We propose a quantum algorithm for projecting to eigenstates of any hermitian operator, provided one can access the associated control-unitary evolution and measurement of the ancilla of the control. The procedure is iterative and the distribution of the projected eigenstates obeys the Born rule. This algorithm can be used as a subroutine in the quantum annealing procedure by measurement to drive the system to the ground state, and we demonstrate its feasibility by simulating the procedure.

I. INTRODUCTION

The Born rule prescribes the measurement of an observable \( \hat{o} \) on a quantum state \( |\psi_0\rangle \) as probabilistic projection to its eigenstate \( |\alpha_n\rangle \) with a probability \( p_n = |\langle \alpha_n | \psi_0 \rangle|^2 \). Whether one can derive it and hence remove it from the postulates of quantum mechanics is of fundamental interest [1]. A general construction of such a procedure for spectral projection is also of practical importance. For example, Ref. [2] constructs a quantum walk approach to achieve such a projection and emphasizes its utility in carrying out a key step of the quantum simulated annealing (QSA) algorithm for optimization problems [3], for use such as landing in the ground state of a Hamiltonian that encodes a problem. In fact, the standard quantum phase estimation (QPE) [4] and its iterative variants [5–7] can also achieve the spectral projection, albeit approximately with the error decreasing as the number of ancillas is used to represent the phase.

The QPE is crucial in many related applications including Ref. [2] and related methods for preparing a thermal Gibbs state [8–11]. The standard QPE uses \( O(n^3) \) gates, where \( n \) is the number of qubits representing the system state, and thus maintaining coherence when carrying out QPE is important for noisy intermediate-scale quantum (NISQ) processors. Here we apply a simple iterative approach to achieve the spectral projection, and in each step only one control unitary is used and the ancilla is measured. We show that the distribution of this eigenstate projection obeys the Born rule. As an application, we simulate the use of our spectral projection algorithm in the 16-qubit transverse-field Ising model and demonstrate that ground states at different transverse field strengths can be successfully obtained with high fidelity using the QSA.

Our other motivation for this study comes from the incentive to devise a simple quantum version of Lanczos algorithm. An approach was recently proposed in Ref. [12] by implementing an effective unitary evolution \( e^{-iH_{eff} \Delta t} \) to simulate the imaginary time evolution \( e^{-iH \Delta t} \) on a quantum state. We wish to take an alternative approach that does not require the searching of the effective Hamiltonian \( H_{eff} \), but uses the control evolution and ancilla measurement. However, as discussed below, the procedure we come up with suffers from high-order effect, but in analyzing this leads us to the procedure of spectral projection.

The remaining of the paper is organized as follows. In Sec. II we discuss our idea to induce a non-unitary, imaginary-time evolved operation on a quantum state and develop one that seemingly can implement such operation. However, we discuss its drawbacks and argue why it does not work in practice. In Sec. III we discuss our main result of a quantum algorithm for spectral projection and illustrate its use using classical simulations. We show that such spectral projection obeys the Born rule for the distribution of projected eigenstates. We also discuss the effect of decoherence. In particular, we simulate how well our algorithm works as a subroutine in the quantum simulated annealing for arriving at ground states of the transverse-field Ising spin chain. In Sec. IV we make some concluding remarks.

II. PRELIMINARY AND SOME NAIVE ALGORITHMS

The basic idea of our approach is to entangle a system with an ancilla qubit prepared in a certain state, and then measure the ancilla in a chosen basis. This is commonly used in many quantum information processing protocols [4]. We will describe how to choose the prepared ancilla state and the measurement basis alongside the process of implementation. Let the system be composed of a number \( k \) of qubits be in the state \( |\psi\rangle \). First we entangle them with an ancilla in the initial state \( |A\rangle = \alpha|0\rangle + \beta|1\rangle \), by the controlled-operation \( eU \equiv |0\rangle \langle 0| \otimes I + |1\rangle \langle 1| \otimes U \), where \( U \) is the unitary evolution of the \( k \) qubits under a Hamiltonian \( \hat{h} \) within a time step \( \Delta t \), i.e., \( U = \exp(-i\hat{h}\Delta t) \). We then measure the ancilla in the basis \( (|0\rangle \pm e^{i\xi}|1\rangle)/\sqrt{2} \), with the \( \pm \) associated with the measurement outcome \( m = 0 \) or \( 1 \), respectively. This measurement collapses the system qubits onto the unnormalized state:

\[
|\psi_m\rangle = \frac{1}{\sqrt{2}} [(|0\rangle + (-1)^m e^{-i\xi}|1\rangle) \alpha|0\rangle|\psi\rangle + \beta|1\rangle U|\psi\rangle] \\
= \frac{1}{\sqrt{2}} [\alpha + (-1)^m e^{-i\xi} \beta U]|\psi\rangle,
\]

(1)
we choose the ancilla's initial state. Suppose we choose the parameters such that '0' is the desired outcome is as follows,

\[|\psi_m\rangle \approx \frac{1}{\sqrt{2}} (\alpha + (-1)^m e^{-i\xi} \beta) \left[ 1 - \frac{(-1)^m e^{-i\xi} \beta i \Delta t}{\alpha + (-1)^m e^{-i\xi} \beta} \right] |\psi\rangle. \tag{2}\]

We want to achieve a nonunitary action on \(|\psi\rangle\) that is to first order \([1 - \hat{h} \Delta t/r]|\psi\rangle\). However, this cannot hold for both outcomes. Suppose we choose the ancilla's initial state and the measurement angle \(\xi\) such that

\[\frac{\alpha}{\beta} e^{i\xi} = -1 + ir, \quad \text{where} \quad r \in \mathbb{R}, \tag{3}\]

then for the measured outcome \(m = 0\) on the ancilla, the nonunitary action is achieved, i.e., the effective action on the system is

\[|\psi\rangle \approx \left[ 1 - \hat{h} \Delta t/r \right] |\psi\rangle. \tag{4}\]

(We note that one may as well choose the parameters so that \(m = 1\) would be the desired outcome; e.g. \(1 - i r\) in Eq. (3).) One choice of the parameters such that '0' is the desired outcome is as follows,

\[\alpha = \frac{-1 + ir}{\sqrt{2 + r^2}}, \quad \beta = \frac{1}{\sqrt{2 + r^2}}, \quad \xi = 0, \tag{5}\]

and the probability for each outcome (without approximation) is

\[p_m = \frac{1}{2} + \frac{(-1)^m}{2 + r^2} \left(-\text{Re}\langle\psi|U|\psi\rangle + r \text{Im}\langle\psi|U|\psi\rangle\right). \tag{6}\]

We note that the measurement on the ancilla is in the Pauli X basis, which can be done by first applying the Hadamard gate \(H\) before measuring in the standard Z basis; see Fig. 1.

However, for the measured outcome '1' on the ancilla, the system will be collapsed to an undesired state (unnormalized below), correct up to the first order in \(\Delta t\),

\[\left[ 1 - i \frac{2}{r^2 + 4} \hat{h} \Delta t + \frac{r}{r^2 + 4} \hat{h} \Delta t \right] |\psi\rangle. \tag{7}\]

By applying to the post-measurement state the 'correcting' unitary (but this is in fact not necessary as it only modifies the relative phases of different eigencomponents, but not the amplitudes)

\[U_{\text{corr}} = \exp \left( i \frac{2}{r^2 + 4} \hat{h} \Delta t \right), \tag{8}\]

the system becomes

\[|\psi\rangle \approx \left[ 1 + \frac{r}{r^2 + 4} \hat{h} \Delta t \right] |\psi\rangle, \tag{9}\]

to first order in \(\Delta t\). The second term inside the bracket of Eq. (9) and Eq. (10) represents the step size of a random walk in the exponent of an action \(e^{\pm \hat{h} \Delta t}\) on a quantum state \(|\psi\rangle\), where \(\Delta t_0 = -\Delta t/r\) and \(\Delta t_1 = \Delta t/(r + 4/r)\), and the probabilities, according to Eq. (6), are to the first order, respectively,

\[p_0 \approx \frac{r^2}{r^2 + 2} \left( \frac{1}{2} - \frac{h_\psi \Delta t}{r} \right), \]
\[p_1 \approx \frac{r^2}{r^2 + 2} \left( \frac{1}{2} + \frac{h_\psi \Delta t}{r} \right) + \frac{2}{r^2 + 2}, \tag{10}\]

where \(h_\psi \equiv \langle\psi|\hat{h}|\psi\rangle\) is the average energy and \(|\psi\rangle\) is the state of the system prior to this iteration.

A. Driving to the ground state by post-selection

By post-selecting the '0' outcome, we have the action shown in Eq. (4), and by repeating this one can achieve exponential decay to the ground state, via

\[e^{-n\Delta t \hat{h}/r} |\psi\rangle. \tag{11}\]

We note that different values of \(r\) and \(\Delta t\) can be used. Such a procedure is the usual imaginary time evolution, employed in many classical numerical methods, such as the iTEBD method for ground states [13]. However, for our quantum procedure the desired branch of having all '0' outcomes occurs with an exponentially small probability, so it is not very useful in practice.

B. An adaptive procedure for implementing imaginary-time evolution

However, instead of post-selection, one can attempt to perform additional operation if the undesired outcome
‘1’ occurs. Let us define one iteration to be the process
from entangling the system with an ancilla to measuring
the ancilla and possibly correcting with the unitary if
needed. If the first step yields the ‘0’ outcome and one
arrives at the desired imaginary-time evolution Eq. (4).
We ask what one can do if one obtains the ‘1’ outcome
and we terminate the iteration when ‘0’ outcome is ob-
erained. Then the desired one-step imaginary-time evolu-
tion will give

\[ \sum_j p^{(j)} \approx \frac{r_{n+1}}{r_1}, \quad (16) \]

which does not decay exponentially. Figure 3 shows the
values of \( r_n \) with \( r_1 = 1 \). (One can start with a larger
\( r_1 \) so as to get a smaller ratio of \( r_n/r_1 \), but the scaling
is still not exponentially small.)

Of course, in reality first-order and higher-order terms
and dependence on \( h^\psi \) need to be included in actual runs.
As seen in Eq. (10), one can increase the probability of
the outcome ‘0’ by subtracting the Hamiltonian \( \hat{h} \) by a
multiple of the identity operator such that \( h^\psi < 0 \) (as-
suming we take \( r > 0 \)). However, as the iteration pro-
cceeds, this also suffers the second-order effect, i.e. the
second-order term \(-2\Delta t/4)\hat{h}^2/(4 + 2r^2)\) that was not in-
cluded in Eq. (12), when the outcome is ‘1’. Such a term
will decrease the relative amplitude of the ground-state
component, if the ground-state energy is not the small-
est in magnitude, and changes nonuniformly the relative
amplitudes of other eigenstates, as well. If one desires
to alleviate the reduction in the ground-state amplitude,
one needs to do the opposite to the above by shifting the
Hamiltonian \( \hat{h} \) by an identity operator such that it is non-
negative, i.e. \( h^\psi \geq 0 \) (assuming we take \( r > 0 \)). However,
this enhances the probability of outcome ‘1’ to occur and
it results in high probability of a long sequence of ‘1’
outcomes. Such conflicting factors make our adaptive al-
gorithm not practically feasible. In the next section, we
will discuss the effect of this additional second-order term
and will argue that this leads to a novel way to achieve
spectral projection.

Let us remark that one may consider other parameter
choices, such as

\[ \frac{\alpha}{\beta} e^{i\xi} = q + ir, \quad (17) \]

and even let \( \Delta t \) to vary, leading to a recursive relation,

\[ \frac{r_{k+1} \Delta t_{k+1}}{(1 + q_{k+1})^2 + r_{k+1}^2} = \frac{r_k \Delta t_k}{(1 + q_k)^2 + r_k^2} + \frac{r_k \Delta t_k}{(1 - q_k)^2 + r_k^2}. \]

But we do not find these alternatives to provide a robust
and deterministic algorithm for imaginary time evolu-
tion.

III. QUANTUM ALGORITHM FOR SPECTRAL
PROJECTION

We can calculate the expected ‘random walk’ of the
Hamiltonian in the exponent,

\[ p_0[-\hat{h} \Delta t/r] + p_1 \left[ \frac{r}{r^2 + 4} \hat{h}\Delta \right] = \frac{2(\Delta t)^2 h^\psi}{4 + r^2} \hat{h} + O((\Delta t)^3). \]

Since this is second order in \( \Delta t \), we should also include
the expansion in the same order that involves \( \hat{h}^2 \) with
a real coefficient, and that contribution comes from the

FIG. 3: The value of \( r_n \) for the first one hundred, start-
ing with \( r_1 = 1 \).
next order not explicitly shown in Eq. (9) and it gives (as we have mentioned earlier)

$$-\frac{(\Delta t)^2}{4 + 2r^2} \hat{h}^2.$$  (20)

Add both expressions, we obtain

$$-\frac{(\Delta t)^2}{4 + 2r^2} \left\{ \left( \hat{h} - \frac{4 + 2r^2}{4 + r^2} \hat{h}_w \right)^2 + \left( \frac{4 + 2r^2}{4 + r^2} \right)^2 \hat{h}_w^2 \right\}.$$  (21)

Thus the repeated procedure on average gives rise to a nonlinear process that in each step \(|\psi\rangle\) is mapped to

$$|\psi\rangle \rightarrow |\psi'\rangle \sim \exp \left\{ -\frac{(\Delta t)^2}{4 + 2r^2} \left( \hat{h} - \frac{4 + 2r^2}{4 + r^2} \hat{h}_w \right)^2 \right\} |\psi\rangle.$$  (22)

The meaning of the above equation is that the procedure tends to suppress components of eigenstates that have eigenvalues further away from \((4 + 2r^2)/(4 + r^2)|\psi\rangle^2\). As one repeatedly applies the procedure, the state \(|\psi\rangle\) itself will change and hence so will the expectation value \(|\langle \hat{h}|\psi\rangle|^2\). It is a slow process if \(\Delta t\) is small, and it is stochastic as the measurement outcome is random. If, towards the end of the procedure, one can gradually reduce the value of \(r\) to zero, then it will eventually drive any initial state to an eigenstate, provided the procedure is sufficiently long. See Fig. 1 for illustration of the energy evolution as the procedure is carried out.

In fact one can directly take the limit \(r \rightarrow 0\) and the procedure still works. In this case, the control ancilla is prepared in \(|-\rangle = (|0\rangle - |1\rangle)/\sqrt{2}\). But if we have chosen to make ‘1’ outcome the desired one, then we would have set

$$\frac{\alpha}{\beta} \ e^{i \xi} = 1 - ir, \quad \text{where} \quad r \in \mathbb{R},$$  (23)

and the \(r \rightarrow 0\) corresponds to the control ancilla being prepared in \(|+\rangle = (|0\rangle + |1\rangle)/\sqrt{2}\). We have indeed tested that using the control ancilla in \(|\pm\rangle\) and a sequence of \(\Delta t\) (e.g. \(\{10, 3, 1, 0.3, 0.1, \ldots\}\)) to carry out the iteration a few times for each \(\Delta t\), the system could be randomly projected to an eigenstate \(|E_n\rangle\).

In fact, it was known that repeated application of the Hadamard test can randomly project the system to an eigenstate in the setting of the quantum walk [2]. Moreover, the QPE uses the control unitary of the form \(cU^{2k}\) that raises the unitary to the power of \(2^k\), and reading out the phase using the inverse quantum Fourier transform does approximately project the wavefunction to eigenstates of \(U\). Variants of the iterative QPE also rely on the use of \(cU^{2k}\) to achieve the approximate projection [5–7]. What we have proposed here is that \(U\) needs not be raised to an integer power, but instead we can use the unitary of the form \(U(\Delta t) = e^{-i \hat{h} \Delta t}\) with random duration \(\Delta t\). Moreover, the initial state of the ancillary qubit needs not be the \(|\pm\rangle\) nor eigenstates of other Pauli operators.

We discuss shortly below how to perform classical simulations in Sec. III A. Even though we do not know the best sequence of \(r\) and \(\Delta t\) (which can also gradually reduce its magnitude), but what we typically start with some large \(\Delta t\) and decrease it gradually, e.g. \(\Delta t = 10, 3, 1, 0.3, 0.1, \ldots\) Using larger \(\Delta t\) helps with the initial convergence, as indicated in Eq. (22). We note that using \(\Delta t > 1\) is fine when one has access to \(e^{-i \hat{h} \Delta t}\) (more precisely, its controlled version), but when the evolution \(e^{-i \hat{h} \Delta t}\) needs to be approximated by the Trotter decomposition (considering \(\hat{h} = \sum_i \hat{h}_i\)), then \(\Delta t\) cannot be chosen to be large. For each fixed \(\Delta t\), we run a few iterations by varying \(r\), e.g. \(r = 10, 3, 1, 0.3, 0.1, \ldots\), similar to \(\Delta t\), except the use of \(r = 0\). But we also note that it is not necessary to decrease \(r\) and \(\Delta t\) monotonically.

But then why would we need \(r \neq 0\)? We find that if the initial state of the system is not a pure state \(|\psi_0\rangle\) but some mixed state \(\rho_0\), or if a depolarizing channel is applied to the initial pure state, the procedure with \(r = 0\) can lead the system to a fixed point which is invariant even under repeated running with different \(\Delta t\). But using steps with nonzero \(r\) takes the system out of such ‘meta-stable’ fixed points and later makes it converged to an eigenstate. Therefore, there is some advantage of using nonzero \(r\)’s in addition to \(r = 0\) in order to make the procedure stable.

Given such a procedure for projecting any initial state to an eigenstate, it is nature to ask how the final distribution of eigenstates depends on the initial state. Does it obey the Born rule for measuring an eigenbasis, i.e. \(p_n = |\langle n|\psi_0\rangle|^2\)? We will prove below that this is indeed the case in Sec. III B.

So we have a quantum algorithm that performs robust projection to eigenstates. When there is a degeneracy, the projection takes to the superposition that depends on the initial overlap with the degenerate states. This procedure is robust against decoherence, as it is constantly driving the system towards eigenstates, so can be better than using the phase estimation. Moreover, the QPE requires the number of ancillary qubits to scale with the accuracy; that is the precision of the projection depends on the number of the ancillary qubits used in QPE. Here, the cost to precision is the number of iterations: at each step only one ancilla is used and the projection to the eigenstates can be made more precise, even with machine precision, with sufficient iterations and without using \(cU^{2k}\) for very large \(k\).

### A. Classical simulations: classical algorithm for driving to eigenstates

For classical simulations, one does not need to go through the circuit of the control unitary, but only needs to compute two (un-normalized) wave functions \(|\psi_m^{(k)}\rangle\) and their norm squares \(p_m^{(k)} = |\langle \psi_m^{(k)}|\psi_m^{(k)}\rangle|^2\) at each step, say, \(k\)-th, given the state from the end of the previous step...
for the system, $|\psi^{(k-1)}\rangle$, the parameters $\alpha_k(r_k), \beta_k(r_k)$, and the unitary $U_k(\Delta t_k) = e^{-i\Delta t_k \hat{h}}$,

$$|\psi^{(k)}\rangle_m = \frac{1}{\sqrt{2}} \left[ \alpha_k |\psi^{(k-1)}\rangle + (-1)^m \beta_k U_k |\psi^{(k-1)}\rangle \right]. \quad (24)$$

One decides to update the state $|\psi^{(k)}\rangle = |\psi^{(k)}\rangle_m / \sqrt{p_m}$ by choosing $m = 0$ or $m = 1$ probabilistically with $p_m$. With a suitable choice of $\{r_k\}$ and $\{\Delta t_k\}$, the long-iterated state $|\psi^{(k\rightarrow 1)}\rangle$ will converge to an eigenstate $|E_n\rangle$.

We note that simulating this procedure for spectral projection also provides us a quantum-inspired classical algorithm to obtain (randomly) excited states, whose accuracy does not depend on other lower lying levels. The costly part is in obtaining $e^{-i\hat{h} \Delta t}$, however, for the purpose of a short-range Hamiltonian, one can use Trotter decomposition and individual $e^{-i\hat{h}_j \Delta t}$ (for $\hat{h} = \sum_j \hat{h}_j$) is not a large matrix.

We did such simulations for 5-qubit Ising model in a transverse field (with the periodic boundary condition),

$$\hat{H}(g) = \sum_{i=1}^N \left[ g \sigma_i^x \sigma_{i+1}^x - (1-g) \sigma_i^z \right], \quad (25)$$

and the results are shown in the caption of Fig. 5. The results for the final eigenstate distribution are consistent with the Born rule, which we prove next.

**B. Born rule**

We mention earlier that from simulations the probability of the outcome seems to obey the Born rule, and we prove here that this is indeed the case. Since we start with an arbitrary initial state $|\psi_0\rangle$ and assume the ancilla’s state is $\alpha|0\rangle + \beta|1\rangle$, the control unitary is $eU = |0\rangle \langle 0| \otimes 1 \otimes |1\rangle \langle 1| \otimes e^{-i\Delta t \hat{H}}$. The initial expectation value of the energy for $|\psi_0\rangle$ is $|\langle \psi_0 | \hat{H} |\psi_0 \rangle|$, and is trivially conserved even after the control unitary

$$(\alpha|0\rangle + \beta|1\rangle) \otimes |\psi_0\rangle \rightarrow \alpha|0\rangle \otimes |\psi_0\rangle + \beta|1\rangle \otimes U |\psi_0\rangle, \quad (26)$$

where $U = e^{-i\Delta t \hat{H}}$. Since the measurement on the ancilla commutes with any operator whose support is on that of $|\psi_0\rangle$, the energy expectation value remains the same, regardless of the ancilla’s measurement basis. Each measurement gives rise to two branches. And subsequent control unitaries and measurements split the branches further. But averaging over all branches, the expectation of the energy remains the same. Suppose the final distribution of energy eigenstates is $\{q_k, E_k\}$, then $\sum_k q_k E_k = \sum_i |\langle E_i |\psi_0 \rangle|^2 E_i$. Since the equality holds for any set of real numbers that represent the set of eigen-energies, we can then choose in principle the very special case that $E_i = \delta_{i,k}$, and we conclude that $q_k = |\langle E_k |\psi_0 \rangle|^2$, hence proving that the distribution of the final eigen-energies driven by the stochastic procedure must obey the Born rule.

**C. Any observable**

In fact, the $\hat{h}$ can be replaced by any hermitian operator $\hat{o}$ and our procedure can be used to project to $|\psi_n\rangle$ its eigenstates. The Born rule will also apply. One may also regard our procedure as a method for “collapsing” to eigenstates of the system indirectly by measurement on ancillary particles one by one.

**D. Eigenvalues and expectation value by repeated measurement**

How do we know it is converged and how do we extract the eigenvalues? Following the idea in the so-called eigenstate witness method [14], one performs tomography on the ancilla qubit (after applying the same control unitary, i.e. fixing $\Delta t$ and $r$). If it remains in a pure state, this means that the system must be in an eigenstate and hence it is converged.

Let us suppose that the system converges to an eigenstate $|E_n\rangle$, then carrying out one step of the procedure (with the parameters $r$ and $\Delta t$) gives the probability of the ancilla be measured to be $m = 0/1$ being

$$p_m = \frac{1}{2(2 + r^2)} |1 + ir + (-1)^m e^{-i\Delta t E_n}|^2, \quad (27)$$

$$= \frac{1}{2} ( -1 )^m \cos(\Delta t E_n) + \frac{r \sin(\Delta t E_n)}{2 + r^2}. \quad (28)$$
FIG. 5: Eigenstates distribution $p_n$ after the procedure (simulations vs. ideal Born rule). The model under consideration is the Ising model in the transverse field with five qubits at the external field $g = 2/3$ and the initial state is $|\psi_0\rangle = |-,+,+,-,\rangle$. The horizontal axis $n$ labels the index of eigen states with eigen-energies ($E_n$) ordered from the lowest to the highest. The statistics were obtaining by averaging over 1,000 runs.

FIG. 6: Effect of decoherence: energy vs. iteration step in our spectral projection algorithm. The runs are similar to those in Fig. 4 except that at step 10 and step 98, we apply a depolarizing channel to every qubit, $D(\rho_i) = (1 - \epsilon)\rho + \epsilon I/2$, using $\epsilon = 0.5$. The ‘disruption’ at step 98 is clearly visible in terms of energy, whereas that at step 10 is not visible as the system is still trying to converge. The converged energy to the closest exact energy eigenvalue has an error from $10^{-3}$ to $10^{-5}$, except one run having $10^{-8}$.

The system remains in its eigenstate $|E_n\rangle$ under such repeated measurements, by fixing the same set of parameters and monitoring the continuing measurements, one can deduce the energy value $E_n$. By changing to a different $r$ or just flipping its sign, one obtains another estimation of the probabilities in terms of $\Delta t E_n$ and we can extract the eigen energy.

One can also use the usual Hadamard test, i.e. using $|+\rangle = (|0\rangle + |1\rangle)/\sqrt{2}$ or $|i\rangle = (|0\rangle + i|1\rangle)/\sqrt{2}$ as the ancilla state for the control bit before the control unitary. Then the difference in the probabilities, $p_0 - p_1$, allows to measure the real and imaginary parts of the phase $e^{-i\Delta t E_k}$. As above, if the system is already in an eigenstate, the Hadamard test will not change the state of the system, so one can repeatedly perform the test.

E. Effect of decoherence

Our method has some resilience to decoherence, but is as robust as error correction. We perform similar runs of spectral projection, similar to those in Fig. 4 except that at step 10 and step 98, we apply a depolarizing channel to every qubit, $D(\rho_i) = (1 - \epsilon)\rho + \epsilon I/2$ with $\epsilon = 0.5$. As can be clearly seen in Fig. 6 the ‘disruption’ at step 98 is clearly visible in terms of energy, whereas that at step 10 is not visible as the system is still trying to converge. The converged energy to the closest exact energy eigenvalue has an error from $10^{-3}$ to $10^{-5}$, except one run having $10^{-8}$. If there can be sufficient number of iteration steps carried out before decoherence takes place, then the system can converge to an eigenstate. Of course, the depolarizing channel takes it out of the eigenstate and the iterative spectral projection procedure may take the system to another eigenstate.

We note that here we assume the ancillary control qubit is relatively error free, and this reminds us of the assumption in the so-called DQC1 quantum computing model [15], where only one qubit is clean.
F. Subroutine in the quantum annealing algorithm

As an application, we simulate the use of our spectral projection algorithm in the 16-qubit transverse-field Ising model demonstrate that ground states at different transverse field strengths can be successfully obtained in the context of QSA [8]. The Hamiltonian we consider $H(g)$ is shown in Eq. (25), where the parameterization is slightly different from the literature. But in terms of the spin-spin coupling strength $J = g$ and the external field $B = (1 - g)$. We begin at the ground state of $g_0 = 0$ (which is $|0^{\otimes N}\rangle$) and as the first step project the system to the eigenstates of $H(g_1)$ with $g_1 = g_0 + 0.025$, and keep increasing the subsequent $g_{k+1} = g_k + 0.025$ until $g = 1$. What is shown in Fig. 7 is the energy after projecting to the eigenstates vs. $g$. The system size we simulate is $N = 16$.

In this particular simulation, we do not use the total Hamiltonian $H(g)$ in implementing the unitary, but instead using $H_e(g)$ and $H_o(g)$ for even and odd bonds. In applying the controlled version of $e^{iH\Delta t}$ we use a 4-th order Trotter decomposition [10]. This also demonstrates the applicability of our approach, as the the control operation needs only act on a smaller part of the system (e.g. sequentially on the control bit and the qubits of each bond). We do see that the final state at $g = 1$ is very close to its ground state, with the error in terms of energy being $10^{-13}$.

IV. CONCLUSION

We have proposed a quantum algorithm for projecting to eigenstates of any hermitian operator, provided one can access the associated control-unitary evolution and measurement of the control ancilla qubit. The procedure is iterative and the distribution of the projected eigenstates obeys the Born rule. It has some resilience against decoherence, namely, the iterative procedure takes the system towards eigenstates, even after the influence of decoherence such as a depolarizing. But it has no capability of error correction or prevention. We do not view this as the alternative of QPE. This algorithm can be used as a subroutine in the quantum annealing procedure by measurement to drive to the ground state. We have simulated that our algorithm indeed works. It will be interesting to see a proof-of-principle demonstration on currently available quantum computers.

Post-selection allows projection to the ground state, but the probability for obtaining the desired post-selected outcome is exceedingly small. The algorithm that we develop for the imaginary time evolution suffers some problems that make it not practical. It will be desirable to see whether there is any way out so that we can have a practical imaginary time evolution quantum algorithm by measuring ancillas.
