Abstract

DNA inside the cellular environment works in a confined space. Depending on the confinement, the dynamics and interaction of bio-molecules changes. Intense research of the transcription and replication of DNA in the confined state is structurally significant to understand the self-assembly of DNA in a chamber or channel. We consider double-stranded DNA (dsDNA) molecules of different length and sequence and study the thermal stability in a confined space of different geometries. We use a statistical model and evaluate the melting profile of DNA in conical as well as cylindrical geometries. Our results show that not only the confinement but also the geometry of the confined space plays a prominent role in the stability and opening manner of the molecule.
I. INTRODUCTION

Deoxyribonucleic acid (DNA) is one of the interesting and complex biomolecule. The importance of this molecule lies in its applications in the molecular motor, DNA computer, origami formation, DNA chip, and biomedicine. The most abundant conformation of this molecule is double helical structure (also known as the Watson-Crick double helix). The genetic information of an entire organism is coded in the sequence of four nucleotides Adenine (A), Guanine (G), Cytosine (C), Thymine (T). It has been observed that on increasing the temperature of the solution containing DNA molecule, the double strand progressively takes a conformational change into the single stranded configuration. This is known as DNA melting or denaturation of DNA and it can be studied by many different ways. The same can be achieved by changing the pH of the solution as well as by pulling either of the strands by a mechanical device. To develop applications like thermal cycling induced DNA melting in the PCR technique and the binding of the short staple strands to the DNA origami, the understanding of the denaturation and renaturation processes of DNA is very important.

In vivo, DNA molecule is confined in a limited space such as the cell chamber or a channel and is in highly dense solvent conditions. The solvent ionic charges allow DNA polymer a smooth sliding translocation through the confinement channel. This confinement restricts the conformation and movement of DNA molecules in the cell. The thermodynamic properties of DNA molecules highly depend on the confined space and on the solvent properties. It is known that conformational properties of biopolymers under confinement are the crucial relevance in living systems like DNA packing in eukaryotic chromosomes, viral capsids etc. In order to have a fair understanding of these properties we should have a deep understanding of the denaturation and renaturation mechanisms of DNA in the confined state. These kinds of studies enable us to use DNA for effective design and to control the self-assembly behavior of the molecule for various applications.

The experimental findings show that the confinement strongly affects the entropy of DNA molecules. In an interesting work, Derrington et al. show that how Mycobacterium smegmatis porin A (MspA) can be used to identify the sequence of DNA. The MspA is a short and narrow constiction that can be used to distinguish the individual nucleotides of single stranded DNA. In an important work, Lau et al. showed that a small DNA strand initially confined in a 4 nm diameter nanotube, exhibit dynamics similar to the unconfined molecule, but the behaviour is drastically changed when the diameter is reduced to 3 nm. From the point of view of biological
purposes and DNA manipulation, carbon nanotubes are used as templates for DNA encapsulation, intracellular penetration via endocytosis and delivery of biological payloads etc \cite{17, 21}. Recently, we have witnessed few works, theoretical as well as experimental, which demonstrate the local properties of the biopolymers translocation in nanochannels \cite{22, 25}. Some experimental studies have been conducted on translocation of biopolymers through conical geometry \cite{26, 27}. It is a matter of interest that which geometry gives the highest possible resolution for reading information along the DNA contour \cite{24, 25}. Franceschini et al. \cite{15} show that during the time of translocation of DNA, how the interior channel possession charges help for the smooth sliding. Their results indicate that the net internal negative surface charge is important to allow the smooth sliding of the opposing negatively charged DNA when it passes through the connector or $\beta$-clamp temperature with varying the angle of the conical geometry using a statistical model.

In all these studies, they have considered either rectangular or spherical geometry of the confinement \cite{12}. Despite recent progress, still little is known about the trajectory profiles of confinement nature of DNA passing through these nano-pores \cite{23}. In the present manuscript, motivated by all these different kinds of experiments in different geometries, we attempt to understand the thermal stability of DNA molecule that is confined in different geometries through a statistical model. The present work is divided into following sections: with a brief introduction to the statistical model in Sec. II, we discuss the melting of DNA in confined geometry in Sec. III. The paper ends with a brief discussion and future scope of the work in Sec. IV.

II. MODEL AND METHODS

To investigate the effect of confinement on the thermal denaturation of DNA molecule, we adopt the well known Peyrard-Bishop-Dauxois model (PBD). The model is quasi-one-dimensional and describes the motion of the molecules through the stretching of the hydrogen bonds between the bases in a pair \cite{28, 29}. The interactions in the DNA, containing $N$ base pairs, are represented as,

$$H = \sum_{i=1}^{N} \left[ \frac{p_i^2}{2m} + V_M(y_i) + V_{sol}(y_i) \right] + \sum_{i=1}^{N-1} [W_S(y_i, y_{i+1})],$$

(1)

here $y_i$ represents the stretching from the equilibrium position of the hydrogen bonds. First term of the model is the momentum term which is $p_i = m\dot{y}_i$. The reduced mass, $m$, is considered the same for both $AT$ and $GC$ base pairs. The interaction between the nearest base pairs along the chain, the stacking interaction, is represented by,

$$W_S(y_i, y_{i+1}) = \frac{k}{2}(y_i - y_{i+1})^2[1 + \rho e^{-b(y_i+y_{i+1})}],$$

(2)
The single strand elasticity is represented by $k$, while the anharmonicity in the strand elasticity is represented by $\rho$. The parameter, $b$, describes the range of anharmonicity. The hydrogen bonding between the two bases in the $i^{th}$ pair is represented by the Morse potential as,

$$V_M(y_i) = D_i(e^{-a_i y_i} - 1)^2.$$  \hspace{1cm} (3)

where $D_i$ represents the potential depth, and $a_i$ represents the inverse of the width of the potential well. These two parameters have a crucial role in DNA denaturation. The dissociation energy, $D_i$, is a representation of the hydrogen bond energy that binds the AT and GC pairs while $a_i$ represents bond stiffness. From previous results, we know that the bond strengths of these two pairs are in an approximate ratio of 1.25 - 1.5 as the GC pairs have three while AT pairs have two hydrogen bonds \cite{30-40}. To take care of solution effect, we add a solvent term, $V_{sol}(y_i)$, in Hamiltonian \cite{41}. This additional term simulates the formation of hydrogen bonds with the solvent, once the hydrogen bonds are stretched by more than their equilibrium values.

$$V_{sol} = -\frac{1}{4}D_i[\tanh(\gamma y_i) - 1]$$  \hspace{1cm} (4)

The $\tanh$ term in the potential enhances the energy of the equilibrium configuration and the height of the barrier below which the base pair is closed \cite{41}. We take $\gamma = 1.0$ Å$^{-1}$ in this problem as a suitable choice for our calculations. The cations present in the solution in the form of $Na^+$ or $Mg^{2+}$ acts as shielding agents that weaken the electrostatic repulsion between the two negative strands of DNA. The concentration of salt that stabilises the DNA molecule can be incorporated through the potential depth, $D_i$ in the Hamiltonian \cite{42-44},

$$D_i = D_0 \left[ 1 + \lambda_1 \ln \left( \frac{C}{C_0} \right) + \lambda_2 \ln^2 \left( \frac{C}{C_0} \right) + \chi \left( \frac{C_0}{C_t} \right) \right]$$  \hspace{1cm} (5)

The melting temperature of the DNA molecule varies linearly with the GC content of the DNA at a fixed salt concentration while it shows a logarithmic dependence with the salt concentration at a fixed base pair composition \cite{42,43}. Therefore, we vary the potential depth, $D_i$, logarithmically with the salt concentration, $C$ (in mol/L). The third term in Eq. (5) is the correction term \cite{43}. Here we make $C$ as a dimensionless quantity by choosing the reference value $C_0 = 1.0$ mol/L. The last term takes care the presence of cations at high salt concentrations. The parameters, $t$ and $\chi$, are the scaling factors \cite{44,46}. The complete set of parameters is $k = 0.015$ eVÅ$^{-2}$, $\rho = 50.0$, $b = 0.35$ Å$^{-1}$, $\lambda_1 = 0.01$, $\lambda_2 = -0.011$, $t = 0.01$ and $\chi = 1.2$, $a_{AT} = 4.2$ Å$^{-1}$, $a_{GC} = 6.3$ Å$^{-1}$ and $D_0 = 0.05$ eV. We can study the thermodynamics of the transition by evaluating the partition
function. For a sequence of $N$ base pairs, the canonical partition function can be written as [47]:

$$Z = \int \prod_{i=1}^{N} \{dy_i dp_i \exp(-\beta H)\} = Z_p Z_c,$$

(6)

where $Z_p$ corresponds to the momentum part of the partition function while the $Z_c$ contributes as the configurational part of the partition function. The momentum part is nothing but $(2\pi mk_BT)^{N/2}$. The configurational part of the partition function, $Z_c$, is defined as [47],

$$Z_c = \int \prod_{i=1}^{N-1} dy_i K(y_i, y_{i+1}) dy_N K(y_N)$$

(7)

where $K(y_i, y_{i+1}) = \exp[-\beta H_c(y_i, y_{i+1})]$.

For the homogeneous chain, one can evaluate the partition function using the transfer integral (TI) method by applying the periodic boundary condition. For a chain with a random sequence of AT and GC pairs, we can evaluate the configurational part of the partition function with the help of the matrix multiplication method [41]. To evaluate the integration, we have to choose the cut-offs for the integral appearing in Eq.(7) carefully. After the proper cut-offs, the next task is to discretise the integral. In order to get a precise value of melting temperature ($T_m$) we have observed that Gaussian quadrature is the most effective quadrature. We have found that discretization of the space with 900 points is sufficient to get an accurate value of $T_m$ [41, 48]. Once we evaluate the partition function, we can determine the thermodynamic quantities of interest by evaluating the Helmholtz free energy of the system. The Helmholtz free energy per base pair is defined as,

$$f(T) = -\frac{1}{2} k_B T \ln (2\pi mk_B T) - \frac{k_B T}{N} \ln Z_c$$

(8)

The configurational part $Z_c$ of the partition function is evaluated using matrix multiplication method [45]. Specific heat, $C_v$, of the system, in the thermal ensemble, is evaluated by taking the second derivative of the free energy, as $C_v = -T(\partial^2 f/\partial T^2)$. The melting temperature ($T_m$) of the chain is evaluated from the peak in the specific heat. The average separation, $\langle y_j \rangle$, of the $j^{th}$ pair of the chain with temperature is given by,

$$\langle y_j \rangle = \frac{1}{Z} \int \prod_{i=1}^{N} y_j \exp(-\beta H) dy_i$$

(9)

In this work, we study the effect of confined geometries on the melting profile of DNA chain of lengths 100, 200, 300, and 350 base pairs. Some interesting studies that reveal many interesting features of the melting of the DNA molecule that is confined in a rectangular geometry [22, 49]. Our focus is mainly on the stability of the DNA molecule that is confined in a conical geometry.
FIG. 1. (a) The schematic representation of the DNA molecule in a confined cell of conical shape. The distance $x$ represents the distance between a pair and the confining wall while $\theta$ is the angle at which the cellular wall is supposed to confine the DNA. Here $z = 3.4 \ast i$, the distance along $x$-axis. (b) The schematic representation of the DNA molecule in a confined cell of cylindrical geometry. The $r$ is the distance of the confined wall from the DNA strand. So the diameter of the cylinder becomes $r$+DNA diameter.

as shown in Fig.1a. For completeness in the analysis we also study the stability of DNA that is confined in a cylindrical geometry as shown in Fig.1b. How the confinement can be realized in the PBD model? We adopt the following scheme. Due to surrounding cellular environment, the movement of base pairs will be restricted which in turn affect the overall movement of the individual base pairs. We restrict the configuration space of the system as shown in Fig. 1a. There is no change in the lower limit of integral, however, the upper limit of integral for each base pair is modified as $x = 3.4 \ast i \ast \tan(\theta)$. Here, $i$ is the site index ($i = 1, 2, 3, ..., N$), where $N$ is the total number of base pairs in the chain. The term $\theta$ is the angular separation between the confining wall and the DNA strand. Since two base pairs are approximately 3.4 Å distance apart we take this as the multiplication factor in calculation. Thus, the configurational space for our calculation extends from -5 Å to $x$ Å. There is another important factor that affects the melting transition is the cross section of the pore. The cross section of the confining wall (or pore diameter) is represented by the term, $\delta$. The value of $\delta = 0$ Å means the distance between the vortex and the DNA strand is 0 Å (as shown in Fig. 1). Using the modified scheme we calculate the partition function and hence evaluate all the thermodynamical properties of the system.

III. RESULTS

A. Melting of DNA in confined geometries

First we consider a homogeneous chain of 100 base pairs. By evaluating the partition function, we calculate free energy per base pair hence specific heat as a function of temperature. The melting temperature $T_m$ of chain at various angular separations are calculated through the peak in specific
heat as a function of temperature [41, 44]. The results are plotted in Fig. 2. The obtained results clearly show that the confinement has a strong effect on the stability of the molecule. We find that the melting temperature \( (T_m) \) of dsDNA increases as the confinement becomes stronger. We vary the angular separation and found that \( T_m \) decreases as the angle changes from 5° to 6°. The melting temperature for an angular separation of 5° is found to be 253.4 K while it reduces to 251 K for an angle of 6°, i.e. a reduction of approximately 2.4 K in the melting temperature. The melting temperature further reduces for the higher angular separations and get saturated at an angle of \( \approx 15° \). The stability of DNA confinement in a cylindrical symmetric wall has been investigated by various researchers using Poland Scheraga model [49, 50].

To investigate the effect of geometry on the stability of the DNA molecule, we consider a DNA chain confined in a cylinder. We change the radius of the cylinder (see Fig. 1b) and calculate the change in the melting temperature of the system. The results are plotted in Fig. 2. When the DNA is confined in a cylinder at \( r = 5 \) Å, we find the melting temperature of the system as \( \sim 360 \) K. The melting temperature reduces drastically to a value of \( \sim 290 \) K for the radial separation of 7 Å. On further increasing the separation the \( T_m \) reduces and almost get saturated at value of \( \sim 225 \) K for the separation of 5 Å. From the plot, we have omitted the data corresponding to \( r = 5 \) Å for better visualization. Since the two geometries suppress the entropy of the system in a
different way, one can believe that DNA which is confined in cylindrical geometry is more stable than the DNA that is confined in conical geometry upto a certain separation. The point to note that while for shorter separation stability is higher for cylindrical confinement but it is lower at higher separation (*please see Fig. 2* for a detail comparision).

Next, we consider a homogeneous DNA molecule of 100 base pairs and study the thermal stability of the system with the change in the pore diameter, $\delta$. Here we calculate the change in the melting temperature with the change in the pore diameter, $\delta$ for a fix value of $\theta$ (the angular separation). The results are shown in Fig. 3. From the Fig. 3 it is clear that with the increase in pore diameter ($\delta$) for a same value of angular separation ($\theta$), the melting temperature decreases. This is due to fact that when the pore diameter increases the end at the vortex of the cone gets more space which increases the end entropy. Due to more entropy, DNA opens at lower temperature.

To understand the microscopic details of opening of the homogeneous DNA chain in a confined space, we calculate the average separation of the chain, $\langle y_i \rangle$, with the change in the angular separation ($\theta$). The surface plot indicates how DNA open under a conical shaped confining wall for different conical angle($\theta$) (see Fig.4 and Fig.8). From the opening profile, the effect of confinement angle is more apparent. When the angular separation is $5^\circ$, the effect lasts for $\sim$19 base pairs while for the $10^\circ$ angular separation, the effect lasts for $\sim$8 base pairs.
FIG. 4. The opening profile of the chain is shown through the 3D plots which shows a variation in $\langle y_j \rangle$ for the homogeneous chain. Here we show the profile for two different angular separation, $\theta = 5^0$ and $\theta = 10^0$ and the pore diameter $\delta = 0 \, \text{Å}$. The $x$-axis is site index while $y$-axis is temperature (in K) and $z$-axis denotes the average separation, $\langle y_j \rangle$ in Å.

**B. The effect of cations on the melting temperature**

Next we consider the homogeneous chain in the concentrated solution [44]. We modify the PBD model to take care the solution concentration. The Morse potential depth is modified as per Eq. (5). Due to presence of cations, the repulsion between $PO_4^-$ groups shielded, hence, the double strand is more stable [32, 43]. For an angular separation of $6^0$, the $T_m$ reduces to 362 K, i.e. a reduction of $\approx 3.8$ K in melting temperature is observed. Again we vary the angle from $5^0 - 45^0$ and calculate the melting temperature. The results are shown in Fig. 8. We also investigate the effect of confinement on different sized DNA molecule by varying the chain size. We consider the chain of 100, 150, 200, 250 & 300 base pairs and investigate the variation in melting temperature with varying angular separation. The resulting plots are shown in Fig. 9. The qualitative feature of all the plots are same, however, the decrease in melting temperature for all the chains is not same. For the chain of 150 bp, the $T_m$ is 349.5 K for an angular separation of $5^0$ which reduces to 348 K for and angle of $6^0$. The asymptotic value of $T_m$ is 344.5 K which occur at $\approx 15^0$ of angular separation. This means for a span of $10^0 \, (15^0 - 5^0 = 10^0)$ the variation in melting temperature vanishes and the decrease in $T_m$ is $\approx 5 \, \text{K}(349.5 - 344.5 = 5 \, \text{K})$. For the 200 bp chain, this shift is about 2.5 K ($342.5 - 340 = 2.5 \, \text{K}$) for a span of $6^0 \, (11^0 - 5^0 = 6^0)$ as it gets the asymptotic value of $T_m$ at $11^0$, while, for 300 bp chain the melting temperature reduces from 336.35 K (at $5^0$) to 335.21 K (at $10^0$) so the shift of $T_m$ is 1.1 K ($336.35 - 335.21 = 1.14 \, \text{K}$). One can clearly see that as the length of the chain increases the change in melting temperature with angle is reducing.
FIG. 5. The change in melting temperature with the change in the angular separation between the confining wall and DNA molecule in concentrated solution ($C = 0.05 \text{ mol/L}$). The pore diameter $\delta = 0 \text{ Å}$.

For chain of length more than 350 base pairs, we observe that there is no change in the melting temperature with the change in the angular separation. The probable argument for the small variation is the entropy of the system that varies with size. The smaller the chain, the stronger the suppression of entropy. For a bigger chain, a large section of the chain might not be seeing the confining wall because the distance between the wall and the DNA chain increases (please refer to Fig.01 a).

C. Melting of Heterogeneous DNA

The real DNA is having a random sequence of $AT$ and $GC$ pairs (Heterogeneous molecule). To investigate the effect of confinement on the opening of a heterogeneous system, we consider chains of three different kinds as per the following details. The three chains are of 100 base pairs each with different sequence. First chain, Het1, is 50AT+50GC while second chain, Het2, is 50 AT and 50 GC pairs in alternate sequence. The third chain, Het3, is having $\sim50\%$ AT and $\sim50\%$ GC in a random manner. The sequence of base pairs in Het3 is as follows:

$$5' - AGTCAGTCAGCGAGATAGTCGAGAGACATAGAGAGAGAGAGAGTTT GAGAGGAGGGAGTGTGAAAAGAGAGCGAGTGTGAGAGAGAATGAGAT - 3'$$

The heterogeneity in the model is mainly introduced via Morse Potential, $D$, the dissociation energy of the pair and $a$, the inverse of the width of the potential well. These two parameters have a crucial role in the DNA denaturation. The dissociation energy is a representation of the hydrogen
FIG. 6. How the effect of confinement changes with the linear size of the molecule is shown here. We consider the homogeneous DNA molecule of different lengths as 150, 200, 250 and 300 in salt concentration $C = 0.05$ mol/L. The pore diameter $\delta = 0$ Å.

bond energy that binds the $AT$ and $GC$. It is a known fact that the bond strength of these two pairs are not same but are in an approximate ratio of $1.25 - 1.5 \ [31, 36, 39, 40, 48]$ because the GC pairs have three while AT pairs have two hydrogen bonds. While for the Het2 and Het3 chains, there is a slight variation in the melting temperature, the chain Het1 has slightly higher melting temperature (see Fig. 7). The main reason behind the stability of this chain is due to the fact that chain has large stronger segments which becomes more stronger due to the confinement. Point to note here is that the GC rich region is at $3'$-end which supresses the entropy of the chain. Since the weaker section of the chain is confined due to wall, the melting temperature of this chain is higher. At $5^0$, angle the $T_m$ for the Het1 is $428$ K while this is $416$ K for the chains Het2 and Het3.

To show the opening of a heterogeneous DNA molecule (Het3) we calculate the average separation, $\langle y_j \rangle$, at three different temperatures. How the different sections of the chain open below the melting temperature of the chain is the matter of interest here. From the plot (fig. 8), the sequence and effect of conical confinement are visible. Since the weaker section of the chain consists of AT
FIG. 8. The opening profile of a random sequence of DNA that is confined in a conical geometry. The angular separation $\theta = 10^\circ$, the pore width $\delta = 0$ Å and the salt concentration is the $C = 0.05$ mol/L.

pairs is more entropic than the section containing GC pairs, the chain opens from 3’-end. Point to note that the melting temperature of this chain is 405 K. While the opening of the homogeneous chain is very smooth, the opening of the heterogeneous chain has bubbles. One can see that how these bubbles disappear above the melting temperature of the chain when the DNA is in the denatured state.
IV. CONCLUSIONS

In this article, we have studied, theoretically, the stability of homogeneous as well as heterogeneous DNA molecule that is confined in a cellular environment of conical as well as cylindrical geometry. We know that a DNA molecule inside the cell exists in a very crowded environment. In most of the theoretical studies, in general, the solution concentration, the effect of confinement of the cellular boundaries are taken as constants of the model. Probably this is the first model based study that studies the impact of angular confinement on the stability of the DNA molecule in a thermal ensemble. Our studies show that not only the confinement but also the geometry of the confinement plays a crucial role in the stability as well the overall activity of the DNA molecule. We have studied the stability of DNA molecule, in thermal ensemble, that is confined in conical as well as cylindrical geometries. We found that the stability of the DNA molecule is higher in the cylindrical confined geometry rather than conical confined geometry up to a particular separation. When the confining wall is closer, the configuration space for the DNA molecule, in cylindrical geometry, is restricted which suppresses the entropy of the chain. Hence the melting temperature of the system in cylindrical geometry is more than the melting temperature of the DNA that is confined in conical geometry. If we compare two cases of the confinement (conical and cylindrical) and ask in which case the decrease in the $T_m$ is higher, the answer will be the DNA confined in cylindrical geometry. The obtained results are consistent with the findings of Huaping et al. Through simulation of the short DNA molecule that is confined in a cylindrical as well as in spherical geometry, they found that the melting temperature of the system decreases with the increasing diameter of the cylinder/sphere. These results indicate the effect of the geometry of the two confinements on the stability of the DNA molecule. In case of cylindrical confinement, the complete chain is restricted while in the case of conical confinement, there is a segment of the chain which might not be seeing the confining wall as the separation is angular. In our previous study, we have investigated the role of molecular crowder on the thermal stability of the DNA molecule. Our study can be extended to investigate the translocation of DNA through a nanopore of different geometries in future.
