{rule INIT1} rule stated in a similar backwards reasoning way as \texttt{APPLY1}, but the preexpectation is somewhat less intuitive. We will illustrate it with a toy example. Assume we want to know what the probability is to measure \(|0\rangle\) after initializing a variable \(x\) with \(|+\rangle\). That is, our postexpectation is \(A := \text{proj}(|0\rangle)\text{ on } x_1\) and our left program is \(x \leftarrow |+\rangle\). We ask for a suitable preexpectation \(B\) in \(\{B\} x \leftarrow |+\rangle \xrightarrow{\text{any}} \text{skip } \{A\}\). The \texttt{INIT1} rule gives us \(B = \text{id}_{x_1} \otimes ((|+\rangle \otimes \text{id}_{-x_1})A(|+\rangle \otimes \text{id}_{-x_1})\). (Here, \(\sim X_1 := X_1^{\text{top}}X_2^{\text{bot}} \setminus X_1.\)) By definition of \(A\), we have that \(((|+\rangle \otimes \text{id}_{-x_1})A(|+\rangle \otimes \text{id}_{-x_1}) = (|\text{proj}(|0\rangle)|+\rangle \otimes \text{id}_{-x_1} = \frac{1}{2}\text{id}_{-x_1}.\) Note that this is not an expectation in our sense because it is an operator on all variables but \(x_1\). But by tensoring with \(\text{id}_{x_1}\), we get the expectation \(B = \frac{1}{2}\text{id}\). Thus the preexpectation is \(\frac{1}{2}\text{id}\) which intuitively means that, no matter what the initial state, the probability of measuring \(|0\rangle\) will be \(\frac{1}{2}\), as we would expect.

\textbf{If:} The \texttt{rule IF1} rules allows us to prove a judgment about an if-statement from judgments about the then- and the else-branch. If the preexpectations from the then- and else-branch are \(A_T\) and \(A_F\), then the preexpectation for the if-statement is \(\downarrow_{\text{true}}^*(A_T) + \downarrow_{\text{false}}^*(A_F)\). (Here \(\downarrow^*_A := (M_i \text{ on } X_1)^*A(M_i \text{ on } X_1)\).) This is natural since \(\downarrow_{\text{true}}^*(A_T)\) is \(A_T\) restricted to the case where the conditional holds, and \(\downarrow_{\text{false}}^*(A_F)\) is \(A_F\) restricted to the case where the conditional does not hold.

A toy example: We want to show \(\{id\} \text{ if } \text{id}[x] \text{ then apply } X \text{ to } x \text{ else skip } \xrightarrow{\text{any}} \text{skip } \{B\}\) with \(B := \text{proj}(|0\rangle)\text{ on } x_1\). Here \(M\) is a computational basis measurement \((M_{\text{true}} = \text{proj}(|1\rangle), M_{\text{false}} = \text{proj}(|0\rangle)\), and \(X\) is the pauli-X matrix (quantum bit flip). That is, with probability 1 (preexpectation is id), if we measure \(x\) in the computational basis, and, in case of outcome 1 flip it, we get \(|0\rangle\) (postexpectation B). We derive easily (using rules \texttt{APPLY1} and \texttt{SKIP}) that \(\{\text{proj}(|1\rangle)\text{ on } x_1\} \text{ apply } X \text{ to } x \xrightarrow{\text{any}} \text{skip } \{B\}\) and \(\{\text{proj}(|0\rangle)\text{ on } x_1\} \text{ skip } \xrightarrow{\text{any}} \text{skip } \{B\}\). From the \texttt{IF1} rule, we then get \(\{A\} \text{ if } \text{id}[x] \text{ then apply } X \text{ to } x \text{ else skip } \xrightarrow{\text{any}} \text{skip } \{B\}\) with \(A = \downarrow_{\text{true}}^*(\text{proj}(|1\rangle)\text{ on } x_1) + \downarrow_{\text{false}}^*(\text{proj}(|0\rangle)\text{ on } x_1)\). Thus \(A = \text{proj}(|1\rangle)\text{ on } x_1 + \text{proj}(|0\rangle)\text{ on } x_1 = \text{id}\), as desired.

\textbf{While:} The \texttt{WHILE1} rule is similar to the \texttt{IF1} rule. (The preexpectation in the conclusion has the same form.) The main difference is that we need to guess the invariant \(A\) because the postexpectation in the premise contains \(A\). The rule also requires us to prove first that the loop is terminating (except in the case of partial correctness). Since this is a statement about a single program (non-relational), it can be shown using existing approaches (e.g., [LY18]) and is outside the scope of this paper.

### 5.3 Two-sided rules

The one-sided rules discussed in the previous section allow us to analyze two programs one statement at a time. However, they are not sufficient if we want to analyze the relationship of two programs that go in lockstep. (E.g., two while loops that always take the same decision whether to terminate.) For handling if- and while-statements that are in sync, our logic provides the two-sided rules \texttt{JOINTIF0}, \texttt{JOINTIF}, and \texttt{JOINTWHILE}. Notice that there are not two-sided analogues to \texttt{APPLY1} and \texttt{INIT1}. This is because the resulting rule would be no different from using the one-sided rule twice. However, when random choices happen, two-sided rules are
useful. In our case, this happens in if- and while-statements because the measurement of the loop-condition introduces randomness.

If: The JointIf rule allows us to compute the preexpectation of two if-statements. It is analogous to the If1 rule, except that the resulting preexpectation is of the form \( \sum_{t,u \in \{true, false\}} \downarrow_{t,u}(A_{t,u}). \) (Here \( \downarrow_{t,u}(A) := ((M_t \text{ on } X_1) \otimes (N_t \text{ on } Y_2))^*A((M_t \text{ on } X_1) \otimes (N_t \text{ on } Y_2)) \)) That is, the preexpectations are restricted to all four combinations of true/false for the two if-conditions. And, consequently, we have a premise for each of those four cases. (The rule is called JointIf because, in the general case, there are nine cases, due to explicit treatment of non-terminating cases.) For convenience, we additionally state rule JointIf which considers only the cases where the two if-statements are in sync (true/true or false/false).

While: Similar to JointIf, the JointWhile rule allows us to reason about while loops that are in sync. Like with While1, in contrast to JointIf, we need to guess the invariant \( A \). For an example, see Section 7. One difference with the While1 rule is that While1 requires us to prove termination in the semipartial and total case (not in the partial case), while JointWhile requires us to prove termination only in the total case. (Intuitively, this is because in the semipartial case, termination is not required, it is only required that both programs terminate with the same probability.)

6 Soundness of the rules

In the following, we state our rules in their generic form (from which the rules in Figure 1 are easily derived) and prove their soundness.

6.1 Basic rules

**Skip**

\[
\{A\} \text{skip} \sim \text{skip} \{A\}
\]

*Proof.* We use Lemma 1 to prove this rule. For any unit quantum memories \( \psi_1, \psi_2 \) over \( X_1^\text{all}, X_2^\text{all} \) as input, the output memories are \( [\text{skip}]^{-1}(\text{proj}(\psi_i)) = \text{proj}(\psi_i), \) \( i = 1, 2. \) So \( \psi_1 \otimes \psi_2 \) is a separable coupling of the output states with the expected value \( \text{tr} A(\text{proj}(\psi_1 \otimes \psi_2)) \) of the postexpectation, as the same as that of the preexpectation. Moreover, note that \([\text{skip}]^{-1}(\text{proj}(|\perp_i\rangle)) = \text{proj}(|\perp_i\rangle)\). Then for input \( \perp \)-bimemories \( |\psi_1 \rangle \otimes |\perp_1\rangle, |\perp_1\rangle \otimes |\psi_2\rangle, \) and \( |\perp_1\rangle \otimes |\perp_2\rangle \), the output \( \perp \)-bimemories keep unchanged. Since the preexpectation and the postexpectation are both \( A \), the expected values of them are also the same. Therefore, the four conditions in Lemma 1 are satisfied, which implies rule Skip. \( \square \)

**ExFalso**

\[
\{0\} \text{c} \sim \varnothing \{B\}
\]

*Proof.* For any separable mixed \( \perp \)-bimemory \( \rho \) as input, we simply choose \( \rho' = [\text{c}]^{-1}(\text{tr}_2 \rho) \otimes [\varnothing]^{-1}(\text{tr}_1 \rho) \) as the separable coupling of the output \( \perp \)-memories, and then \( \text{tr} 0 \rho = 0 \leq \text{tr} B \rho' \). From Definition 4, the rule holds. \( \square \)
From Definition 4, the rule holds.

Proof. For any separable mixed \( \perp \)-bimemory \( \rho \) on \( \ell^2[\mathbb{X}^\text{all}]^\perp \otimes \ell^2[\mathbb{X}^\text{all}]^\perp \), let \( \rho' := \mathcal{D}^{-1}(\text{tr}_2 \rho) \) and \( \rho_2 := \mathcal{D}^\perp(\text{tr}_1 \rho) \). Then it follows from Definition 4, it suffices to find a separable coupling \( \rho' \) of \( \rho_2 \) and \( \rho_1' \) such that

\[
\text{tr}(\mathcal{S}WAP_\perp \cdot A \cdot \mathcal{S}WAP_\perp) \rho \leq \text{tr}(\mathcal{S}WAP_\perp \cdot B \cdot \mathcal{S}WAP_\perp) \rho'.
\]

Let \( \rho_{12} := \mathcal{S}WAP_\perp \cdot \rho \cdot \mathcal{S}WAP_\perp^* \). Then it is easy to verify that \( \text{tr}_1 \rho_{12} = \text{tr}_2 \rho \) and \( \text{tr}_2 \rho_{12} = \text{tr}_1 \rho \). Furthermore, \( \{A\} \mathcal{C} \bowtie \mathcal{D} \{B\} \) implies that for input \( \perp \)-bimemory \( \rho_{12} \), there is a separable coupling \( \rho_2' \) of \( \rho_1' \) and \( \rho_2' \) such that \( \text{tr}A\rho_{12} \leq \text{tr}B\rho_{12}' \). Now let \( \rho' := \mathcal{S}WAP_\perp \cdot \rho_{12}' \cdot \mathcal{S}WAP_\perp \), then the result immediately follows from

\[
\text{tr}(\mathcal{S}WAP_\perp \cdot A \cdot \mathcal{S}WAP_\perp) \rho = \text{tr}A\rho_{12} \text{ and } \text{tr}(\mathcal{S}WAP_\perp \cdot B \cdot \mathcal{S}WAP_\perp) \rho' = \text{tr}B\rho_{12}'.
\]

Proof. For any separable mixed \( \perp \)-bimemory \( \rho \) as input, \( \{A\} \mathcal{C} \bowtie \mathcal{D} \{B\} \) implies that there is a separable coupling \( \theta \) of output \( \perp \)-memories \( \theta_1 := \mathcal{C}_1^{-1}(\text{tr}_2 \rho) \), \( \theta_2 := \mathcal{D}_1^{-1}(\text{tr}_1 \rho) \), such that \( \text{tr}A\rho \leq \text{tr}B\theta \). Furthermore, \( \{B\} \mathcal{C} \bowtie \mathcal{D}_2 \{C\} \) implies that for separable mixed \( \perp \)-bimemory \( \theta \) as input, there is a separable coupling \( \sigma \) of the output \( \perp \)-memories \( \sigma_1 := \mathcal{C}_2^{-1}(\theta_1) = [\mathcal{C}_1; \mathcal{C}_2]^{-1}(\text{tr}_2 \rho) \) and \( \sigma_2 := \mathcal{D}_2^{-1}(\theta_2) = [\mathcal{D}_1; \mathcal{D}_2]^{-1}(\text{tr}_1 \rho) \) such that \( \text{tr}B\theta \leq \text{tr}C\sigma \). Then we have \( \text{tr}A\rho \leq \text{tr}B\theta \leq \text{tr}C\sigma \). From Definition 4, \( \{A\} \mathcal{C} \bowtie \mathcal{D}_1; \mathcal{D}_2 \{C\} \) is obtained.

Proof. For any separable mixed \( \perp \)-bimemory \( \rho \) as input, \( \{A\} \mathcal{C} \bowtie \mathcal{D} \{B\} \) implies that there is a separable coupling \( \rho' \) of the output memories such that \( \text{tr}A\rho \leq \text{tr}B\rho' \), then it follows immediately from \( A' \leq A \) and \( B' \leq B \) that

\[
\text{tr}A'\rho \leq \text{tr}A\rho \leq \text{tr}B\rho' \leq \text{tr}B'\rho'.
\]

From Definition 4, the rule holds.
Proof. For any separable mixed \( \perp \)-bimemory \( \rho \) as input, \( \{A\} c \overset{\text{gen}}{\sim} d \{B\} \) implies that there is a separable coupling \( \rho' \) of the output memories such that \( \text{tr} A \rho \leq \text{tr} B \rho' \), then we have \( \text{tr}(\lambda A) \rho = \lambda \text{tr} A \rho \leq \lambda \text{tr} B \rho' = \text{tr}(\lambda B) \rho' \). The rule follows from Definition 4.

### 6.2 One sided rules

\[
\begin{align*}
\text{APPLY1} & \quad \{(U \text{ on } X_1)^* A (U \text{ on } X_1) + \downarrow_{\perp 1}^* (A)\} \ \text{apply} \ U \ \text{to} \ X \ \overset{\text{gen}}{\sim} \ \text{skip} \ A \\
& \quad \text{Here, } \downarrow_{\perp 1}^* (A) := P_1 A P_{\perp} \text{ is the dual of } \downarrow_{\perp} \text{ as } \text{tr} \downarrow_{\perp 1}^* (A) \rho = \text{tr} A \downarrow_{\perp} (\rho).
\end{align*}
\]

Proof. We use Lemma 1 to prove this rule. For any unit quantum memories \( \psi_1, \psi_2 \) over \( X_1^{\text{all}}, X_2^{\text{all}} \) as input, the expected values of the preexpectation are also the same, noting that

\[
\begin{align*}
\text{tr}(A (U \text{ on } X_1) \text{proj}(\psi_1, \psi_2) (U \text{ on } X_1)^*)
\end{align*}
\]

of the postexpectation, as the same as the expected value

\[
\begin{align*}
\text{tr}[(U \text{ on } X_1)^* A (U \text{ on } X_1) + \downarrow_{\perp 1}^* (A)] \text{proj}(\psi_1, \psi_2) = \text{tr}(U \text{ on } X_1)^* A (U \text{ on } X_1) \text{proj}(\psi_1, \psi_2)
\end{align*}
\]

of the preexpectation. Similarly, it is easy to see that for \( \perp \)-bimemories \( |\psi_1\rangle \otimes |\perp_2\rangle \), \( |\perp_1\rangle \otimes |\psi_2\rangle \), and \( |\perp_1\rangle \otimes |\perp_2\rangle \) as input, the expected values of the preexpectation and of the postexpectation are also the same, noting that \( \text{tr}[(U \text{ on } X_1)^* \text{proj}(|\perp_1\rangle)] = \text{proj}(\perp_1) \) and \( \text{tr}[(\text{proj}(|\perp_2\rangle))] = \text{proj}(\perp_2) \).

\[
\begin{align*}
\text{INT1} & \quad \{\text{id}_{X_1} \otimes (\psi^* \otimes \text{id}_{-X_1}) A (\psi \otimes \text{id}_{-X_1}) + \downarrow_{\perp 1}^* (A)\} \ X \leftarrow \psi \ \overset{\text{gen}}{\sim} \ \text{skip} \ A \\
& \quad \text{Here, } \neg X_1 := X_1^{\text{all}} X_2^{\text{all}} \setminus X_1. \text{ Here we use that } \psi \in \ell^2[X_1] \text{ can be interpreted as an operator } \psi : C \to \ell^2[X_1], \text{ hence } \psi \otimes \text{id}_{-X_1} \text{ is an operator } \neg X_1 \to X_1^{\text{all}} X_2^{\text{all}}. \text{ Thus the preexpectation is a positive operator on } X_1^{\text{all}} X_2^{\text{all}} \text{ as required.}
\end{align*}
\]

Proof. We use Lemma 1 to prove this rule. For any unit quantum memories \( \phi_1, \phi_2 \) over \( X_1^{\text{all}}, X_2^{\text{all}} \) as input, the expected values are

\[
\begin{align*}
\text{proj}(\psi) \otimes (\text{tr}_{X_1} \text{proj}(\phi_1)) \otimes \text{proj}(\phi_2) = (\psi \otimes \text{id}_{-X_1}) [\text{tr}_{X_1} \text{proj}(\phi_1 \otimes \phi_2)] (\psi^* \otimes \text{id}_{-X_1})
\end{align*}
\]

is a separable coupling of the output memories with the expected value

\[
\begin{align*}
& \text{tr} A (\psi \otimes \text{id}_{-X_1}) [\text{tr}_{X_1} \text{proj}(\phi_1 \otimes \phi_2)] (\psi^* \otimes \text{id}_{-X_1}) \\
& \overset{\text{□}}{=} \text{tr}(\psi^* \otimes \text{id}_{-X_1}) A (\psi \otimes \text{id}_{-X_1}) [\text{tr}_{X_1} \text{proj}(\phi_1 \otimes \phi_2)] \\
& = \text{tr} (\text{id}_{X_1} \otimes (\psi^* \otimes \text{id}_{-X_1}) A (\psi \otimes \text{id}_{-X_1}) \text{proj}(\phi_1 \otimes \phi_2)
\end{align*}
\]
of the postexpectation, as the same as the expected value
\[
\text{tr} [\text{id}_{X_1} \otimes (\psi \otimes \text{id}_{-X_1})] A (\psi \otimes \text{id}_{-X_1}) + J^\perp (A) \text{proj} (\phi_1 \otimes \phi_2)
\]
of the preexpectation. Here (\*) is due to the circularity of the trace (i.e., \(\text{tr} AB = \text{tr} BA\) for a trace class operator \(A\) and a bounded operator \(B\)). Similarly, it is easy to see that for \(\perp\)-bimemories \(|\psi_1\rangle \otimes |\perp\rangle\), \(|\perp\rangle \otimes |\psi_2\rangle\), and \(|\perp\rangle \otimes |\perp\rangle\) as input, the expected values of the preexpectation and of the postexpectation are also the same, noting that \([X \leftarrow \psi]^\perp (\text{proj}(\perp_1)) = \text{proj}(\perp_1)\) and \([\text{skip}]^\perp (\text{proj}(\perp_2))) = \text{proj}(\perp_2)\).

\[
\text{tr} 1 \begin{align*}
\{A_T\} c_T & \cong \mathcal{D} \{B\} & \{A_F\} c_F & \cong \mathcal{D} \{B\} \\
\{\downarrow^\ast (A_T) + \downarrow^\ast (A_F) + \downarrow^\perp (A_\perp)\} \text{ if } M[X] & \text{ then } c_T & \text{ else } c_F & \cong \mathcal{D} \{B\}
\end{align*}
\]

Here \(\downarrow^T = (M_t \text{ on } X_1)^* A (M_t \text{ on } X_1)\) is the Heisenberg-Schrödinger dual of \(\downarrow_t\) for \(t = \text{true}, \text{false}\), as \(\text{tr} A \downarrow_t (\rho) = \text{tr} A \downarrow_t (A) \rho\). Note that in this rule, \(c_\perp\) occurs only in the premises. It can thus be chosen arbitrarily. Typical choices would include \(c_\perp := \text{skip}\) or \(c_\perp := \text{abort}\).

\textbf{Proof.} We use Lemma 1 to prove this rule. For any unit quantum memories \(\psi_1, \psi_2\) over \(X_1\), \(X_2\) as input, the output memories are
\[
\rho_1 := \left[\text{if } M[X] \text{ then } c_T \text{ else } c_F\right]^\perp (\text{proj}(\psi_1)) = \left[\text{proj}(\psi_1)\right] + \left[\text{false}(\text{proj}(\psi_1))\right]
\]
and \(\rho_2 := \left[\mathcal{D}\right]^\perp (\text{proj}(\psi_2))\). Let \(p \cdot \alpha_T := \downarrow_\text{true}(\text{proj}(\psi_1)), (1 - p) \cdot \alpha_F := \downarrow_\text{false}(\text{proj}(\psi_1))\), where \(p \in [0, 1]\) and \(\text{tr} \alpha_T = \text{tr} \alpha_F = 1\). Then \(\{A_T\} c_T \cong \mathcal{D} \{B\}\) implies that there is a separable coupling \(\rho_T\) of \(\left[\text{proj}(\psi_1)\right] + \left[\text{false}(\text{proj}(\psi_1))\right]\) and \(\rho_2\) such that \(\text{tr} A_T (\alpha_T \otimes \text{proj}(\psi_2)) \leq \text{tr} B \rho_B\), and \(\{A_F\} c_F \cong \mathcal{D} \{B\}\) implies that there is a separable coupling \(\rho_F\) of \(\left[\text{proj}(\psi_1)\right] + \left[\text{false}(\text{proj}(\psi_1))\right]\) and \(\rho_2\) such that \(\text{tr} A_F (\alpha_F \otimes \beta) \leq \text{tr} B \rho_F\). Then \(\rho := p \cdot \rho_T + (1 - p) \cdot \rho_F\) is a separable coupling of \(\rho_1\) and \(\rho_2\) satisfying that
\[
\text{tr} \left(\downarrow^\ast (A_T) + \downarrow^\ast (A_F) + \downarrow^\perp (A_\perp)\right) \text{proj}(\psi_1 \otimes \psi_2) = \text{tr} A_T [\downarrow_\text{true}(\text{proj}(\psi_1)) \otimes \text{proj}(\psi_2)] + \text{tr} A_T [\downarrow_\text{false}(\text{proj}(\psi_1)) \otimes \text{proj}(\psi_2)] + 0
\]
\[
= p \text{ tr} A_T (\alpha_T \otimes \beta) + (1 - p) \text{ tr} A_F (\alpha_F \otimes \beta) \leq p \text{ tr} B \rho_T + (1 - p) \text{ tr} B \rho_F = \text{tr} B \rho.
\]

Similarly, we have
\[
\text{tr} \left(\downarrow^\ast (A_T) + \downarrow^\ast (A_F) + \downarrow^\perp (A_\perp)\right) \text{proj}(\psi_1 \otimes |\perp\rangle) = \text{tr} A_T (\alpha_T \otimes P_\perp) + (1 - p) \text{ tr} A_F (\alpha_F \otimes P_\perp)
\]
\[
\leq p \text{ tr} B [\left[\text{proj}(\psi_1)\right] \otimes P_\perp] + (1 - p) \text{ tr} B [\left[\text{false}(\text{proj}(\psi_1))\right] \otimes P_\perp] = \text{tr} B (\rho_1 \otimes P_\perp).
\]

Here, (\*) is because \(\text{tr} A_T (\alpha_T \otimes P_\perp) \leq \text{tr} B [\left[\text{proj}(\psi_1)\right] \otimes P_\perp]\) and \(A_F (\alpha_F \otimes P_\perp) \leq \text{tr} B [\left[\text{false}(\text{proj}(\psi_1))\right] \otimes P_\perp]\) directly follow from the premises. Moreover,
\[
\text{tr} \left(\downarrow^\ast (A_T) + \downarrow^\ast (A_F) + \downarrow^\perp (A_\perp)\right) \text{proj}(P_\perp \otimes \beta) = \text{tr} A_\perp (P_\perp \otimes \beta)
\]
\[
\leq \text{tr} B [P_\perp \otimes \left[\mathcal{D}\right]] (\beta),
\]
where, (\**\*) is from the premise \(\{A_\perp\} c_\perp \cong \mathcal{D} \{B\}\). Then the proof is completed by choosing \(\beta = \psi_2\) and \(|\perp\rangle\). \(\square\)
\[\text{WHILE1} \quad \{A\} c \xleftrightarrow{\text{skip}} \{\downarrow_*^{\text{true}}(A) + \downarrow_*^{\text{false}}(B)\} \quad \text{while} \ M[X] \text{ do } c \text{ is terminating} \]

\[\{\downarrow_*^{\text{true}}(A) + \downarrow_*^{\text{false}}(B)\} \quad \text{while} \ M[X] \text{ do } c \xleftrightarrow{\text{skip}} \{B\}\]

Here, the rule WHILE1 for quantum while loops is established by using an invariant of the form \(\downarrow_*^{\text{true}}(A) + \downarrow_*^{\text{false}}(B)\). Such a form of quantum invariant was proposed in quantum Hoare logic [Yin12] for reasoning about (non-relational) quantum while loops.

Note that this rule requires us to establish termination of \textbf{while} \(M[X] \text{ do } c\) as a precondition. Since this is a statement about a single program (non-relational), it can be shown using existing approaches (e.g., [LY18]) and is outside the scope of this paper.

**Proof.** We use Lemma 1 to prove the conclusion from the premises. Note that the preexpectation enjoys

\[\text{(3)} \quad [\downarrow_*^{\text{true}}(A) + \downarrow_*^{\text{false}}(B)](\text{tr} \downarrow \otimes \text{id}) = 0,\]

then the expected value of the preexpectation is always 0 for any input \(\downarrow\)-bimemory of form \(\text{proj}(\downarrow \otimes \phi)\) where \(\phi \in \mathcal{E}^2[X_2^{\text{all}}]^{-}\). So, it suffices to prove that

\[\text{(4)} \quad \text{tr}(\downarrow_*^{\text{true}}(A) + \downarrow_*^{\text{false}}(B))(\alpha \otimes \beta) \leq \text{tr} B(\rho \otimes \beta),\]

where \(\alpha := \text{proj}(\psi_1)\), \(\rho := [\text{while} M[X] \text{ do } c]^\perp(\alpha)\), and \(\beta := \text{proj}(\psi_2)\) or \(P_1\), for any unit quantum memories \(\psi_1, \psi_2\) over \(X_1^{\text{all}}, X_2^{\text{all}}\) respectively. Note that \(\rho = [\text{while} M[X] \text{ do } c](\alpha)\) since \textbf{while} \(M[X] \text{ do } c\) is terminating. To express \(\rho\) in a more explicit form, let \(\alpha_0 := \alpha\), and for \(n = 0, 1, \ldots\), let \(\alpha_{n+1} := [c] \circ \downarrow_*^{\text{true}}(\alpha_n)\). Then \(\rho = \sum_{n=0}^{\infty} \downarrow_*^{\text{false}}(\alpha_n)\) by definition of the semantics of \textbf{while}.

From the premise \(\{A\} c \xleftrightarrow{\text{skip}} \{\downarrow_*^{\text{true}}(A) + \downarrow_*^{\text{false}}(B)\}\), we have

\[\text{tr} A(\downarrow_*^{\text{true}}(\alpha_n) \otimes \beta) \leq \text{tr}(\downarrow_*^{\text{true}}(A) + \downarrow_*^{\text{false}}(B))([c] \circ \downarrow_*^{\text{true}}(\alpha_n) \otimes \beta)\]

\[\xrightarrow{\text{(3)}} \quad \text{tr}(\downarrow_*^{\text{true}}(A) + \downarrow_*^{\text{false}}(B))([c] \circ \downarrow_*^{\text{true}}(\alpha_n) \otimes \beta) = \text{tr}(\downarrow_*^{\text{true}}(A) + \downarrow_*^{\text{false}}(B))(\alpha_n + 1) \otimes \beta),\]

noting that \([c] \circ \downarrow_*^{\text{true}}(\alpha_n) \otimes \beta\) is the unique separable coupling of the output \(\downarrow\)-memories as \(\beta\) is the density operator of a pure \(\downarrow\)-memory. It further implies that

\[\text{(5)} \quad \text{tr} A(\downarrow_*^{\text{true}}(\alpha_n) \otimes \beta) - \text{tr} A(\downarrow_*^{\text{true}}(\alpha_{n+1}) \otimes \beta) = \text{tr} A(\downarrow_*^{\text{true}}(\alpha_n) \otimes \beta) - \text{tr} \downarrow_*^{\text{false}}(A)(\alpha_{n+1} \otimes \beta)\]

\[\leq \text{tr} \downarrow_*^{\text{false}}(B)(\alpha_{n+1} \otimes \beta) = \text{tr} B(\downarrow_*^{\text{false}}(\alpha_{n+1}) \otimes \beta).\]

Therefore,

\[\text{(6)} \quad \text{tr}(\downarrow_*^{\text{true}}(A) + \downarrow_*^{\text{false}}(B))(\alpha \otimes \beta) = \text{tr} B(\downarrow_*^{\text{false}}(\alpha_0) \otimes \beta) + \text{tr} A(\downarrow_*^{\text{true}}(\alpha_0) \otimes \beta)\]

\[= \text{tr} B(\downarrow_*^{\text{false}}(\alpha_0) \otimes \beta) + \text{tr} A(\downarrow_*^{\text{true}}(\alpha_0) \otimes \beta)\]

\[+ \sum_{i=0}^{n-1} \text{tr} A(\downarrow_*^{\text{true}}(\alpha_i) \otimes \beta) - \text{tr} A(\downarrow_*^{\text{true}}(\alpha_{i+1}) \otimes \beta)]\]

\[\leq \text{tr} B(\downarrow_*^{\text{false}}(\alpha_0) \otimes \beta) + \text{tr} A(\downarrow_*^{\text{true}}(\alpha_0) \otimes \beta) + \sum_{i=0}^{n-1} \text{tr} B(\downarrow_*^{\text{false}}(\alpha_{i+1}) \otimes \beta)\]

\[= \text{tr} B(\sum_{i=0}^{n} \downarrow_*^{\text{false}}(\alpha_i) \otimes \beta) + \text{tr} A(\downarrow_*^{\text{true}}(\alpha_0) \otimes \beta) \leq \text{tr} B(\rho \otimes \beta) + \text{tr} A(\downarrow_*^{\text{true}}(\alpha_0) \otimes \beta).\]
On the other hand, note that
\[
\text{tr} \downarrow_{\text{true}}(\alpha_n) = \text{tr} \alpha_n - \text{tr} \downarrow_{\text{false}}(\alpha_n) = \text{tr}[c] \circ \downarrow_{\text{true}}(\alpha_{n-1}) - \text{tr} \downarrow_{\text{false}}(\alpha_n) \\
\leq \text{tr} \downarrow_{\text{true}}(\alpha_{n-1}) - \text{tr} \downarrow_{\text{false}}(\alpha_n),
\]
by induction on \( n \), it is easy to prove that
\[
\text{tr} \downarrow_{\text{true}}(\alpha_n) = 1 - \sum_{i=0}^{n} \text{tr} \downarrow_{\text{false}}(\alpha_i) \xrightarrow{n \to \infty} 1 - \text{tr} \rho(c).
\]
(7)

Here (*) is due to the termination of \textbf{while} \( M[X] \) \textbf{do} \( c \). Noting that \( A \) is a bounded operator, then Equation 7 implies that \( \lim_{n \to \infty} \text{tr} A(\downarrow_{\text{true}}(\alpha_n) \otimes \beta) = 0 \), which further implies Equation 4 together with Equation 6.

We refer to the symmetric rules of \textbf{APPLY1}, \textbf{INIT1}, \textbf{IF1}, and \textbf{WHILE1} (obtained by applying \textbf{SYM} as \textbf{APPLY2}, \textbf{INIT2}, \textbf{IF2}, and \textbf{WHILE2}. For example:

\[
\text{IF2} \quad \{A_T\} c \xrightarrow{gen} \mathfrak{d}_T \{B\} \quad \{A_F\} c \xrightarrow{gen} \mathfrak{d}_F \{B\} \quad \{A_\bot\} c \xrightarrow{gen} c_\bot \{B\} \quad \{\downarrow^*_{\text{true}}(A_T) + \downarrow^*_{\text{false}}(A_F) + \downarrow^*_{\bot}(A_\bot)\} c \xrightarrow{gen} \text{if } N[Y] \text{ then } \mathfrak{d}_T \text{ else } \mathfrak{d}_F \{B\}
\]

6.3 Two sided rules

\[
\text{JOIN9} \quad \{A_{t,u}\} c_t \xrightarrow{gen} \mathfrak{d}_u \{B\} \text{ for } t, u \in \{\text{true, false, } \bot\}
\]

\[
\{\sum_{t,u \in \{\text{true, false, } \bot\}} \downarrow^*_{t,u}(A_{t,u})\} \xrightarrow{gen} \text{if } M[X] \text{ then } c_{\text{true}} \text{ else } c_{\text{false}} \text{ if } N[Y] \text{ then } \mathfrak{d}_{\text{true}} \text{ else } \mathfrak{d}_{\text{false}} \{B\}
\]

\[
\text{Proof.} \text{ For convenience, we denote by } \downarrow^*_{i,t} \text{ the action of } \downarrow^* \text{ from the i-th program, for } i = 1, 2 \text{ and } t = \text{true, false, } \bot. \text{ Then } \downarrow^*_{t,u} = \downarrow^*_{1,t} \circ \downarrow^*_{2,u} = \downarrow^*_{2,u} \circ \downarrow^*_{1,t}. \text{ By using rule IF1, it follows from the premises for every } u \in \{\text{true, false, } \bot\} \text{ that}
\]
\[
\{\downarrow^*_{1,\text{true}}(A_{\text{true},u}) + \downarrow^*_{1,\text{false}}(A_{\text{false},u}) + \downarrow^*_{1,\bot}(A_{\bot,u})\} \text{ if } M[X] \text{ then } c_{\text{true}} \text{ else } c_{\text{false}} \xrightarrow{gen} \mathfrak{d}_u \{B\}. \quad (8)
\]

Let \( A_u := \downarrow^*_{1,\text{true}}(A_{\text{true},u}) + \downarrow^*_{1,\text{false}}(A_{\text{false},u}). \text{ Then by using rule IF2, it follows from Equation 8 for all } u \in \{\text{true, false, } \bot\} \text{ that}
\]
\[
\{A\} \text{ if } M[X] \text{ then } c_{\text{true}} \text{ else } c_{\text{false}} \xrightarrow{gen} \text{ if } N[Y] \text{ then } \mathfrak{d}_{\text{true}} \text{ else } \mathfrak{d}_{\text{false}} \{B\},
\]

where \( A := \downarrow^*_{2,\text{true}}(A_{\text{true}}) + \downarrow^*_{2,\text{false}}(A_{\text{false}}) + \downarrow^*_{2,\bot}(A_{\bot}) = \sum_{t,u \in \{\text{true, false, } \bot\}} \downarrow^*_{t,u}(A_{t,u}). \)

\[
\text{JOINWHILE} \quad \{A\} c \xrightarrow{gen} \mathfrak{d} \{\downarrow^*_{\text{true, true}}(A) + \downarrow^*_{\text{false, false}}(B)\} \text{ while } M[X] \text{ do } c \text{ \textbf{while} } N[Y] \text{ do } \mathfrak{d} \text{ is terminating}
\]

\[
\{\downarrow^*_{\text{true, true}}(A) + \downarrow^*_{\text{false, false}}(B)\} \text{ while } M[X] \text{ do } c \xrightarrow{gen} \text{ while } N[Y] \text{ do } \mathfrak{d} \{B\}
\]

Note that this rule requires us to establish termination of \textbf{while} \( M[X] \) \textbf{do} \( c \) as a precondition. Since this is a statement about a single program (non-relational), it can be shown using existing approaches (e.g., [LY18]) and is outside the scope of this paper.

22
Proof. We use Lemma 1 to prove the conclusion from the premises. Note that the preexpectation enjoys
\[ \mathcal{E}(A) + \mathcal{E}(B) = \mathcal{E}(A) + \mathcal{E}(B) \]
the expected value of the preexpectation is always 0 for any input \( \perp \)-bimemory of form \( \text{proj}(\perp \otimes \varphi) \) or \( \text{proj}(\psi \otimes \perp) \). So it suffices to prove for any normalized quantum memories \( \psi_1, \psi_2 \) over \( X_1^{\text{all}} \times X_2^{\text{all}} \) that there is a separable coupling \( \rho \) of \( \rho_1 + (1 - \text{tr} \rho_1) P_\perp \) and \( \rho_2 + (1 - \text{tr} \rho_2) P_\perp \) such that
\[ \text{tr} (\mathcal{E}(A) + \mathcal{E}(B)) \text{proj}(\psi_1 \otimes \psi_2) \leq \text{tr} B \rho, \]
where \( \rho_1 := [\text{while} M[X] \text{ do } c](\text{proj}(\psi_1)) \) and \( \rho_2 := [\text{while} N[Y] \text{ do } b](\text{proj}(\psi_2)) \) are the output memories. Let
\[ \text{d}_t = \langle t \rangle t, t = \text{true}, \text{false}. \]
Then \( \text{d}_t \text{true}(\rho) := (M_t \text{ on } X_1) \rho(M_t \text{ on } X_1)^*, \quad \text{d}_t \text{false}(\rho) := (N_t \text{ on } Y_2) \rho(N_t \text{ on } Y_2)^* \),
for \( t = \text{true}, \text{false} \). Then \( \text{d}_t \text{true} = \text{d}_t \text{false} \otimes \text{d}_t \text{false} \). Let \( \alpha_0 := \text{proj}(\psi_1), \beta_0 := \text{proj}(\psi_2), \alpha_{n+1} := [c] \circ \text{d}_t \text{true}(\alpha_n) \) and \( \beta_{n+1} := [b] \circ \text{d}_t \text{false}(\beta_n) \) for \( n = 0, 1, \ldots \). Then it is easy to verify that
\[ \rho_1 = \sum_{n=0}^{\infty} \text{d}_t \text{false}(\alpha_n), \quad \rho_2 = \sum_{n=0}^{\infty} \text{d}_t \text{false}(\beta_n). \]
Now we construct by induction on \( n \) a sequence of separable mixed bimeasures \( \eta_0, \eta_1, \ldots, \eta_n \ldots \) over \( \ell^2[X_1^{\text{all}} \times X_2^{\text{all}}] \) as follows: let \( \eta_0 := \alpha_0 \otimes \beta_0 \) as the basis; suppose \( \eta_n \) has been constructed, then from \( \{A \} c \otimes \eta \{\text{true}, \text{false}(\mathcal{E}(B)) \}, \) we choose \( \text{d}_t \text{true}(\eta_n) \) as the (unnormalized) input \( \perp \)-bimemory and construct \( \eta_{n+1} \) as the separable coupling of the output \( \perp \)-memories, i.e.,
\[ \text{tr} \eta_{n+1} = [c] \circ \text{tr} \text{d}_t \text{true}(\eta_n), \quad \text{tr} \eta_{n+1} = [b] \circ \text{tr} \text{d}_t \text{false}(\eta_n), \quad \text{tr} \text{true}(\eta_n) \leq \text{tr} \text{true}(\text{true}(\text{true}(A) + \text{false}, \text{false}(B))) \eta_{n+1}. \]
Now we construct \( \eta_{n+1} := \text{d}_t \text{true}(\eta_{n+1}). \) It follows from Equation 9 that
\[ \text{tr} (\text{d}_t \text{true}(A) + \text{d}_t \text{false}(B)) \eta_{n+1} = \text{tr} (\text{d}_t \text{true}(A) + \text{d}_t \text{false}(B)) \eta_{n+1}. \]
Then Equation 12 actually means that
\[ A \text{true}, \text{true}(\eta_n) - A \text{true}, \text{true}(\eta_{n+1}) \leq B \text{false}, \text{false}(\eta_{n+1}). \]
Furthermore, we prove by induction on \( n \) that \( \text{tr} \eta_n \leq \alpha_n \) and \( \text{tr} \eta_n \leq \beta_n \) for \( n = 0, 1, \ldots \). The result obviously holds for \( \eta_0 = \alpha_0 \otimes \beta_0 \). Suppose the result holds for \( n \), then we prove for \( n+1 \). To this end, we note that
\[ \text{tr} \eta_n = \text{tr} \text{true}(\text{true}(\eta_n) - \text{true}, \text{true}(\eta_{n+1}) \leq \text{true}, \text{true}(\eta_{n+1}). \]
Here (*) follows since \( N^* \text{true}, \text{true}(A) + N^* \text{false}, \text{false}(B) = \text{id} \) by definition of binary measurements and hence \( \text{tr} \circ \text{true}(\text{true}(\text{true}(A) + \text{false}, \text{false}(B)) = \text{id}. \) We have
\[ \text{tr} \eta_{n+1} = \text{tr} \text{true}(\eta_{n+1}) \leq \sum_{n=0}^{\infty} \text{true}, \text{true}(\eta_n) \leq \sum_{n=0}^{\infty} \text{true}, \text{true}(\eta_n) \leq \text{true}, \text{true}(\eta_{n+1}). \]
Here (*) is from the induction hypothesis \( \text{tr} \eta_n \leq \alpha_n \). Hence \( \text{tr} \eta_n \leq \alpha_n \) for all \( n \). Similarly, \( \text{tr} \eta_n \leq \beta_n \) for all \( n \).
Let \( \eta := \sum_{n=0}^{\infty} {\downarrow^{\text{false,false}}(\eta_n)} \) Then it is a separable state such that

\[
\text{tr}_2 \eta = \sum_{n=0}^{\infty} \text{tr}_2 {\downarrow^{\text{false,false}}(\eta_n)} \leq \sum_{n=0}^{\infty} \downarrow^{\text{false}}(\alpha_n) = \rho_1,
\]

and similarly, \( \text{tr}_1 \eta \leq \rho_2 \). Here \((\ast)\) is proven analogously to (14). Now construct

\[
\rho := \eta + [\rho_1 - \text{tr}_2 \eta + (1 - \text{tr} \rho_1)P_\perp] \otimes [\rho_2 - \text{tr}_1 \eta + (1 - \text{tr} \rho_2)P_\perp]/(1 - \text{tr} \eta).
\]

It is easy to verify that \( \eta \leq \rho, \text{tr}_2 \rho = \rho_1 + (1 - \text{tr} \rho_1)P_\perp, \) and \( \text{tr}_1 \rho = \rho_2 + (1 - \text{tr} \rho_2)P_\perp \). Now we have

\[
\text{tr}(\downarrow^{\ast}(A) + \downarrow^{\ast}(B))\text{proj}(\psi_1 \otimes \psi_2) = \text{tr} B \downarrow^{\text{false,false}}(\eta_0) + \text{tr} \text{A} \downarrow^{\text{true,true}}(\eta_0)
\]

\[
= \text{tr} B \downarrow^{\text{false,false}}(\eta_0) + \text{tr} \text{A} \downarrow^{\text{true,true}}(\eta_0) + \sum_{i=0}^{n-1} [\text{tr} A \downarrow^{\text{true,true}}(\eta_i) - \text{tr} A \downarrow^{\text{true,true}}(\eta_{i+1})]
\]

\[
\leq \text{tr} B \downarrow^{\text{false,false}}(\eta_0) + \text{tr} \text{A} \downarrow^{\text{true,true}}(\eta_0) + \sum_{i=0}^{n-1} \text{tr} B \downarrow^{\text{false,false}}(\eta_{i+1})
\]

\[
= \text{tr} B \sum_{i=0}^{n} \downarrow^{\text{false,false}}(\eta_i) + \text{tr} \text{A} \downarrow^{\text{true,true}}(\eta_{i}) \leq \text{tr} B \eta + \text{tr} \text{A} \downarrow^{\text{true,true}}(\eta_{i})
\]

\[
\leq \text{tr} B \rho + \text{tr} \text{A} \downarrow^{\text{true,true}}(\eta_{i}),
\]

for any \( n \geq 1 \). From the premise we assume without loss of generality that \textbf{while} \( M \sqsubseteq X \) \textbf{do} \( c \) is terminating. Then similar to Equation 7,

\[
\text{tr} \downarrow^{\text{true,true}}(\eta_{i}) \leq \downarrow^{\text{false}}(\text{tr}_2 \eta_{i}) \leq \downarrow^{\text{true}}(\alpha_{i}) \leq 0.
\]

Equation 10 immediately follows from Equation 15. \(\square\)

### 6.4 While rules for partial correctness

\[
\textbf{While1Par} \quad \begin{array}{c}
\{A\} c \triangleq \textbf{skip} \{\downarrow^{\ast}(A) + \downarrow^{\ast}(B)\} \quad A \leq \text{id} \\
\{\downarrow^{\ast}(A) + \downarrow^{\ast}(B)\} \textbf{while} M \sqsubseteq X \textbf{do} \ c \triangleq \textbf{skip} \{B\}
\end{array}
\]

\textbf{Proof.} Consider any normalized quantum memories \( \psi, \phi \) as input of the programs, and let \( \alpha \triangleq \text{proj}(\psi), \beta \triangleq \text{proj}(\phi) \) be their density operators and \( \sigma := [\textbf{while} \ M \sqsubseteq X \ 	extbf{do} \ c](\alpha) \), then by Lemma 4, we choose \( \sigma \otimes \beta \) as the subcoupling of output memories, and it suffices to show

\[
\text{tr} (\downarrow^{\ast}(A) + \downarrow^{\ast}(B))(\alpha \otimes \beta) \leq \text{tr} B(\sigma \otimes \beta) + 1 - \text{tr} \sigma.
\]

To express \( \sigma \) in a more explicit form, let \( \alpha_0 := \alpha \), and for \( n = 0, 1, \ldots \), let \( \alpha_{n+1} := [c] \circ \downarrow^{\text{true}}(\alpha_n) \), then \( \sigma = \sum_{n=0}^{\infty} \downarrow^{\text{false}}(\alpha_n) \) by definition of the semantics of \textbf{while}.

The precondition \( \{A\} c \triangleq \textbf{skip} \{\downarrow^{\ast}(A) + \downarrow^{\ast}(B)\} \) implies that for input bimemory \( \downarrow^{\text{true}}(\alpha_n) \otimes \beta \), there is a subcoupling \( \rho_n \) of the output memories \( [c] \circ \downarrow^{\text{true}}(\alpha_n) = \alpha_{n+1} \) and \( \text{tr} \downarrow^{\text{true}}(\alpha_n) \otimes \beta \), such that \( \downarrow^{\text{true}}(\alpha_n) + \text{tr} \rho_n \geq \text{tr} \alpha_{n+1} + \text{tr} [\downarrow^{\text{true}}(\alpha_n) \otimes \beta] \), and

\[
\text{tr} A(\downarrow^{\text{true}}(\alpha_n) \otimes \beta) \leq \text{tr} [\downarrow^{\ast}(A) + \downarrow^{\ast}(B)] \rho_n + \text{tr} \downarrow^{\text{true}}(\alpha_n) - \text{tr} \rho_n.
\]

Note that \( \beta \) is the density operator of a pure quantum memory, it is easy to verify that
\[ \rho_n = \alpha_{n+1} \otimes \beta. \] Then (17) can be rewritten as

\[
\text{tr}(\text{id} - B)\left(\downarrow_{\text{false}}(\alpha_{n+1} \otimes \beta)\right) \leq \text{tr}(\text{id} - A)\left(\downarrow_{\text{true}}(\alpha_n - \alpha_{n+1}) \otimes \beta\right),
\]

then

\[
\text{tr}(\text{id} - B)\left(\downarrow_{\text{false}}\left(\sum_{i=1}^{n+1} \alpha_i \otimes \beta\right)\right) \leq \text{tr}(\text{id} - A)\left[\downarrow_{\text{true}}\left(\sum_{i=0}^{n} (\alpha_i - \alpha_{i+1}) \otimes \beta\right)\right]
\]

\[
= \text{tr}(\text{id} - A)\left(\downarrow_{\text{true}}(\alpha_0 - \alpha_{n+1}) \otimes \beta\right) \triangleleft \text{tr}(\text{id} - A)\left(\downarrow_{\text{true}}(\alpha_0) \otimes \beta\right).
\]

Here (\triangleleft) is from the precondition \( A \leq \text{id} \). Now, let \( n \to \infty \) then we have.

\[
\text{tr}(\text{id} - B)\left[\sigma \otimes \beta - \downarrow_{\text{false}}(\alpha) \otimes \beta\right] \leq \text{tr}(\text{id} - A)\left(\downarrow_{\text{true}}(\alpha) \otimes \beta\right)
\]

which can be rewritten as (16).

\[ \square \]

\[
\text{JointWhilePar}\ \{ A \} \left\{ c \right\} \overset{\text{ns}}{\xrightarrow{\omega}} d \left\{ \downarrow_{\text{true,true}}(A) + \downarrow_{\text{false,false}}(B) \right\} \quad A \leq \text{id}
\]

\[
\left\{ \downarrow_{\text{true,true}}(A) + \downarrow_{\text{false,false}}(B) \right\} \text{ while } M[X] \text{ do } c \overset{\text{ns}}{\xrightarrow{\omega}} \text{ while } N[Y] \text{ do } d \left\{ B \right\}
\]

**Proof.** Consider any separable mixed bimemory \( \rho \) as coupling of the inputs of the programs, and let \( \xi_1 := [\text{while } M[X] \text{ do } c][\text{tr} \rho] \) and \( \xi_2 := [\text{while } N[Y] \text{ do } d][\text{tr} \rho] \) be the output states. Then by Lemma 3, we only need to find a separable subcoupling \( \sigma \) of \( \xi_1 \) and \( \xi_2 \) such that \( \text{tr} \rho + \text{tr} \sigma \geq \text{tr} \xi_1 + \text{tr} \xi_2 \) and

\[
\text{tr}\left(\downarrow_{\text{true,true}}(A) + \downarrow_{\text{false,false}}(B)\right) \rho \leq \text{tr} B \sigma + \text{tr} \rho - \text{tr} \sigma.
\] (18)

We decompose \( \xi_1 \) and \( \xi_2 \) according to the semantic functions of the while loops. Let

\[
\downarrow_{t,t} (\rho) := (M_t \text{ on } X)\rho (M_t \text{ on } X)^*, \quad \downarrow_{t,l} (\rho) := (N_t \text{ on } Y)\rho (N_t \text{ on } Y)^*,
\]

for \( t = \text{true}, \text{false}. \) Then \( \downarrow_{t,t} = \downarrow_{1,t} \otimes \downarrow_{2,t}. \) It is easy to verify that

\[
\xi_1 = \sum_{n=0}^{\infty} \downarrow_{1,\text{false}} \circ ([c] \circ \downarrow_{1,\text{true}})^n (\text{tr} \rho), \quad \xi_2 = \sum_{n=0}^{\infty} \downarrow_{2,\text{false}} \circ ([d] \circ \downarrow_{2,\text{true}})^n (\text{tr} \rho).
\]

We write \( c_n = \sum_{k=0}^{n} \downarrow_{1,\text{false}} \circ ([c] \circ \downarrow_{1,\text{true}})^k \) and \( d_n = \sum_{k=0}^{n} \downarrow_{2,\text{false}} \circ ([d] \circ \downarrow_{2,\text{true}})^k \) for the superoperators of finite sum.

In order to prove (18), we construct a separable mixed memory \( \sigma_n \) for each number \( n = 0, 1, \cdots \), such that

\[
\text{tr} \sigma_n \leq c_n (\text{tr} \rho), \quad \text{tr} \sigma_n \leq d_n (\text{tr} \rho), \quad \text{tr} \rho + \text{tr} \sigma_n \geq \text{tr} c_n (\text{tr} \rho) + \text{tr} d_n (\text{tr} \rho)
\]

\[
\text{tr}\left(\downarrow_{\text{true,true}}(A) + \downarrow_{\text{false,false}}(B)\right) \rho \leq \text{tr} B \sigma_n + \text{tr} \rho - \text{tr} \sigma_n.
\] (19)

Then \( \sigma \) can be constructed as the limit point of the sequence \( \sigma_0, \sigma_1, \cdots \).

We construct by induction on \( n \). For \( n = 0 \), we can put \( \sigma_0 = \downarrow_{\text{true,true}}(\rho) \), then (19) is easily checked for a product memory \( \rho \), and further verified for general separable \( \rho \) by additivity. Now assuming that the result is true for \( n \), we prove for the case of \( n + 1 \). From \( \{ A \} c \overset{\text{ns}}{\xrightarrow{\omega}} d \left\{ \downarrow_{\text{true,true}}(A) + \downarrow_{\text{false,false}}(B) \right\}, \) we choose \( \downarrow_{\text{true,true}}(\rho) \) as the (unnormalized) input cou-
pling and construct $\rho'$ as the corresponding subcoupling of the output states, i.e.,

$$\begin{align*}
tr_2 \rho' &\leq [\mathcal{E}] (tr_2 \downarrow_{\text{true,true}}(\rho)), \\
tr_1 \rho' &\leq [\mathcal{D}] (tr_1 \downarrow_{\text{true,true}}(\rho)),
\end{align*}$$

(20)

$$tr \downarrow_{\text{true,true}}(\rho) + tr \rho' \geq tr [\mathcal{E}] (tr_2 \downarrow_{\text{true,true}}(\rho)) + tr [\mathcal{D}] (tr_1 \downarrow_{\text{true,true}}(\rho))$$

(21)

$$tr A \downarrow_{\text{true,true}}(\rho) \leq tr (\downarrow_{\text{true,true}}^*(A) + \downarrow_{\text{false,false}}^*(B)) \rho' + tr \downarrow_{\text{true,true}}(\rho) - tr \rho'.
$$

(22)

Furthermore, we employ the induction hypothesis on the case of $n$ for input coupling $\rho'$. Let the subcoupling of output states be $\sigma'$, then

$$\begin{align*}
tr_2 \sigma' &\leq c_n(tr_2 \rho'), tr_1 \sigma' \leq d_n(tr_1 \rho'), tr \rho' + tr \sigma' \geq tr c_n(tr_2 \rho') + tr d_n(tr_1 \rho')
\end{align*}$$

(23)

The result (18) for the case of $n + 1$ can be achieved by putting

$$\sigma_{n+1} = \sigma' + (c_{n+1} \otimes \downarrow_{2,\text{true}})(\rho) + (\downarrow_{1,\text{true}} \otimes d_{n+1})(\rho) - \downarrow_{\text{true,true}}(\rho),$$

(24)

together with (20)-(23). Therefore, the result is true for every $n$.

Now, note that $tr \sigma_n = tr(tr_2 \sigma_n) \leq tr c_n(\rho) \leq tr \rho$ is upper-bounded. Moreover, from (24) one can easily prove that $\sigma_n \leq \sigma_{n+1}$ for every $n$ by induction. Thus, the sequence $\sigma_0, \sigma_1, \cdots$ converges as it is an ascending chain of trace class operators with a uniform upper bound on the trace. Let $\sigma = \lim_{n \to \infty} \sigma_n$, then (18) immediately follows from (19). \hfill \square

---

**JointWhileSemi**

$$\begin{align*}
\{ A \} \mathcal{E} \xrightarrow{\text{semi}} \mathcal{D} \{ \downarrow_{\text{true,true}}^*(A) + \downarrow_{\text{false,false}}^*(B) \} & \quad A \leq \text{id} \\
\{ \downarrow_{\text{true,true}}^*(A) + \downarrow_{\text{false,false}}^*(B) \} \textbf{while } M[X] \textbf{ do } \mathcal{E} \xrightarrow{\text{semi}} \textbf{while } N[Y] \textbf{ do } \mathcal{D} \{ B \}
\end{align*}$$

---

**Proof.** From Lemma 1, the semipartial correctness can be characterized in a similar way of Lemma 3: $\{ A \} \mathcal{E} \xrightarrow{\text{semi}} \mathcal{D} \{ B \}$ if and only if for any separable mixed bimemory $\rho$ as coupling of the inputs of the programs, there exists a separable subcoupling $\sigma$ of the output states such that $tr A \rho \leq tr B \sigma + \min\{ tr[\mathcal{E}](tr_2 \rho), tr[\mathcal{D}](tr_1 \rho) \} - tr \sigma$.

Consider any separable mixed bimemory $\rho$ as coupling of the inputs of the programs, and let $\xi_1 := [\textbf{while } M[X] \textbf{ do } \mathcal{E}](tr_2 \rho)$ and $\xi_2 := [\textbf{while } N[Y] \textbf{ do } \mathcal{D}](tr_1 \rho)$ be the output states. Then we only need to find a separable subcoupling $\sigma$ of $\xi_1$ and $\xi_2$ such that

$$tr (\downarrow_{\text{true,true}}^*(A) + \downarrow_{\text{false,false}}^*(B)) \rho \leq tr B \sigma + \min\{ tr \xi_1, tr \xi_2 \} - tr \sigma.$$ 

(25)

Note that $\xi_1$ and $\xi_2$ can be decomposed as

$$\begin{align*}
\xi_1 = \sum_{n=0}^{\infty} \downarrow_{1,\text{false}} \circ (\{ \mathcal{E} \} \circ \downarrow_{1,\text{true}})^n(tr_2 \rho), \\
\xi_2 = \sum_{n=0}^{\infty} \downarrow_{2,\text{false}} \circ (\{ \mathcal{D} \} \circ \downarrow_{2,\text{true}})^n(tr_1 \rho).
\end{align*}$$

We write $c_n = \sum_{k=0}^{\infty} \downarrow_{1,\text{false}} \circ (\{ \mathcal{E} \} \circ \downarrow_{1,\text{true}})^k$ and $d_n = \sum_{k=0}^{\infty} \downarrow_{2,\text{false}} \circ (\{ \mathcal{D} \} \circ \downarrow_{2,\text{true}})^k$ for the superoperators of finite sum.

In order to prove (25), we construct a separable mixed memory $\sigma_n$ for each number $n = 0, 1, \cdots$ such that

$$\begin{align*}
tr_2 \sigma_n &\leq c_n(tr_2 \rho), tr_1 \sigma_n \leq d_n(tr_1 \rho), \\
tr (\downarrow_{\text{true,true}}^*(A) + \downarrow_{\text{false,false}}^*(B)) \rho &\leq tr B \sigma_n + \min\{ tr c_n(tr_2 \rho), tr d_n(tr_1 \rho) \} - tr \sigma_n.
\end{align*}$$

(26)

Then $\sigma$ can be constructed as the limit point of the sequence $\sigma_0, \sigma_1, \cdots$. 

26
We construct by induction on \( n \). For \( n = 0 \), we can put \( \sigma_0 = \downarrow_{\text{true,true}}(\rho) \), then (26) is easily checked for a product memory \( \rho \), and further verified for general separable \( \rho \) by additivity. Now assuming that the result is true for \( n \), we prove for the case of \( n + 1 \). From \( \{A \} \downarrow_{\text{true}} \sim \{B \} \downarrow_{\text{false,false}} \), we choose \( \downarrow_{\text{true,true}}(\rho) \) as the (unnormalized) input coupling and construct \( \rho' \) as the corresponding subcoupling of the output states, i.e.,

\[
\begin{align*}
\text{tr}_2 \rho' & \leq [c] (\text{tr}_2 \downarrow_{\text{true,true}}(\rho)), \quad \text{tr}_1 \rho' \leq [0] (\text{tr}_1 \downarrow_{\text{true,true}}(\rho)), \\
\text{tr}_n \downarrow_{\text{true,true}}(\rho) & \leq \text{tr}\left( \downarrow_{\text{true,true}}(A) + \downarrow_{\text{false,false}}(B) \right) \rho' \\
& \quad + \min\{\text{tr}[c] (\text{tr}_2 \downarrow_{\text{true,true}}(\rho)), \text{tr}[0] (\text{tr}_1 \downarrow_{\text{true,true}}(\rho))\} - \text{tr} \rho'.
\end{align*}
\]

(27) Furthermore, we employ the induction hypothesis on the case of \( n \) for input coupling \( \rho' \). Let the subcoupling of output states be \( \sigma' \), then

\[
\begin{align*}
\text{tr}_2 \sigma' & \leq c_n(\text{tr}_2 \rho'), \quad \text{tr}_1 \sigma' \leq d_n(\text{tr}_1 \rho'), \\
\text{tr}\left( \downarrow_{\text{true,true}}(A) + \downarrow_{\text{false,false}}(B) \right) \rho' & \leq B \sigma + \min\{\text{tr} c_n(\text{tr}_2 \rho'), \text{tr} d_n(\text{tr}_1 \rho')\} - \text{tr} \sigma'.
\end{align*}
\]

The result (25) for the case of \( n + 1 \) can be achieved by putting

\[
\sigma_{n+1} = (\sigma' + c_{n+1} \otimes \downarrow_{\text{true,true}}(\rho)) - \downarrow_{\text{true,true}}(\rho),
\]

(30) together with (27)-(29). Therefore, the result is true for every \( n \).

Now, note that \( \text{tr} \sigma_n = \text{tr}(\text{tr}_2 \sigma_n) \leq \text{tr} c_n(\rho) \leq \text{tr} \rho \) is upper-bounded. Moreover, from (30) one can easily prove that \( \sigma_n \leq \sigma_{n+1} \) for every \( n \) by induction. Thus, the sequence \( \sigma_0, \sigma_1, \ldots \)
converges as it is an ascending chain of trace class operators with a uniform upper bound on the trace. Let \( \sigma = \lim_{n \to \infty} \sigma_n \), then (25) immediately follows from (26) \( \square \)

7 Example: Quantum Zeno effect

**Motivation.** In this section, we study (one specific incarnation of) the quantum Zeno effect as an example of application of our logic. The Zeno effect implies that the following processes have the same effect:

- Start with a qubit in state \(|0]\). Apply a continuous rotation (with angular velocity \( \omega \)) to it. (Thus, after time \( t \), the state will have rotated by angle \( \omega t \).)
- Start with a qubit in state \(|0]\). Continuously observe the state. Namely, at time \( t \), measure whether the qubit has rotated by angle \( \omega t \).

The quantum Zeno effect implies that in both processes, the state evolves in the same way (and that the measurement in the second situation always gives answer “yes”). Notice that this means that the measurements can be used to rotate the state.

In our formalization, we will consider the discrete version of this phenomenon: The rotation is split into \( n \) rotations by a small angle, and the continuous measurement consists of \( n \) measurements. In the limit \( n \to \infty \), both processes yield the same state, but if we consider the situation for a concrete value of \( n \), the result of the processes will be slightly different. (And the difference can be quantified in terms of \( n \).) This makes this example a prime candidate for our logic: We want to compare two processes (hence we need relational Hoare logic), but the processes are not exactly equivalent (hence we cannot use qRHL from [Unr19]) but only close to equivalent (and the “amount of equivalence” can be expressed using expectations).

**Formalizing the processes.** We now formalize the two processes as programs in our language. Let \( n \geq 1 \) be an integer.

In the first process, we have a continuous rotation, broken down into \( n \) small rotations. For simplicity, we will rotate by the angle \( \pi/2 \) within \( n \) steps, thus each small rotation rotates by
angle $\frac{\pi}{2n}$. This is described by the rotation matrix $R := \left( \begin{array}{cc} \cos \frac{\pi}{2n} & -\sin \frac{\pi}{2n} \\ \sin \frac{\pi}{2n} & \cos \frac{\pi}{2n} \end{array} \right)$. Let $y$ be a variable of type \{0,1\} (i.e., the qubit that is rotated). In order to apply the rotation $n$ times, we will need a counter $x$ for the while loop. Let $x$ be a variable of type $\mathbb{Z}$. We will have a loop that continues while (informally speaking) $x < n$. This is formalized by the projector $P_{<n}$ onto states $|i\rangle$ with $i < n$. I.e., $P_{<n} := \sum_{-\infty < i < n} \text{proj}(i)$. In slight abuse of notation, we also write $P_{<n}$ for the binary measurement with Kraus operators $\{P_{<n}, \text{id} - P_{<n}\}$. Furthermore, we need to increase the counter. For this let $\text{INCR}$ be the unitary on $l^2(\mathbb{Z})$ with $\text{INCR}|i\rangle \mapsto |i+1\rangle$. Then the program that initializes $y$ with $|0\rangle$ and then applies the rotation $R$ $n$ times can be written as:

$$c := x \leftarrow 0; \ y \leftarrow 0; \ \text{while} \ P_{<n}[x] \ \text{do} \ (\text{apply} \ \text{INCR} \ \text{to} \ x; \ \text{apply} \ R \ \text{to} \ y)$$

In the second process, instead of applying $R$, we measure the state in each iteration of the loop. In the first iteration, we expect the original state $\phi_0 := |0\rangle$, and after the $i$-th iteration, we expect the state $\phi_i := R\phi_{i-1}$ for $i \geq 1$. This can be done using the program $\text{if} \ \text{proj}(\phi_i)[y] \ \text{then} \ \text{skip} \ \text{else} \ \text{skip}$ where we again write in slight abuse of notation $\text{proj}(\phi_i)$ for the corresponding binary measurement. Since the if-statement first measures $y$ and then executes one of the skip-branches, this is effectively just a measurement. We abbreviate this as $\text{if} \ \text{proj}(\phi_i)[y]$.

However, we cannot simply write $\text{if} \ \text{proj}(\phi_i)[y]$ in our loop body, because $i$ should be the value of $x$. So we need to define the projector that projects onto $\phi_i$ when $x = |i\rangle$. This is done by the following projector on $l^2[xy]$:

$$P_{i} := \sum_{i \leq j < n} \text{proj}(|i\rangle \otimes \phi_j).$$

Then $\text{if} \ P_{i}[y]$ will measure whether $y$ contains $\phi_i$ whenever $x$ contains $|i\rangle$.

Armed with that notation, we can now formulate the second process as a program:

$$d := x \leftarrow 0; \ y \leftarrow 0; \ \text{while} \ P_{<n}[x] \ \text{do} \ (\text{apply} \ \text{INCR} \ \text{to} \ x; \ \text{if} \ P_{i}[xy])$$

**Equivalence of the programs.** We claim that the two processes, i.e., the programs $c,d$ have approximately the same final state in $y$. Having the same state can be expressed using the “quantum equality” described in Section 2. Specifically, the postexpectation $\text{EQUAL on } y_1, y_2$ corresponds to $y_1$ and $y_2$ having the same state. For example, $\{\text{id}\} c \simeq d \{\text{EQUAL on } y_1, y_2\}$ implies that the final state of $c$ and $d$ is the same (if we trace out all variables except $y_1, y_2$).

The fact that the final states are approximately equal can be expressed by multiplying the preexpectation with a real number close to 1. Specifically, in our case we claim that

$$\{\varepsilon^n \cdot \text{id}\} c \simeq d \{\text{EQUAL on } y_1, y_2\}$$

Here $\varepsilon := (\cos \frac{\pi}{2n})^2$. This indeed means that the final states of $c$ and $d$ are the same asymptotically since $\varepsilon^n = (\cos \frac{\pi}{2n})^{2n} \stackrel{n \to \infty}{\longrightarrow} 1$.

**Warm up.** Before we prove (33), we investigate a simpler case as a warm up. We investigate the special where $n = 3$, and instead of a while-loop, we simply repeat the loop body three times.

$$c' := y \leftarrow |0\rangle; \ \text{apply} \ R \ \text{to} \ y; \ \text{apply} \ R \ \text{to} \ y; \ \text{apply} \ R \ \text{to} \ y$$

$$d' := y \leftarrow |0\rangle; \ \text{if} \ \text{proj}(\phi_1)[y]; \ \text{if} \ \text{proj}(\phi_2)[y]; \ \text{if} \ \text{proj}(\phi_3)[y]$$

We claim:

$$\{\varepsilon^3 \cdot \text{id}\} c' \simeq d' \{\text{EQUAL on } y_1, y_2\}$$

\footnote{This is seen as follows: The judgment implies that the finals states are marginals of a state that is invariant under the projector $\text{EQUAL on } y_1, y_2$, i.e., a state with support in the space $Y_1 \equiv_q Y_2$. That means that this state is invariant under swapping $Y_1, Y_2$, and thus the marginals corresponding to $Y_1$ and $Y_2$ are equal.}

28
First, we strengthen the postcondition. Let \( A_3 := (\text{proj}(\phi_3 \otimes \phi_3) \on y_1 y_2) \). (This postcondition is intuitively what we expect to (approximately) hold at the end of the execution. It means that \( y_1 \) and \( y_2 \) are both in state \( \phi_3 \), the result by rotating three times using \( R \). Since \( \phi_3 \otimes \phi_3 \) is in the image of the projector \text{EQUAL}, it follows that \( A_3 \leq (\text{EQUAL on } y_1 y_2) \). By rule CONSEQ it is thus sufficient to show \( \{ \varepsilon^3 \cdot \text{id} \} c' \rotate{\approx} \delta' \{ A_3 \} \). And by rule SEQ, we can show that the following sequence of Hoare judgments for some \( A_0, A_1, A_2 \):

\[
\begin{aligned}
\{ \varepsilon^3 \cdot \text{id} \} y \leftarrow (0) & \ \rotate{\approx} \ y \leftarrow (0) \ \{ A_0 \} \\
& \ \rotate{\approx} \ \text{if proj}(\phi_1)y \ \{ A_1 \} \\
& \ \rotate{\approx} \ \text{if proj}(\phi_2)y \ \{ A_2 \} \\
& \ \rotate{\approx} \ \text{if proj}(\phi_3)y \ \{ A_3 \}
\end{aligned}
\]

(These are four judgments, we just use a more compact notation to put them in one line.) We will derive suitable values \( A_0, A_1, A_2 \) by applying our rules backwards from the postcondition.

By applying rule APPLY1, we get \( \{ A'_1 \} \ \rotate{\approx} \ \text{if proj}(\phi_3)y \ \{ A'_3 \} \) where \( A'_3 := (R^* \on y_1) \cdot A_3 \) and where we use \( A \cdot B \) as an abbreviation for \( ABA^* \). And by rule IF2 (using rule SKIP for its premises), we get

\[
\left\{ (\text{proj}(\phi_3) \on y_2) \right\} A'_3 + (1 - \text{proj}(\phi_3) \on y_2) \cdot A'_3 \ \rotate{\approx} \ \text{if proj}(\phi_3)y \ \{ A'_3 \}.
\]

The precondition is lower bounded by \( A_2 := (\text{proj}(\phi_3) \on y_2) \cdot A'_3 \). (The second term corresponds to the measurement failing to measure \( \phi_3 \), in this case all is lost anyway, so we remove that term.) Hence (with rules SEQ and CONSEQ), \( \{ A_3 \} \ \rotate{\approx} \ \text{if proj}(\phi_3)y \ \{ A_3 \} \) as desired in (36).

Analogously, we can instantiate

\[
A_1 := (\text{proj}(\phi_2) \on y_2) \cdot (R^* \on y_1) \cdot A_2 \quad \text{and} \quad A_0 := (\text{proj}(\phi_1) \on y_2) \cdot (R^* \on y_1) \cdot A_1
\]

in (36). We can simplify the expressions for \( A_0, A_1, A_2 \) some more. We have

\[
A_2 = (\text{proj}(\phi_3) \on y_2) \cdot (R^* \on y_1) \cdot (\text{proj}(\phi_3 \otimes \phi_3) \on y_1 y_2) = \text{proj}(R^* \phi_3 \otimes \text{proj}(\phi_3) \phi_3) \on y_1 y_2 = \text{proj}(\phi_2 \otimes \phi_3) \on y_1 y_2.
\]

And

\[
A_1 = (\text{proj}(\phi_2) \on y_2) \cdot (R^* \on y_1) \cdot (\text{proj}(\phi_2 \otimes \phi_3) \on y_1 y_2) = \text{proj}(R^* \phi_2 \otimes \text{proj}(\phi_2) \phi_3) \on y_1 y_2 = \varepsilon \text{proj}(\phi_1 \otimes \phi_2) \on y_1 y_2.
\]

(Note the slight difference: instead of \( \text{proj}(\phi_3) \phi_3 \) have \( \text{proj}(\phi_2) \phi_3 \) here, which simplifies to \( \phi_2 \cdot \phi_2' \phi_3 = \phi_2 \cdot \sqrt{\varepsilon} \)). Analogously

\[
A_0 = \varepsilon^2 \text{proj}(\phi_0 \otimes \phi_1) \on y_1 y_2.
\]

It is left to show the first judgment in (36), namely \( \{ \varepsilon^3 \cdot \text{id} \} y \leftarrow (0) \rotate{\approx} y \leftarrow (0) \ \{ A_0 \} \). By rules INIT1 and INIT2 (starting from the right), we have

\[
\begin{aligned}
\{ \varepsilon^3 \cdot \text{id} \} & \rotate{\approx} \left\{ \text{id}_{y_2} \otimes (0|y_2 \otimes \text{id}_{-y_2}) \right\} \varepsilon^2(\text{proj}(\phi_1) \on y_2) \rotate{\approx} \text{skip} \ \{ A_0 \} \\
& \rotate{\approx} \left\{ \text{id}_{y_1} \otimes (0|y_1 \otimes \text{id}_{-y_1}) \right\} A_0 \ \rotate{\approx} \ y \leftarrow (0) \rotate{\approx} \text{skip} \ \{ A_0 \}. \quad (37)
\end{aligned}
\]

Here (⋆) uses that \( \phi_0 = |0 \rangle \) and thus \( \langle 0|\text{proj}(\phi_0)|0 \rangle = 1 \), and (⋆⋆) uses that \( \phi_1' \phi_0 = \sqrt{\varepsilon} \) and thus \( \langle 0|\text{proj}(\phi_0)|0 \rangle = \varepsilon \).

The first judgment in (36) then follows by rule SEQ.

This completes the analysis, we have shown (35).
Analysis of the while-programs. Given the experiences from the analysis of the special case (the programs from (31)), we now can solve the original problem, namely analyzing the programs \( c, d \) from (31),(32).

As before, we can replace the postcondition in (33) by the stronger postcondition \( B := (\text{proj}([n] \otimes [n] \otimes \phi_n \otimes \phi_n) \text{on } x_1 x_2 y_1 y_2) \). By rule CONSEQ, it is sufficient to show \( \{\varepsilon^n \cdot \text{id} \} \overset{\text{eq}}{\sim} \{B\} \). By rule SEQ, this follows if we can show

\[
\begin{align*}
\{\varepsilon^n \cdot \text{id}\} & \overset{\text{seq}}{\sim} \{x \leftarrow 0\} \ \{D\} \ y \leftarrow 0 \ \{C\} \ \text{while}_x \ \{B\} \\
& \overset{\text{seq}}{\sim} \{y \leftarrow 0\} \ \{\text{while}_y \ \{B\}\}
\end{align*}
\]

with

\[
\text{while}_x := \text{while } P_{<n}[x] \ \text{do } (\text{apply } \text{INCR } \text{to } x; \ \text{apply } R \ \text{to } y)
\]

\[
\text{while}_y := \text{while } P_{<n}[x] \ \text{do } (\text{apply } \text{INCR } \text{to } x; \ \text{if } P_0[xy])
\]

for suitably chosen expectations \( C, D \).

To prove the last judgment \( \{C\} \ \text{while}_x \ \{B\} \) in (38), we use rule JOINWHILE. This rule requires us to come up with a loop invariant \( A \). To understand what the right loop invariant is, we draw from our experiences in the special case. There, we had defined the expectations \( A_0, \ldots, A_3 \), where \( A_i \) described the state of the programs right after the \( i \)-th application of \( \text{apply } R \ \text{to } y \) and \( \text{if } \text{proj}(\phi_n)[y] \). We had

\[
A_i = \varepsilon^{2-i} \text{proj}(\phi_i \otimes \phi_{i+1}) \text{on } y_1 y_2 \quad \text{for } i = 0, 1, 2 \quad \text{and} \quad A_3 = \text{proj}(\phi_3 \otimes \phi_3) \text{on } y_1 y_2
\]

One sees easily that this would generalize as

\[
A_i = \varepsilon^{n-i-1} \text{proj}(\phi_i \otimes \phi_{i+1}) \text{on } y_1 y_2 \quad \text{for } i < n
\]

and

\[
A_n = \text{proj}(\phi_n \otimes \phi_n) \text{on } y_1 y_2
\]

for values \( n \neq 3 \). Thus we expect that these expectations \( A_i \) also hold in the programs while\(_x\), while\(_y\) after the \( i \)-th iteration (or before the \((i+1)\)-st iteration). Additionally, we keep track of the counter \( x \), which should be \( |i| \) after the \( i \)-th iteration (or before the \((i+1)\)-st iteration). This would be expressed by the expectation \( \text{proj}([i] \otimes [i]) \text{on } x_1 x_2 \). Thus, for the \( i \)-th iteration, we use the “conjunction”

\[
A_i^x := A_i \cdot (\text{proj}([i] \otimes [i]) \text{on } x_1 x_2)
\]

\[
= \begin{cases} \\
\varepsilon^{n-i-1} \text{proj}([i] \otimes [i] \otimes \phi_i \otimes \phi_{i+1}) \text{on } x_1 x_2 y_1 y_2 & (i < n) \\
\text{proj}([n] \otimes [n] \otimes \phi_n \otimes \phi_n) \text{on } x_1 x_2 y_1 y_2 & (i = n)
\end{cases}
\]

(Note that \( \cdot \) is not generally a sensible operation on expectations. But in this case, \( \text{fv}(A_i) = y_1 y_2 \) and \( \text{fv}(\text{proj}([i] \otimes [i]) \text{on } x_1 x_2) = x_1 x_2 \), so the expectations commute and their product is again an expectation.)

The final loop invariant \( A \) is then the “disjunction” of the \( A_i^x \) for \( i = 0, \ldots, n - 1 \), meaning that in every iteration, one of the \( A_i^x \) should hold. (We do not include \( A_i^x \) with \( i = n \) here because when applying the JOINWHILE rule, we only need the invariant to hold when the loop guard was passed.) We define \( A := \sum_{i=0}^{n} A_i^x \). (In general, summation is not a sensible operation representation of “disjunction”, but in the present case, all summands are orthogonal.)

We have now derived a suitable candidate for the invariant \( A \) to use in rule JOINWHILE. We stress that the above argumentation (involving words like “disjunction” and “conjunction” of expectations, and claims that an expectation “holds” at a certain point) was not a formally well-defined argument, merely an explanation how we arrived at our specific choice for \( A \). From the formal point of view, all we will need in the following are the definitions of \( A, A_i^x \). The rest of the argument above was semi-formal motivation.
We will now show the rightmost judgment in (38), namely \( \{ C \} \) while \( \epsilon \overset{\text{w}}{\Rightarrow} \) while \( \{ B \} \) (for some suitable \( C \)). If we apply rule JOINTWHILE (with \( A \) as defined above) to this, we get the premise\(^{20}\)

\[
\{ A \} \overset{\text{apply INCR to } x; \text{ apply } R \text{ to } y}{\Rightarrow} \{ P^\text{both} \circ A + (P^\text{none}) \circ B \}
\]

with \( P^\text{both} := P_{<n} \otimes P_{<n} \text{ on } x_1 x_2 \) and \( P^\text{none} := (id - P_{<n}) \otimes (id - P_{<n}) \text{ on } x_1 x_2 \). (Here we write \( A \circ B \) as an abbreviation for \( ABA^* \).) By applying rules \text{If2}, \text{Apply2}, and twice \text{Apply1} (with \text{SEQ in between}), we get

\[
\{ (\text{INCR on } x_1) \circ (R \text{ on } y_1) \circ (\text{INCR on } x_2) \circ B \} \text{ body}_\epsilon \overset{\text{w}}{\Rightarrow} \text{ body}_\delta \{ C \}
\]

where \( B_2 := (P_\phi \text{ on } x_2 y_2) \circ C' + (id - P_\phi \text{ on } x_2 y_2) \circ C' \). Since \( B_2 \geq (P_\phi \text{ on } x_1 y_1) \circ C' \), by rule CONSEQ we can weaken this to

\[
\{ A' \} \text{ body}_\epsilon \overset{\text{w}}{\Rightarrow} \text{ body}_\delta \{ C \}
\]

with \( A' := (\text{INCR on } x_1) \circ (R \text{ on } y_1) \circ (\text{INCR on } x_2) \circ (P_\phi \text{ on } x_2 y_2) \circ C' =: L \)

If we can show that \( A \leq A' \) then we have proven (39). By definition of \( \Lambda_x^*, L, R, P_\phi, \text{ INCR}, P^\text{both} \), we have

\[
L \cdot P^\text{both}_{<n} \cdot A^*_x = \varepsilon^{n-i-1} \text{proj}(\text{INCR}^*|i) \otimes \text{INCR}^*|i) \otimes R^x_\phi \text{proj}(\phi_i \phi_{i+1}) \text{ on } x_1 x_2 y_1 y_2
\]

\[
= \varepsilon^{n-i} \text{proj}(|i - 1) \otimes |i - 1) \otimes \phi_{i-1} \otimes \phi_{i} \text{ on } x_1 x_2 y_1 y_2 = A^*_{x-1}.
\]

And \( L \cdot P^\text{both}_{<n} \cdot A^*_x = 0 \) since \( P^\text{both}_{<n} \cdot A^*_x = 0 \). Thus \( L \cdot P^\text{both}_{<n} \cdot A = \sum_{i=0}^{n-1} A^*_{x-1} \geq \sum_{i=0}^{n-2} A^*_{x-1} \). And by definition of \( B, L, R, P_\phi, \text{ INCR}, P^\text{none} \), we have

\[
L \cdot P^\text{none}_{<n} \cdot B = \text{proj}(\text{INCR}^*|n) \otimes \text{INCR}^*|n) \otimes R^x_\phi \text{proj}(\phi_n \phi_{n+1}) \text{ on } x_1 x_2 y_1 y_2
\]

\[
= \text{proj}(|n - 1) \otimes |n - 1) \otimes \phi_{n-1} \otimes \phi_{n} \text{ on } x_1 x_2 y_1 y_2 = A^*_{n-1}.
\]

Thus \( A' = L \cdot C' \geq \sum_{i=0}^{n-2} A^*_{x-1} + A^*_{x-2} = A \). Thus we have proven (39). By rule JOINTWHILE, this implies \( \{ C \} \) while \( \epsilon \overset{\text{w}}{\Rightarrow} \) while \( \{ B \} \) with \( C' \) as defined in (39). With \( C := A^*_{x-1} \leq C', \{ C \} \) while \( \epsilon \overset{\text{w}}{\Rightarrow} \) while \( \{ B \} \) follows by rule CONSEQ. This is the rightmost judgment in (38).

Using rules \text{Init1}, \text{Init2}, and \text{SEQ}, we get \( \{ D \} y \leftarrow |0 \} \overset{\text{w}}{\Rightarrow} \{ D \} y \leftarrow |0 \} \{ C \} \) with \( D := \varepsilon^{n} \cdot \text{proj}(0 \otimes |0 \text{ on } x_1 x_2) \). (This is done very similarly to (37).) This shows the middle judgment in (38).

Also using rules \text{Init1}, \text{Init2}, and \text{SEQ}, we get \( \{ \varepsilon^{n} \cdot \text{id} \} x \leftarrow |0 \} \overset{\text{w}}{\Rightarrow} x \leftarrow |0 \} \{ D \}. \) This shows the leftmost judgment in (38).

Thus we have shown the three judgments in (38). By rule \text{SEQ}, it follows that \( \{ \varepsilon^{n} \cdot \text{id} \} \epsilon \overset{\text{w}}{\Rightarrow} \{ B \} \). Since \( B \leq (\text{EQUAL on } y_1 y_2) \), by rule CONSEQ, we get (33).

Acknowledgments. We thank Gilles Barthe, Tore Vincent Carstens, and Justin Hsu for valuable discussions. This work was supported by the Air Force Office of Scientific Research through the project “Verification of quantum cryptography” (AOARD Grant FA2386-17-1-4022), by institutional research funding IUT2-1 of the Estonian Ministry of Education and Research, by the Estonian Centre of Excellence in IT (EXCITE) funded by ERDF, by the project “Research and preparation of an ERC grant application on Certified Quantum Security” (MOBERC12), by the National Natural Science Foundation of China (Grant No: 61872342), and by the ERC consolidator grant CerQuS (819317).

\(^{20}\)We also additionally get the premise that while \( \epsilon \) is terminating. This can be shown with techniques from prior work (e.g., [LY18]) and is quite obvious in the present case. Alternatively, we could have stated this example with respect to partial correctness instead of total correctness. In that case, we do not need to prove termination.
A Comparison with Barthe et al.

In this section, we compare our logic with the one presented in [Bar+19]. To make the comparison easier, when we refer to results from [Bar+19], we restate them in our notation (e.g., we write $\{A\} \psi \phi [\{B\}]$ instead of $\psi \phi A \Rightarrow B$, and we use our syntax for programs).

- The most important difference is that we define judgments with respect to separable couplings (see Definitions 2.4). We believe that this design choice makes rules in our logic easier to prove and thus makes the logic potentially more powerful. See footnote 14 for the reasons why using separable couplings simplifies things.

- We allow infinite dimensional Hilbert spaces (i.e., the types of variables can be infinite sets such as integers or reals). In contrast, [Bar+19] only allows finite dimensional Hilbert space (e.g., bits or bounded integers are possible but not integers).

- [Bar+19] does not behave well with non-terminating programs. The definition requires the existence of a coupling of $[c](\rho_1), [d](\rho_2)$ for any two initial states $\rho_1, \rho_2$. This implies that for all (possibly unrelated) input states, $c, d$ need to have exactly the same termination probability. In contrast, we can also express Hoare logic with total/partial correctness.

- In [Bar+19], not only judgments $\{A\} \psi \phi [\{B\}]$ are considered, but also an extended form $\Sigma \vdash \{A\} \psi \phi [\{B\}]$. This means that $\{A\} \psi \phi [\{B\}]$ holds under certain conditions on the coupling of the input states (e.g., separability of some of the variables or the fact that some variables, when measured, have the same outcome probability distribution). Such conditional judgments occur as the result from various reasoning rules in [Bar+19], e.g., IF1 (analogue to our JOINTIF), LP1 (analogue to our JOINTWHILE), FRAME. These extended judgments make reasoning much harder as we will elaborate. They are not needed in our logic.

In [Bar+19], the SC rule (analogue to rule SEQ here) allows to combine judgments $\{A\} \psi \phi [\{B\}]$ and $\{B\} \psi \phi' [\{C\}]$ into $\{A\} \psi \phi [\{B\} \Rightarrow [\{C\} \psi \phi']$. However, it does not apply to judgments of the form $\Sigma \vdash \{A\} \psi \phi [\{B\}]$. For this purpose, [Bar+19] introduces an extended rule SC+: $\Sigma \vdash \{A\} \psi \phi [\{B\}] \quad \Sigma' \vdash \{B\} \psi \phi' [\{C\}]$ $\Σ \vdash \{A'\} \psi \phi [\{B\} \Rightarrow [\{C\} \psi \phi']$.

Here $\Sigma \vdash \{A\} \psi \phi [\{B\}]$ (“coupling-entails”) means that for input states $\rho_1, \rho_2$ with a coupling satisfying $\Sigma$, every coupling of $[c](\rho_1), [d](\rho_2)$ satisfies $\Sigma'$. The necessity of using this rule leads to two difficulties:

- The logic does not provide support for deriving the premise $\Sigma \vdash \{A\} \psi \phi [\{B\}]$. That is, the preservation of the side-conditions needs to be shown by direct recourse to the semantics of $c, d$ (i.e., to the functions $[c], [d]$), and to the definition of $\Sigma \vdash \{A\} \psi \phi [\{B\}]$. In the examples from [Bar+19], only very simple programs $c, d$ occur here and the premises $\Sigma \vdash \{A\} \psi \phi [\{B\}]$ are stated as obvious. However, if $c, d$ themselves are nontrivial programs, then proving $\Sigma \vdash \{A\} \psi \phi [\{B\}]$ might be infeasible.\(^{21}\) In fact, whether $\Sigma'$ is satisfied might

---

\(^{21}\)The full version of [Bar+19] (Appendix A13) gives an algorithm for reasoning about measurability conditions (not separability conditions, though) by collecting constraints. However, that algorithm runs in exponential time in the number of qubits in the programs (because it directly computes the operators that the programs apply to the quantum state). In particular, if the size of the programs we analyze is parametric in some parameter $n$ (e.g., if we are verifying Grover’s algorithm on $n$ qubits where $n$ is not explicitly given), then we cannot apply...
depend on how the probabilities in the executions of $c, \mathcal{D}$ are related which is basically the kind of judgments we are trying to derive using the relational Hoare logic in the first place. Thus an additional Hoare logic for deriving $\vdash (c, \mathcal{D})$ would be needed.

- $\Sigma \vdash (c, \mathcal{D}) \Sigma'$ is actually a surprisingly strong requirement. This is because $\Sigma'$ needs to hold for all couplings of the final states of $c, \mathcal{D}$, not only the ones we actually care about in the further reasoning. For example, let $c$ be a program that assigns uniformly randomly $|0\rangle$ or $|1\rangle$ to $x$, and $\mathcal{D} := c$. (Such a program can be easily constructed from an initialization and a measurement.) Let $\Sigma$ be the side-condition that means that $x_1, x_2$ are separable. (This is a typical side-condition as considered in [Bar+19].) Then $\Sigma \vdash (c, \mathcal{D}) \Sigma$ does not hold! Even though $x_1, x_2$ are assigned independent values (and thus intuitively should be separable), there exists a coupling of $x_1, x_2$ (namely an EPR pair) that is not separable. Essentially, this means that $SC+$ probably can be very rarely used when a separability condition is involved and the first program in the composition initializes the involved variables in a way that involves probabilism (e.g., a program with measurements).

Furthermore, [Bar+19] does not provide rules IF+ or LP+ analogous to SC+. The rules IF1 (an analogue to our JointIF) and LP1 (analogous to our JointWhile) only apply when the premises all hold without side-conditions. So if we have an if-statement or a while-loop where the judgments concerning the then/else-branches or the loop-body hold only under a side-condition, we have no way of proving judgments about the if-statement or the while-loop, even if we want the latter judgments to hold only under side-conditions.

- One-to-one comparison of rules:
  - **Skip vs. Skip**: Same rule in both logics.
  - **Init1 vs. Init, Init-L**: Our rule Init1 and the rule Init-L from [Bar+19] are the same, except for the minor difference that we allow to specify the assigned state $\psi$. (In our rule the precondition for the program $x \leftarrow |0\rangle$ is $id_{x_1} \otimes (\psi^* \otimes id_{\xi_1})A(\psi \otimes id_{\xi_1})$ while in [Bar+19] it is written as $\sum_{ij} (|i\rangle \langle 0| \otimes |j\rangle \langle 0|)A(|0\rangle \langle i| \otimes |0\rangle \langle j|)$ but it is easy to verify that both formulas evaluate to the same operator in the finite dimensional case.) We did not explicitly write down a direct analogue to the two-sided Init rule from [Bar+19] but we note that the two sided rule follows immediately by sequentially applying Init1 and Init2 (combined with Seq).
  - **Apply1 vs. UT, UT-L**: Our rule Apply1 and the rule UT-L from [Bar+19] are the same.$^{22}$
  - **Seq vs. SC**: Our rule Seq and the rule SC from [Bar+19] are the same.
  - **Conseq vs. Conseq**: Our rule Conseq and the rule Conseq from [Bar+19] are the same.
  - **IF1 vs. IF-L**: Our IF1 and the rule IF-L from [Bar+19] are essentially the same, only with a slight difference on the number of branches.

Furthermore, in the presence of nested while-loops, the algorithm does not terminate. For any while-loop with loop-body $c$, the algorithm computes $[c]$ explicitly ($P^*$ in line 15 of the algorithm) for which there is no terminating algorithm if $c$ itself contains a loop.

Finally, no formal connection between the algorithm and judgments $\Sigma \vdash (c, \mathcal{D}) \Sigma'$ is given. It is shown that the algorithm outputs side conditions $\Sigma$ that makes the programs “comparable” (defined in Appendix A13), but it is not clear how comparability of $c, \mathcal{D}$ implies $\Sigma \vdash (c, \mathcal{D}) \Sigma'$ for suitable $\Sigma, \Sigma'$. (In particular, what would be $\Sigma''$?)

$^{22}$UT-L is stated only for the application of unitaries. Apply1 is stated more generally for the application of isometries. However, since [Bar+19] only considers the finite dimensional case, and in finite dimensions unitaries and isometries coincide (for square matrices), this is only seemingly a difference.
– **JointIf, JointIf9 vs. IF:** Our two-sided rule JointIf9 and the rule IF from [Bar+19] are essentially the same, only with a slight difference on the number of branches. Additionally we have the rule JointIf as a consequence of rule JointIf9, which is also true in the logic of [Bar+19].

– **While1 vs. LP-L:** Our rule While1 and the rule LP-L from [Bar+19] are the same for terminating quantum loops, but the rule for non-terminating quantum loops in partial and semipartial correctness is unique in our logic.

– **JointWhile vs. LP:** The comments made for While1 and LP-L apply for the two-sided loop rules as well. In addition, we stress that our JointWhile rule does not require the termination of the while rules on both sides in the partial and semipartial case. In contrast, LP requires that all while loops are terminating.

– **Case:** The rule Case is only present in [Bar+19]. It states

\[
\text{Case} \quad \\{ p_i \} \text{ is a probability distribution} \quad \{ A_i \} \overset{\text{bhyz}}{\sim} \{ B \} \\
\{ \sum p_i A_i \} \overset{\text{bhyz}}{\sim} \{ B \}
\]

This rule might allow to do a reasoning via case distinction but it is not obvious how exactly it is applied. For example, if we try to prove \( \{ \text{proj}([0]) + \text{proj}([1]) \} \overset{\text{bhyz}}{\sim} \{ B \} \) by showing \( \{ \text{proj}([i]) \} \overset{\text{bhyz}}{\sim} \{ B \} \) for \( i = 0, 1 \), then an application of Case only gives us \( \{ \frac{1}{2}(\text{proj}([0]) + \text{proj}([1])) \} \overset{\text{bhyz}}{\sim} \{ B \} \), not \( \{ \text{proj}([0]) + \text{proj}([1]) \} \overset{\text{bhyz}}{\sim} \{ B \} \). (Case is not used in the examples in [Bar+19].)

– **Frame:** [Bar+19] contains a frame rule

\[
\text{Frame} \quad \{ A \} \overset{\text{bhyz}}{\sim} \{ B \} \\
\Sigma \vdash \{ A \otimes C \} \overset{\text{bhyz}}{\sim} \{ B \otimes C \}
\]

where \( C \) is an expectation operating on variables distinct from those \( e, d, A, B \) operate on. Such a rule without the additional separability condition \( \Sigma \) is very useful for modular analysis of programs (we can analyze \( e, d \) with respect to the local expectations \( A, B \) first, and then derive global statements involving \( C \)). Such a rule is unfortunately missing in our logic. (It is an open problem whether it holds in our logic.)

However, as we mentioned previously, the rule Frame in the current form becomes useless in derivations due to the extra separability condition \( \Sigma \). (Frame is not used in the examples in [Bar+19].)

– **ExFalso:** This rule is only stated in our paper but is trivial to prove for [Bar+19] when additionally assuming termination of the programs.

\[ \text{CNOT} \text{ (Generalized) CNOT} \]
\[ \text{tr}_X \rho \text{ Partial trace (removing variables } X) \]
\[ \mathbb{N} \text{ Natural numbers } 1, 2, 3, \ldots \]
\[ \mathbb{R}_{\geq 0} \text{ Nonnegative reals} \]
\[ \mathbb{Z} \text{ Integers} \]
\[ x, y, z \text{ (Program) variable} \]
\[ C \text{ Complex numbers} \]
\[ |x\rangle \text{ Basis state } x \]
\[ X, Y, Z \text{ List/set of program variables} \]
\[ \ell^2(X) \text{ Hilbert space with basis indexed by } X \]
\[ \langle x| \text{ Adjoint of } |x\rangle, \text{i.e., } |x\rangle^* \]
\[ \text{true} \text{ Boolean truth value true} \]
\[ \downarrow^*_A, \downarrow^*_{\perp}(A) \text{ Dual of the restriction } \downarrow \text{ on states} \]
\[ \downarrow\perp(\rho), \downarrow\perp_f(\rho) \text{ } \perp\text{-memory restricted to measurement outcome } |\perp\rangle / \text{the orthogonal of } |\perp\rangle \]
\[ \mathcal{E}_\perp(\rho) \text{ Measurement whether a mixed } \perp\text{-memory is } \perp \]
\[ \mathcal{H} \text{ A Hilbert space} \]
\[ \ell^2[X]^\perp \text{ Pure quantum } \perp\text{-memories on } X \]
\[ \ell^2[X] \text{ Pure quantum memories on } X \]
\[ A \otimes B \text{ Tensor product of vectors/operators/spaces } A \text{ and } B \]
\[ m \text{ An assignment} \]
\[ A, B, C \text{ (Quantum) expectations} \]
\[ U \text{ on } X \text{ Operator } U \text{ applied to variables } X \]
span $A$ Span, smallest subspace containing $A$
$\|\psi\|$ Norm of vector $\psi$
\texttt{SWAP}$X_1$,$X_2$ Unitary that swaps $X_1$ and $X_2$
$X \equiv_q X'$ Predicate (subspace): $X$ and $X'$ are in the same state
$\llbracket c \rrbracket$ Denotation of a program $c$
\texttt{abort} Nonterminating program
$\downarrow_i (\rho)$ Mixed state restricted to measurement outcome $i$
\texttt{id} Identity
\texttt{tr} $M$ Trace of matrix/operator $M$
$a^*$ Adjoint of operator/vector $a$
\texttt{proj}(\psi) Projector onto $\psi$, i.e., $\psi\psi^*$
\texttt{EQUAL} Quantum equality
$\llbracket c \rrbracket^\perp$ Denotation of a program $c$
$\mathcal{E}$ Usually stands for a superoperator
\texttt{INCR} Unitary mapping $|i\rangle$ to $|i+1\rangle$
