Abstract

The goal of a decision-based adversarial attack on a trained model is to generate adversarial examples based solely on observing output labels returned by the targeted model. We develop HopSkipJumpAttack†, a family of algorithms based on a novel estimate of the gradient direction using binary information at the decision boundary. The proposed family includes both untargeted and targeted attacks optimized for $\ell_2$ and $\ell_\infty$ similarity metrics respectively. Theoretical analysis is provided for the proposed algorithms and the gradient direction estimate. Experiments show HopSkipJumpAttack requires significantly fewer model queries than Boundary Attack, a powerful existing decision-based attack. It also achieves competitive performance in attacking adversarially trained models on MNIST.

1 Introduction

Although deep neural networks have achieved state-of-the-art performance on a variety of tasks, they have been shown to be vulnerable to adversarial examples—that is, maliciously perturbed examples that are almost identical to original samples in human perception, but cause models to make incorrect decisions [1]. The vulnerability of neural networks to adversarial examples implies a security risk in applications with real-world consequences, such as self-driving cars, robotics, financial services, and criminal justice; in addition, it highlights fundamental differences between human learning and existing machine-based systems. The study of adversarial examples is thus necessary to identify the limitation of current machine learning algorithms, provide a metric for robustness, investigate the potential risk, and suggest ways to improve the robustness of models.

Recent years have witnessed a flurry of research on the design of new algorithms for generating adversarial examples [1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16]. Adversarial examples can be categorized according to at least three different criteria: the similarity metric, the attack goal, and the threat model. Commonly used similarity metrics are $\ell_p$-distances between adversarial and original examples with $p \in \{0, 2, \infty\}$. The goal of attack is either untargeted or targeted. The goal of an untargeted attack is to perturb the input so as to cause any type of misclassification, whereas the goal of a targeted attack is to alter the decision of the model to a pre-specific target class. Changing the loss function allows for switching between two types of attacks [3,4,5,6].

Perhaps the most important criterion in practice is the threat model, of which there are two primary types: white-box and black-box. In the white-box setting, an attacker has complete access to the model, including its structure and weights. Under this setting, the generation of adversarial examples is often formulated as an optimization problem, which is solved either via treating misclassification loss as a regularization [1,6] or via tackling the dual as a constrained optimization problem [2,3,7]. In the black-box setting, an attacker can only access outputs of the target model. Based on whether one has access to the full probability or the label of a given input, black-box attacks are further divided into score-based and decision-based. See

†HopSkipJumpAttack was named Boundary Attack++ in a previous version of the preprint.
Figure 1. An illustration of accessible components of the target model for each of the three threat models. A white-box threat model assumes access to the whole model; a score-based threat model assumes access to the output layer; a decision-based threat model assumes access to the predicted label alone.

The most practical threat model is that in which an attacker has access to decisions alone. A widely studied type of the decision-based attack is transfer-based attack. Liu et al. [11] showed that adversarial examples generated on an ensemble of deep neural networks from a white-box attack can be transferred to an unseen neural network. Papernot et al. [12] [13] proposed to train a substitute model by querying the target model. However, transfer-based attack requires access to training data, and sometimes a carefully-designed substitute model. Moreover, they can be defended against via training on a data set augmented by adversarial examples from an ensemble of substitute models [17]. In recent work, Brendel et al. [14] proposed Boundary Attack, which generates adversarial examples via rejection sampling. While relying neither on training data nor on the assumption of transferability, this attack method achieves comparable performance with state-of-the-art white-box attacks such as C&W attack [6]. One limitation of Boundary Attack, however, is that it requires a relatively large number of model queries, rendering it impractical for real-world applications. It is more realistic to evaluate the vulnerability of a machine learning system under the decision-based attack with a limited budget of model queries. Moreover, Boundary Attack was formulated only for the $\ell_2$-distance.

In this paper, we study decision-based attacks under an optimization framework, and propose a novel family of algorithms for generating both targeted and untargeted adversarial examples that are optimized for minimum distance with respect to either the $\ell_2$-distance or $\ell_\infty$ distance. The family of algorithms is iterative in nature, with each iteration involving three steps: estimation of the gradient direction, step-size search via geometric progression, and Boundary search via a binary search. We refer to the algorithm as HopSkipJumpAttack\(^2\). In summary, our contributions are the following:

- We propose a novel unbiased estimate of gradient direction at the decision boundary based solely on access to model decisions, and propose ways to control the error from deviation from the boundary.
- We design a family of algorithms, HopSkipJumpAttack, based on the proposed estimate and our analysis, which is hyperparameter-free, query-efficient and equipped with a convergence analysis.
- We demonstrate the superior efficiency of our algorithm over Boundary Attack through extensive experiments, and evaluate the performance of our algorithm on adversarially trained models.

\(^2\)A hop, skip, and a jump originally referred to an exercise or game involving these movements dating from the early 1700s, but by the mid-1800s it was also being used figuratively for the short distance so covered.
Roadmap. In Section 2 we describe previous work on decision-based adversarial attacks and their relationship to our algorithm. We also discuss the connection of our algorithm to zeroth-order optimization. In Section 3 we propose and analyze a novel iterative algorithm which requires access to the gradient information. Each step carries out a gradient update from the boundary, and then projects back to the boundary again. In Section 4 we introduce a novel asymptotically unbiased gradient-direction estimate at the boundary, and a binary-search procedure to approach the boundary. We also discuss how to control errors with deviation from the boundary. The analysis motivates a decision-based algorithm, HopSkipJumpAttack (Algorithm 2). Experimental results are provided in Section 5. We conclude in Section 6 with a discussion of future work.

2 Related work

2.1 Decision-based attacks

Most related to our work is the Boundary Attack method introduced by Brendel et al. [14]. Boundary Attack is an iterative algorithm based on rejective sampling, initialized at an image that lies in the target class. At each step, a perturbation is sampled from a proposal distribution, which reduces the distance of the perturbed image towards the original input. If the perturbed image still lies in the target class, the perturbation is kept. Otherwise, the perturbation is dropped. Boundary Attack achieves performance comparable to state-of-the-art white-box attacks on deep neural networks for image classification. The key obstacle to its practical application is, however, the demand for a large number of model queries. In practice, the required number of model queries for crafting an adversarial example directly determines the level of the threat imposed by a decision-based attack. One source of inefficiency in Boundary Attack is the rejection of perturbations which deviate from the target class. In our algorithm, the perturbations are used for estimation of a gradient direction.

Several other decision-based attacks have been proposed to improve efficiency. Brunner et al. [15] introduced Biased Boundary Attack, which biases the sampling procedure by combining low-frequency random noise with the gradient from a substitute model. Biased Boundary Attack is able to significantly reduce the number of model queries. However, it relies on the transferability between the substitute model and the target model, as with other transfer-based attacks. Our algorithm does not rely on the additional assumption of transferability. Instead, it achieves a significant improvement over Boundary Attack through the exploitation of discarded information into the gradient-direction estimation. Cheng et al. [16] introduced Opt-Attack, which transforms the original problem to a continuous version, and solves the new problem via randomized zeroth-order gradient update. However, Opt-Attack queries the model in a sequence and suffers from clock-time inefficiency. Our algorithm approaches the original problem directly via a novel gradient-direction estimate. The majority of model queries in HopSkipJumpAttack come in mini-batches, which also leads to improved clock-time efficiency over Boundary Attack.

2.2 Zeroth-order optimization

Zeroth-order optimization refers to the problem of optimizing a function f based only on access to function values f(x), as opposed to gradient values \( \nabla f(x) \). Such problems have been extensively studied in the convex optimization and bandit literatures. Flaxman et al. [18] studied one-point randomized estimate of gradient for bandit convex optimization. Agarwal et al. [19] and Nesterov and Spokoiny [20] demonstrated that faster convergence can be achieved by using two function evaluations for estimating the gradient. Duchi et al. [21] established optimal rates of convex zeroth-order optimization via mirror descent with two-point gradient estimates. Zeroth-order algorithms have been applied to the generation of adversarial examples under the score-based threat model [8, 9, 10]. Subsequent work [22] proposed and analyzed an algorithm based on variance-reduced stochastic gradient estimates.

We formulate decision-based attack as an optimization problem. A core component of our proposed algorithm is a gradient-
direction estimate, the design of which is motivated by zeroth-order optimization. However, the problem of decision-based attack is more challenging than zeroth-order optimization, essentially because we only have binary information from output labels of the target model, rather than function values.

3 An optimization framework

In this section, we describe an optimization framework for finding adversarial instances for an m-ary classification model of the following type. The first component is a discriminant function $F : \mathbb{R}^d \to \mathbb{R}^m$ that accepts an input $x \in [0, 1]^d$ and produces an output $y \in \Delta_m := \{ y \in [0, 1]^m \mid \sum_{c=1}^m y_c = 1 \}$. The output vector $y = (F_1(x), \ldots, F_m(x))$ can be viewed as a probability distribution over the label set $[m] = \{1, \ldots, m\}$. Based on the function $F$, the classifier $C : \mathbb{R}^d \to [m]$ assigns input $x$ to the class with maximum probability—that is,

$$C(x) := \arg\max_{c \in [m]} F_c(x).$$

We study adversaries of both the untargeted and targeted varieties. Given some input $x^*$, the goal of an untargeted attack is to change the original classifier decision $c^* := C(x^*)$ to any $c \in [m] \setminus \{c^*\}$, whereas the goal of a targeted attack is to change the decision to some pre-specified $c^1 \in [m] \setminus \{c^*\}$. Formally, if we define the function $S_{x^*} : \mathbb{R}^d \to \mathbb{R}$ via

$$S_{x^*}(x') := \begin{cases} \max_{c \neq c^*} F_c(x') - F_{c^*}(x') & \text{(Untargeted)} \\ F_{c^*}(x') - \max_{c \neq c^1} F_c(x') & \text{(Targeted)} \end{cases}$$

then a perturbed image $x'$ is a successful attack if and only if $S_{x^*}(x') > 0$. The boundary between successful and unsuccessful perturbed images is

$$\text{bd}(S_{x^*}) := \{ z \in [0, 1]^d \mid S_{x^*}(z) = 0 \}.$$

As an indicator of successful perturbation, we introduce the Boolean-valued function $\phi_{x^*} : [0, 1]^d \to \{-1, 1\}$ via

$$\phi_{x^*}(x') := \text{sign}(S_{x^*}(x')) = \begin{cases} 1 & \text{if } S_{x^*}(x') > 0, \\ -1 & \text{otherwise}. \end{cases}$$

This function is accessible in the decision-based setting, as it can be computed by querying the classifier $C$ alone. The goal of an adversarial attack is to generate a perturbed sample $x'$ such that $\phi_{x^*}(x') = 1$, while keeping $x'$ close to the original sample $x^*$. This can be formulated as the optimization problem

$$\min_{x'} \, d(x', x^*) \quad \text{such that} \quad \phi_{x^*}(x') = 1,$$

where $d$ is a distance function that quantifies similarity. Standard choices of $d$ studied in past work include the usual $\ell_p$-norms, for $p \in \{0, 2, \infty\}$.

3.1 An iterative algorithm for $\ell_2$ distance

Consider the case of the optimization problem with the $\ell_2$-norm $d(x, x^*) = \|x - x^*\|_2$. We first specify an iterative algorithm that is given access to the gradient $\nabla S_{x^*}$. Given an initial vector $x_0$ such that $S_{x^*}(x_0) > 0$ and a stepsize sequence $\{\xi_t\}_{t \geq 0}$, it performs the update

$$x_{t+1} = \alpha_t x^* + (1 - \alpha_t) \left( x_t + \xi_t \frac{\nabla S_{x^*}(x_t)}{\|\nabla S_{x^*}(x_t)\|_2} \right),$$

where $\xi_t$ is a positive step size. Here the line search parameter $\alpha_t \in [0, 1]$ is chosen such that $S_{x^*}(x_{t+1}) = 0$—that is, so that the next iterate $x_{t+1}$ lies on the boundary. The motivation for this choice is that our gradient-direction estimate in Section is only valid near the boundary.
We now analyze this algorithm with the assumption that we have access to the gradient of \( S_{x^*} \) in the setting of binary classification. Assume that the function \( S_{x^*} \) is twice differentiable with a locally Lipschitz gradient, meaning that there exists \( L > 0 \) such that for all \( x, y \in \{ z : \| z - x^* \|_2 \leq \| x_0 - x^* \|_2 \} \), we have
\[
\| \nabla S_{x^*}(x) - \nabla S_{x^*}(y) \|_2 \leq L \| x - y \|_2,
\]
where \( x_0 \) is the initialization point. In addition, we assume the gradient is bounded away from zero on the boundary: there exists a positive \( c > 0 \) such that \( \| \nabla S_{x^*}(z) \| > c \) for any \( z \in \text{bd}(S_{x^*}) \).

We analyze the behavior of the updates (3) in terms of the angular measure
\[
r(x_t, x^*) := \cos \angle (x_t - x^*, \nabla S_{x^*}(x_t))
= \frac{\langle x_t - x^*, \nabla S_{x^*}(x_t) \rangle}{\| x_t - x^* \|_2 \| \nabla S_{x^*}(x_t) \|_2},
\]

where \( \| \cdot \|_2 \) is the Euclidean norm, \( \langle \cdot, \cdot \rangle \) denotes the inner product, and \( \| \cdot \|_2 \) is the two-norm of a vector. The following theorem guarantees that, with a suitable step size, the updates converge to such a stationary point:

**Theorem 1.** Under the previously stated conditions on \( S_{x^*} \), suppose that we compute the updates (3) with the step size \( \xi_t = \| x_t - x^* \|_2 \ell^{-q} \) for some \( q \in (\frac{1}{4}, \frac{1}{2}) \). Then there is a universal constant \( c > 0 \) such that
\[
0 \leq 1 - r(x_t, x^*) \leq c \frac{1}{\ell^{\frac{1}{2} - q}} \quad \text{for all iterations } t = 1, 2, \ldots
\]

In particular, the algorithm converges to a stationary point of problem (2).

See Appendix A.1 for the proof.

### 3.2 Extension to \( \ell_\infty \)-distance

We now describe how to extend these updates so as to minimize the \( \ell_\infty \)-distance. Consider the \( \ell_2 \)-projection of a point \( x \) onto the sphere of radius \( \alpha_t \) centered at \( x^* \):
\[
\Pi_{\| \cdot \|_2, \alpha_t}^2(x^*) := \text{arg min}_{\| y - x^* \|_2 \leq \alpha_t} \| y - x \|_2 = \alpha_t x^* + (1 - \alpha_t)x.
\]

In terms of this operator, our \( \ell_2 \)-based update (3) can be rewritten in the equivalent form
\[
x_{t+1} = \Pi_{\| \cdot \|_2, \alpha_t}^2 \left( x_t + \xi_t \frac{\nabla S_{x^*}(x_t)}{\| \nabla S_{x^*}(x_t) \|_2} \right).
\]

This perspective allows us to extend the algorithm to other \( \ell_p \)-norms for \( p \neq 2 \). For instance, in the case \( p = \infty \), we can define the \( \ell_\infty \)-projection operator \( \Pi_{\| \cdot \|_\infty, \alpha}^\infty \). It performs a per-pixel clip within a neighborhood of \( x^* \), such that the \( i \)-th entry of \( \Pi_{\| \cdot \|_\infty, \alpha}^\infty(x) \) is
\[
\Pi_{\| \cdot \|_\infty, \alpha}^\infty(x)_i := \max \{ \min \{ x_i^*, x_i - c, x_i^* + c \} \},
\]

where \( c := \alpha \| x - x^* \|_\infty \). We propose the \( \ell_\infty \)-version of our algorithm by carrying out the following update iteratively:
\[
x_{t+1} = \Pi_{\| \cdot \|_\infty, \alpha_t}^\infty \left( x_t + \xi_t \text{sign}(\nabla S_{x^*}(x_t)) \right),
\]

where \( \alpha_t \) is chosen such that \( S_{x^*}(x_{t+1}) = 0 \), and “sign” returns the element-wise sign of a vector. We use the sign of the gradient for faster convergence in practice, similar to previous work [2, 3, 7].
3.3 Connection to existing white-box attacks

In this subsection, we discuss the connection between our proposed updates (7) and (8), and existing white-box attacks.

Connecting the update (7) to penalty methods A common approach to approach the constrained problem (4) is to approximate it with a penalty function formulation [23]:

$$\min_x \frac{1}{2} \|x - x^*\|^2 - \rho S_{x^*}(x),$$

for a carefully chosen penalty parameter \(\rho\). A similar relaxation has been proposed in previous work in adversarial attacks [1, 6].

At the \(t\)-th step, the update of gradient descent is

$$x_{t+1} = x_t - \alpha_t ((x_t - x^*) - \rho_t \nabla S_{x^*}(x_t))$$

$$= \alpha_t x^* + (1 - \alpha_t)\left(x_t + \frac{\rho_t}{1 - \alpha_t} \nabla S_{x^*}(x_t)\right)$$

$$= \Pi_{x^*,\alpha_t}^{2,\rho_t} \left(x_t + \frac{\rho_t}{1 - \alpha_t} \frac{\nabla S_{x^*}(x_t)}{\|\nabla S_{x^*}(x_t)\|_2}\right),$$

where we rewrite the update gradient as a weighted average of the original sample \(x^*\) and the \(t\)-th update \(x_t\) perturbed along the direction of \(\nabla S_{x^*}(x_t)\) with an appropriately chosen size \(\xi_t\). This has exactly the same form as our proposed update, Equation (6). However, the hyperparameters \(\alpha_t\) and \(\rho_t\) in previous work [1, 6] are often chosen via hyperparameter tuning or fixed as constant. Here, we choose choose \(\alpha_t\) so that \(x_{t+1}\) is at the boundary \(S(x_{t+1}) = 0\), which is a requirement to use our proposed gradient estimate to be introduced in Section 4.

Connecting the update (8) to projected gradient descent In the untargeted case, each update of Basic Iterative Method proposed by Kurakin et al. [3] is of the form

$$x_{t+1} = \text{Clip}_{x^*,\alpha_t} \left(x_t + \xi_t \text{sign}(\nabla J(x_t, c_{\text{true}}))\right),$$

where \(J\) is the cross-entropy loss with respect to the true label \(c^* = C(x^*)\). The operator Clip\(_{x^*,\alpha_t}\) performs per-pixel clip within the \(\alpha\)-neighborhood of the corresponding pixel of \(x^*\). As pointed out by Madry et al. [7], the Basic Iterative Method can be interpreted as projected gradient descent in the \(L_\infty\)-norm.

We observe that the clip operator coincides with the \(L_\infty\)-projection operator \(\Pi_{x^*,\alpha_t}^{\infty}\). The cross entropy loss \(J\) is a monotonic function of \(S_{x^*}\), and so introduces only a scaling difference between \(\nabla J\) and \(\nabla S_{x^*}\). As a consequence, apart from the choice of \(\alpha_t\), each update (8) of our algorithm has the same form as the Basic Iterative Method. On the other hand, we need to choose \(\alpha_t\) carefully so that \(x_{t+1}\) lies at the boundary for gradient-direction estimation.

4 A decision-based algorithm based on a novel gradient estimate

We now extend our procedures to the decision-based setting, in which we have access only to the Boolean-valued function \(\phi_{x^*}(x) = \text{sign}(S_{x^*}(x))\)—that is, the method cannot observe the underlying discriminant function \(F\) or its gradient. In this section, we introduce a gradient-direction estimate based on \(\phi_{x^*}\) when \(x_t \in \text{bd}(S_{x^*})\) (so that \(S_{x^*}(x_t) = 0\) by definition). We proceed to discuss how to approach the boundary. Then we discuss how to control the error of our estimate with a deviation from the boundary. We will summarize the analysis with a decision-based algorithm.
4.1 At the boundary

Given an iterate $x_t \in \partial (S_{x^*})$ we propose to approximate the direction of the gradient $\nabla S_{x^*}(x_t)$ via the Monte Carlo estimate

$$\tilde{\nabla} S(x_t, \delta) := \frac{1}{B} \sum_{b=1}^{B} \phi_{x^*}(x_t + \delta u_b) u_b,$$

where $\{u_b\}_{b=1}^{B}$ are i.i.d. draws from the uniform distribution over the $d$-dimensional sphere, and $\delta$ is small positive parameter. (The dependence of this estimator on the fixed centering point $x^*$ is omitted for notational simplicity.)

The perturbation parameter $\delta$ is necessary, but introduces a form of bias in the estimate. Our first result controls this bias, and shows that $\tilde{\nabla} S(x_t, \delta)$ is asymptotically unbiased as $\delta \rightarrow 0^+$.

**Theorem 2.** For a boundary point $x_t$, suppose that $S_{x^*}$ has $L$-Lipschitz gradients in a neighborhood of $x_t$. Then the cosine of the angle between $\tilde{\nabla} S(x_t, \delta)$ and $\nabla S_{x^*}(x_t)$ is bounded as

$$\cos \angle \left( \mathbb{E}[\tilde{\nabla} S(x_t, \delta)], \nabla S_{x^*}(x_t) \right) \geq 1 - \frac{9L^2\delta^2d^2}{8\|\nabla S(x_t)\|_2^2}.$$  

(12)

In particular, we have

$$\lim_{\delta \rightarrow 0} \cos \angle \left( \mathbb{E}[\tilde{\nabla} S(x_t, \delta)], \nabla S_{x^*}(x_t) \right) = 1,$$

showing that the estimate is asymptotically unbiased as an estimate of direction.

See Appendix [A.2] for the proof of this theorem. As will be seen in the sequel, the size of perturbation $\delta$ should be chosen proportionally to $d^{-1}$; see Section 4.3 for details.

4.2 Approaching the boundary

The proposed estimate (11) is only valid at the boundary. Now we describe how we approach the boundary via a binary search. Let $\tilde{x}_t$ denote the updated sample before the operator $\Pi_{x^*,\delta_t}$ is applied:

$$\tilde{x}_t := x_t + \xi_tv_t(x_t, \delta_t), \quad \text{such that}$$

$$v_t(x_t, \delta_t) = \begin{cases} \frac{\tilde{\nabla} S(x_t, \delta_t)}{\|\tilde{\nabla} S(x_t, \delta_t)\|_2}, & \text{if } p = 2, \\ \text{sign}(\tilde{\nabla} S(x_t, \delta_t)), & \text{if } p = \infty, \end{cases}$$

(14)

where $\tilde{\nabla} S$ will be introduced later in equation (18), as a variance-reduced version of $\nabla S$, and $\delta_t$ is the size of perturbation at the $t$-th step.

We hope $\tilde{x}_t$ is at the opposite side of the boundary to $x$ so that the binary search can be carried out. Therefore, we initialize at $\tilde{x}_0$ at the target side with $\phi_{x^*}(\tilde{x}_0) = 1$, and set $x_0 := \Pi_{x^*,\alpha_0}^p(\tilde{x}_0)$, where $\alpha_0$ is chosen via a binary search between 0 and 1 to approach the boundary, stopped at $x_0$ lying at the target side with $\phi_{x^*}(x_0) = 1$. At the $t$-th iteration, we start at $x_t$ lying at the target side $\phi_{x^*}(x_t) = 1$. The step size is initialized as

$$\xi_t := \|x_t - x^*\|_p/\sqrt{t},$$

(15)

as suggested by Theorem [in the $\ell_2$ case, and is decreased by half until $\phi_{x^*}(\tilde{x}_t) = 1$, which we call geometric progression of $\xi_t$. Having found an appropriate $\tilde{x}_t$, we choose the projection radius $\alpha_t$ via a binary search between 0 and 1 to approach the boundary, which stops at $x_{t+1}$ with $\phi_{x^*}(x_{t+1}) = 1$. See Algorithm [for the complete binary search, where the binary search threshold $\theta$ is set to be some small constant.
Algorithm 1 Bin-Search

Require: Samples $x', x$, with a binary function $\phi$, such that $\phi(x') = 1, \phi(x) = 0$, threshold $\theta$, constraint $\ell_p$.
Ensure: A sample $x''$ near the boundary.

Set $\alpha_l = 0$ and $\alpha_u = 1$.

while $|\alpha_l - \alpha_u| > \theta$ do

Set $\alpha_m \leftarrow \frac{\alpha_l + \alpha_u}{2}$.

if $\phi(\Pi_{x,\alpha_m}(x')) = 1$ then

Set $\alpha_u \leftarrow \alpha_m$.

else

Set $\alpha_l \leftarrow \alpha_m$.

end if

end while

Output $x'' = \Pi_{x,\alpha_u}(x')$.

4.3 Controlling errors of deviations from the boundary

Binary search never places $x_{t+1}$ exactly onto the boundary. We analyze the error of the gradient-direction estimate, and propose two approaches for reducing the error.

**Appropriate choice of the size of random perturbation** First, the size of random perturbation $\delta_t$ for estimating the gradient direction is chosen as a function of image size $d$ and the binary search threshold $\theta$. This is different from numerical differentiation, where the optimal choice of $\delta_t$ is at the scale of round-off errors (e.g., [24]). Below we characterize the error incurred by a large $\delta_t$ as a function of distance between $\tilde{x}_t$ and the boundary, and derive the appropriate choice of $\xi_t$ and $\delta_t$.

In fact, with a Taylor approximation of $S_{x^*}$ at $x_t$, we have

$$S_{x^*}(x_t + \delta_t u) = S_{x^*}(x_t) + \delta_t \langle \nabla S_{x^*}(x_t), u \rangle + O(\delta_t^2).$$

At the boundary $S_{x^*}(x_t) = 0$, the error of gradient approximation scales at $O(\delta_t^2)$, which is minimized by reducing $\delta_t$ to the scale of root round-off error. However, the outcome $x_t$ of a finite-step binary search lies close to, but not exactly on the boundary.

When $\delta_t$ is small enough that second-order terms can be omitted, the first-order Taylor approximation implies that $\phi_{x^*}(x_t + \delta_t u) = -1$ if and only if $x_t + \delta_t u$ lies on the spherical cap $C$, with

$$C := \left\{ u \mid \frac{\nabla S_{x^*}(x_t)}{\|\nabla S_{x^*}(x_t)\|_2}, u \right\} \leq -\delta_t^{-1} \frac{S_{x^*}(x_t)}{\|S_{x^*}(x_t)\|_2}. $$

On the other hand, the probability mass of $u$ concentrates on the equator in a high-dimensional sphere, which is characterized by the following inequality [25]:

$$P(u \in C) \leq \frac{2}{c} \exp\left\{ -\frac{c^2}{2} \right\}, \text{ where } c = \frac{\sqrt{d - 2} S_{x^*}(x_t)}{\delta_t \|\nabla S_{x^*}(x_t)\|_2}. \tag{16}$$

A Taylor expansion of $x_t$ at $x'_t := \Pi_{x^*}(x_t)$ yields

$$S_{x^*}(x_t) = \nabla S_{x^*}(x'_t)^T (x_t - x'_t) + O(\|x_t - x'_t\|_2^2) = \nabla S_{x^*}(x_t)^T (x_t - x'_t) + O(\|x_t - x'_t\|_2^2). $$

By the Cauchy-Schwarz inequality and the definition of $\ell_2$-projection, we have

$$|\nabla S_{x^*}(x_t)^T (x_t - x_t')| \leq \|\nabla S_{x^*}(x_t)\|_2 \|x_t - \Pi_S(x_t)\|_2$$

$$\leq \left\|\frac{\|\nabla S_{x^*}(x_t)\|_2 \theta \|\tilde{x}_{t-1} - x^*\|_p}{\|\nabla S_{x^*}(x_t)\|_2 \theta \|\tilde{x}_{t-1} - x^*\|_p \sqrt{d}}\right\|$$

This yields

$$c = O\left(\frac{\theta \|\tilde{x}_{t-1} - x^*\|_p^2}{\delta_t}\right),$$

where $q = 1 - (1/p)$ is the dual exponent. In order to avoid a loss of accuracy from concentration of measure, we let $\delta_t = d^\theta \|\tilde{x}_{t-1} - x^*\|_2$. To make the approximation error independent of dimension $d$, we set $\theta$ at the scale of $d^{-q-1}$, so that $\delta_t$ is proportional to $d^{-1}$, as suggested by Theorem 2. This leads to a logarithmic dependence on dimension for the number of model queries. In practice, we set

$$\theta = 0.001d^{-q-1}; \delta_t = 0.001d^{-1}\|\tilde{x}_{t-1} - x^*\|_p.$$  

(17)

**A baseline for variance reduction in gradient-direction estimation** Another source of error comes from the variance of the estimate, where we characterize variance of a random vector $v \in \mathbb{R}^d$ by the trace of its covariance operator: $\text{Var}(v) := \sum_{i=1}^d \text{Var}(v_i)$. When $x_t$ deviates from the boundary and $\delta_t$ is not exactly zero, there is an uneven distribution of perturbed samples at the two sides of the boundary:

$$|\mathbb{E}[\phi_{x^*}(x_t + \delta_t u)]| > 0,$$

as we can see from Equation (16). As an attempt to control variance, we introduce a baseline $\overline{\phi_{x^*}}$ into the estimate, with

$$\overline{\phi_{x^*}} := \frac{1}{B} \sum_{b=1}^B \phi_{x^*}(x_t + \delta_t u_b).$$

which yields the following estimate:

$$\overline{\nabla S}(x_t, \delta) := \frac{1}{B - 1} \sum_{b=1}^B (\phi_{x^*}(x_t + \delta_t u_b) - \overline{\phi_{x^*}}) u_b.$$  

(18)

It can be easily observed that the above estimate is equal to the previous estimate in expectation, and thus still asymptotically unbiased at the boundary: When $x_t \in \text{bd}(S_{x^*})$, we have

$$\text{cos} \angle \left(\mathbb{E}[\nabla S(x_t, \delta)], \nabla S_{x^*}(x_t)\right) \geq 1 - \frac{9L^2 \delta_t^2 d^2}{8\|\nabla S(x_t)\|_2^2} \text{ and } \lim_{\delta_t \rightarrow 0} \text{cos} \angle \left(\mathbb{E}[\nabla S(x_t, \delta)], \nabla S_{x^*}(x_t)\right) = 1.$$

Moreover, the introduction of baseline reduces the variance when $\mathbb{E}[\phi_{x^*}(x_t + \delta u)]$ deviates from 0. In particular, the following theorem shows that whenever $|\mathbb{E}[\phi_{x^*}(x_t + \delta u)]| = \Omega(\sqrt{d})$, then introducing a baseline reduces the variance.

**Theorem 3.** Defining $\sigma^2 := \text{Var}(\phi_{x^*}(x_t + \delta u)u)$ as the variance of one-point estimate, we have

$$\text{Var}(\overline{\nabla S}(x_t, \delta)) \leq \text{Var}(\nabla S(x_t, \delta))(1 - \psi),$$

where

$$\psi = \frac{2}{\sigma^2(B - 1)} (2B\mathbb{E}[\phi_{x^*}(x_t + \delta u)]^2 - 1) - \frac{2B - 1}{(B - 1)^2}.$$

See Appendix A.3 for the proof. We also present an experimental evaluation of our gradient-direction estimate when the sample deviates from the boundary in Section 5.3, where we show our proposed choice of $\delta_t$ and the introduction of baseline yield a performance gain in estimating gradient.
4.4 HopSkipJumpAttack

We now combine the above analysis into an iterative algorithm, HopSkipJumpAttack. It is initialized with a sample in the target class for untargeted attack, and with a sample blended with uniform noise that is misclassified for targeted attack. Each iteration of the algorithm has three components. First, the iterate from the last iteration is pushed towards the boundary via a binary search (Algorithm 1). Second, the gradient direction is estimated via Equation (18). Third, the updating step size along the gradient direction is initialized as Equation (15) based on Theorem 1, and is decreased via geometric progression until perturbation becomes successful. The next iteration starts with projecting the perturbed sample back to the boundary again. The complete procedure is summarized in Algorithm 2. Figure 2 provides an intuitive visualization of the three steps in $\ell_2$.

For all experiments, we initialize the batch size at 100 and increase it with $\sqrt{t}$ linearly, so that the variance of the estimate reduces with $t$. When the input domain is bounded in practice, a clip is performed at each step by default.

Algorithm 2 HopSkipJumpAttack

Require: Classifier $C$, a sample $x$, constraint $\ell_p$, initial batch size $B_0$, iterations $T$.
Ensure: Perturbed image $x_t$.

Set $\theta$ (Equation (17)).
Initialize at $\tilde{x}_0$ with $\phi_{x^*}(\tilde{x}_0) = 1$.
Compute $d_0 = \|\tilde{x}_0 - x^*\|_p$.
for $t$ in $1, 2, \ldots, T - 1$ do

(Boundary search)
\begin{align*}
x_t &= \text{BIN-SEARCH}(\tilde{x}_{t-1}, x, \theta, \phi_{x^*}, p)\end{align*}

(Gradient-direction estimation)
Sample $B_t = B_0 \sqrt{t}$ unit vectors $u_1, \ldots, u_{B_t}$.
Set $\delta_t$ (Equation (17)).
Compute $v_t(x_t, \delta_t)$ (Equation (14)).

(Step size search)
Initialize step size $\xi_t = \|x_t - x^*\|_p / \sqrt{t}$.
while $\phi_{x^*}(x_t + \varepsilon_t v_t) = 0$ do
\begin{align*}
\xi_t &\leftarrow \xi_t / 2.
\end{align*}
end while
Set $\tilde{x}_t = x_t + \xi_t v_t$.
Compute $d_t = \|\tilde{x}_t - x^*\|_p$.
end for

Output $x_t = \text{BIN-SEARCH}(\tilde{x}_{t-1}, x, \theta, \phi_{x^*}, p)$. 
Table 1. Median distance at various model queries. The smaller median distance at a given model queries is bold-faced. BA and HSJA stand for Boundary Attack and HopSkipJumpAttack respectively.

5 Experiments

In this section, we carry out experimental analysis of HopSkipJumpAttack. We compare the efficiency of HopSkipJumpAttack with Boundary Attack, a powerful decision-based attack proposed by Brendel et al. [14]. In addition, we demonstrate the performance of our attack method on adversarially trained models. We also validate the proposed methods for reducing errors of gradient direction estimate when there is deviation from the boundary. All experiments were carried out on a Tesla K80 GPU, with code for the experiments available on GitHub. Our algorithm is also available on CleverHans and Foolbox, which are two popular Python packages to craft adversarial examples for machine learning models.

5.1 Efficiency evaluation

Data and models We compare HopSkipJumpAttack with Boundary Attack on image classification tasks. For a comprehensive evaluation of HopSkipJumpAttack, we use a wide range of data and models, with varied image dimensions, data set sizes, complexity levels of task and model structures.

The experiments are carried out over four image data sets: MNIST, CIFAR-10, CIFAR-100, and ImageNet with the standard train/test split. The four data sets have varied image dimensions and class numbers. MNIST contains 70K 28 × 28 gray-scale images of handwritten digits in the range 0-9. CIFAR-10 and CIFAR-100 are both composed of 32 × 32 × 3 images. CIFAR-10 has 10 classes, with 6K images per class, while CIFAR-100 has 100 classes, with 600 images per class.

3https://github.com/Jianbo-Lab/HSJA
We also use models of varied structure, from simple to complex. For MNIST, we use a simple convolutional network composed of two convolutional layers followed by a hidden dense layer with 1024 units. Two convolutional layers have 32, 64 filters respectively, each of which is followed by a max-pooling layer. For both CIFAR-10 and CIFAR-100, 1,000 correctly classified test images are used, which are randomly drawn from the test data set, and evenly distributed across classes. For ImageNet, we use 100 correctly classified test images, evenly distributed among 10 randomly selected classes. The selection scheme follows Metzen et al. [31] for reproducibility.

We also use models of varied structure, from simple to complex. For MNIST, we use a simple convolutional network composed of two convolutional layers followed by a hidden dense layer with 1024 units. Two convolutional layers have 32, 64 filters respectively, each of which is followed by a max-pooling layer. For both CIFAR-10 and CIFAR-100, we train a 20-layer ResNet [32] and 121-layer DenseNet [33] respectively, with the canonical network structure [30]. For ImageNet, we use a pre-trained 50-layer ResNet [32]. All models achieve close to state-of-the-art accuracy on the respective data set. All pixels are scaled to be in the range $[0,1]$. For all experiments, we clip the perturbed image into the input domain $[0,1]$ for both algorithms by default.

**Initialization** For untargeted attack, we initialize both HopSkipJumpAttack and Boundary Attack by blending an original image with uniform random noise, and increasing the weight of uniform noise gradually until it is misclassified, a procedure which is available on a widely-used python package, Foolbox [27], as the default initialization of Boundary Attack. For targeted attack, the target class is sampled uniformly among the incorrect labels. The same target class and a common initialization image are used for the two attacks.

**Metrics** The first metric is the median $\ell_p$ distance between perturbed and original samples over a subset of test images, which was commonly used in previous work, such as Carlini and Wagner [6]. A version normalized by image dimension was
employed by Brendel et al. [14] for evaluating Boundary Attack. The \( \ell_2 \) distance can be interpreted in the following way: Given a byte image of size \( h \times w \times 3 \), perturbation of size \( d \) in \( \ell_2 \) distance on the rescaled input image amounts to perturbation on the original image of \( \lceil d/\sqrt{h \times w \times 3} \rceil \) bits per pixel on average, in the range \([0, 255]\). The perturbation of size \( d \) in \( \ell_\infty \) distance amounts to a maximum perturbation of \([255 \cdot d]\) bits across all pixels on the raw image.

As an alternative metric, we also plot the success rate at various distance thresholds for both algorithms given a limited budget of model queries. An adversarial examples is defined a success if the size of perturbation does not exceed a given distance threshold. The success rate can be directly related to the accuracy of a model on perturbed data under a given distance threshold:

\[
\text{perturbed acc.} = \text{original acc.} \times (1 - \text{success rate}).
\]

Throughout the experiments, we limit the maximum budget of queries per image to 25,000, the setting of practical interest, due to limited computational resources.

**Results** Table 1 summarizes the median distance when the number of queries is fixed at 500, 1,000, 2,000, 5,000, and 10,000 for Boundary Attack and HopSkipJumpAttack across all distance types, data, models and objectives.

Figure 5 and 6 show the median distance (on a log scale) against the queries, with the first and third quartiles used as lower and upper error bars. Figure 5 and 6 show the success rate against the distance threshold. Figure 5 and 5 contain results on MNIST with CNN, and CIFAR-10 with ResNet, Denset, subsequently from the top row to the bottom row. Figure 4 and 6 contain results on CIFAR-100 with ResNet and DenseNet, and ImageNet with ResNet, subsequently from the top row to the bottom row. The four columns are for untargeted \( \ell_2 \), targeted \( \ell_2 \), untargeted \( \ell_\infty \) and targeted \( \ell_\infty \) attacks respectively.
HopSkipJumpAttack: A Query-Efficient Decision-Based Attack

Figure 5. Success rate versus distance threshold for MNIST with CNN, and CIFAR-10 with ResNet, DenseNet from top to bottom rows. 1st column: untargeted $\ell_2$, 2nd column: targeted $\ell_2$, 3rd column: untargeted $\ell_\infty$, 4th column: targeted $\ell_\infty$.

With a limited number of queries, HopSkipJumpAttack is able to craft adversarial examples of a significantly smaller distance with the corresponding original examples across all data sets. As a concrete example, Table I shows that untargeted $\ell_2$-optimized HopSkipJumpAttack achieves a median distance of 0.559 on CIFAR-10 with a ResNet model at 1,000 queries, which amounts to below 3/255 per pixel on average. At the same budget of queries, Boundary Attack only achieves a median $\ell_2$-distance of 2.78. The difference in efficiency becomes more significant for $\ell_\infty$ attacks, because Boundary Attack was designed to optimize $\ell_2$-distance alone. As shown in Figure 5 under an untargeted $\ell_\infty$-optimized HopSkipJumpAttack with 1,000 queries, all pixels are within an 8/255-neighborhood of the original image for around 70% of adversarial examples, a success rate achieved by Boundary Attack only after 20,000 queries.

By comparing the odd and even columns of Figure 5, we can find that targeted HopSkipJumpAttack takes more queries than the untargeted one to achieve a comparable distance. This phenomenon becomes more explicit on CIFAR-100 and ImageNet, which have more classes. With the same number of queries, there is an order-of-magnitude difference in median distance between untargeted and targeted attacks (Figure 3 and 4). For $\ell_2$-optimized HopSkipJumpAttack, while the untargeted version is able to craft adversarial images by perturbing 4 bits per pixel on average with 500 queries for 50%-80% of images in CIFAR-10 and CIFAR-100, the targeted counterpart takes 2,000-5,000 queries. Boundary Attack fails to achieve a comparable performance even with 20,000 queries. On ImageNet, untargeted $\ell_2$-optimized HopSkipJumpAttack is able to fool the model with a perturbation of size 6 bits per pixel on average for around 70% of images with 2,000 queries; untargeted $\ell_\infty$-optimized HopSkipJumpAttack controls the maximum perturbation across all pixels within 8 bits for 50% images with 2,000 queries. The targeted BoundaryAttack is not able to control the perturbation size to such a small scale until after around 20,000 queries. On the one hand, the larger query budget requirement results from a strictly more powerful formulation of targeted attack than untargeted attack. On the other hand, this is also because we initialize targeted HopSkipJumpAttack from an arbitrary image in the target class. The algorithm may be trapped in a bad local minimum with such an initialization. Future work can address systematic approaches to better initialization.
As a comparison between data sets and models, we can see adversarial images often have a larger distance to their corresponding original images on MNIST than on CIFAR-10 and CIFAR-100, which has also been observed in previous work (e.g., [6]). This might be because it is more difficult to fool a model on simpler tasks. On the other hand, HopSkipJumpAttack also converges in a fewer number of queries on MNIST, as is shown in Figure 3. It does not converge even after 25,000 queries on ImageNet. We conjecture the query budget is related to the input dimension, and the smoothness of decision boundary. We also observe the difference in model structure does not have a large influence on decision-based algorithms, if the training algorithm and the data set keep the same. For ResNet and DenseNet trained on a common data set, a decision-based algorithm achieves comparable performance, although DenseNet has a more complex structure than ResNet.

As a comparison with state-of-the-art white-box targeted attacks, C&W attack [6] achieves an average $\ell_2$-distance of 0.33 on CIFAR-10, and BIM [3] achieves an average $\ell_{\infty}$-distance of 0.014 on CIFAR-10. Targeted HopSkipJumpAttack achieves a comparable distance with 5K-10K model queries on CIFAR-10, without access to model details. On ImageNet, targeted C&W attack and BIM achieve an $\ell_2$-distance of 0.96 and an $\ell_{\infty}$-distance of 0.01 respectively. Untargeted HopSkipJumpAttack achieves a comparable performance with 10,000 – 15,000 queries. The targeted version is not able to perform comparably as targeted white-box attacks when the budget of queries is limited within 25,000.

Visualized trajectories of HopSkipJumpAttack optimized for $\ell_2$ and $\ell_{\infty}$ distances along varied queries on CIFAR10 and ImageNet can be found in Figure 7. On CIFAR-10, we observe untargeted adversarial examples can be crafted within around 500 queries; targeted HopSkipJumpAttack is capable of crafting human indistinguishable targeted adversarial examples within around 1,000-2,000 queries. On ImageNet, untargeted HopSkipJumpAttack is able to craft good adversarial examples with 1,000 queries, while targeted HopSkipJumpAttack takes 10,000-20,000 queries.
5.2 Robustness of adversarially trained models under decision-based attack

Adversarial training [2, 3, 7, 17] has been widely known as one of the most effective defense mechanisms against adversarial perturbation [34, 55]. We investigate the performance of a publicly available adversarially trained model under the threat of decision-based attacks, which is trained through a robust optimization method proposed by Madry et al. [7]. The model achieves close to 90% accuracy on MNIST under adversarial perturbation, although the same approach becomes less effective on more complex data sets such as CIFAR-10 and ImageNet.
Figure 8 shows the success rate at different distance thresholds. When the $\ell_\infty$-distance is thresholded at 0.3, a perturbation size proposed by Madry et al. [7] to measure adversarial robustness, HopSkipJumpAttack achieves a success rate of 9.8%. As a comparison, BIM has a success rate of 7.4% at the given distance threshold. The success rate of $\ell_\infty$-HopSkipJumpAttack transfers to an accuracy of 88.76% on adversarially perturbed data, close to the state-of-the-art performance achieved by white-box attacks. The $\ell_2$-optimized HopSkipJumpAttack also achieves superior performance to C&W attack on this task. This suggests that an adversarially trained model can be vulnerable to a decision-based attack as well.

5.3 Sensitivity analysis for gradient direction estimation

We carry out experiments for validating proposed tricks for estimating gradient direction when the sample deviates from the boundary. In particular, we focus on the choice of $\delta_t$ and the introduction of baseline analyzed in Section 4.

We use a 20-layer ResNet [32] trained over CIFAR-10 [28]. Over a subset of randomly sampled images, we run the $\ell_2$-optimized HopSkipJumpAttack for 60 iterations. Gradient-direction estimation is carried out at perturbed images at the $i$th iteration, for $i = 10, 20, 30, 40, 50, 60$. We use the inner product between the gradient-direction estimate and the truth gradient of the model as a metric.

Figure 9 shows the box plots of two gradient-direction estimates as $\delta_t$ varies among $0.01\delta^*_t, 0.1\delta^*_t, \delta^*_t, 10\delta^*_t, 100\delta^*_t$, where $\delta^*_t = 10\sqrt{d_\theta}\|\tilde{x}_{t-1} - x^*\|_2$ is our proposed choice. We observe that our proposed choice of $\delta_t$ yields the highest inner product on average. Also, the baseline in $\nabla S$ further improves the performance, in particular when $\delta_t$ is not chosen optimally so that there is severe unevenness in the distribution of perturbed images.

*See https://github.com/MadryLab/mnist_challenge for details of such white-box attacks.*
6 Discussion

We have proposed a family of query-efficient algorithms based on a novel gradient-direction estimate, HopSkipJumpAttack, for decision-based generation of adversarial examples, which is capable of optimizing $\ell_2$ and $\ell_\infty$-distances for both targeted and untargeted attacks. Convergence analysis has been carried out given access to the gradient. We have also provided analysis for the error of our Monte Carlo estimate of gradient direction, which comes from three sources: bias at the boundary for a nonzero perturbation size, bias of deviation from the boundary, and variance. Theoretical analysis has provided insights for selecting the step size and the perturbation size, which leads to a hyperparameter-free algorithm. We have also carried out extensive experiments, showing HopSkipJumpAttack compares favorably to Boundary Attack in query efficiency. It also achieves competitive performance in attacking adversarially trained models on MNIST.

Future work may include a more comprehensive theoretical analysis for the proposed algorithm, and an investigation on the impact of HopSkipJump Attack on other types of tasks and models. On the theoretical side, it should be meaningful to incorporate the error of the Monte Carlo gradient estimate into the convergence analysis, and characterize the performance of HopSkipJumpAttack given a limited budget of model queries. Such an analysis may provide further insights for allocating model queries between the gradient estimation step and the binary search step.

On the empirical side, it is of practical interest to extend the application of HopSkipJumpAttack to other tasks or other widely-used machine learning models. Given the fact that HopSkipJumpAttack is able to craft a human-indistinguishable adversarial example within a realistic budget of queries, it also becomes important for the community to consider the real-world impact of decision-based threat models.
References

A Proofs

For notational simplicity, we use the shorthand $S \equiv S_{x^*}$ throughout the proofs.

A.1 Proof of Theorem 1

For notational simplicity, let us denote $\tau_t := \xi_t/\|\nabla S(x_t)\|_2$, so that the update (3) at iterate $t$ can be rewritten as

$$x_{t+1} = x^* + (1 - \alpha_t)(x_t + \tau_t \nabla S(x_t)). \quad (20)$$

Recalling our step size choice $\xi_t = \eta_t \|x_t - x^*\|$ with $\eta_t := t^{-q}$, we have $\tau_t = \eta_t \|x_t - x^*\|$.

The squared distance ratio is

$$\frac{\|x_{t+1} - x^*\|^2}{\|x_t - x^*\|^2} = \frac{\|(1 - \alpha_t)(\tau_t \nabla S(x_t) + x_t - x^*)\|^2}{\|x_t - x^*\|^2}. \quad (21)$$

By a second-order Taylor series, we have

$$0 = \langle \nabla S(x_t), x_{t+1} - x_t \rangle + \frac{1}{2}(x_{t+1} - x_t)^T H_t(x_{t+1} - x_t), \quad (22)$$

where $H_t = \nabla^2 S(\beta x_{t+1} + (1 - \beta)x_t)$ for some $\beta \in [0, 1]$. Plugging equation (20) into equation (22) yields

$$\langle \nabla S(x_t), -\alpha_t v_t + \tau_t \nabla S(x_t) \rangle + \frac{1}{2}(-\alpha_t v_t + \tau_t \nabla S(x_t))^T H_t(-\alpha_t v_t + \tau_t \nabla S(x_t)) = 0. \quad (23)$$

where we define $v_t := x_t - x^* + \tau_t \nabla S(x_t)$. This can be rewritten as a quadratic equation with respect to $\alpha$:

$$v_t^T H_t v_t \alpha^2 - 2\nabla S(x_t)^T (I + \tau_t H_t) v_t \alpha + \nabla S(x_t)^T (\tau_t^2 H_t + 2\tau_t I) \nabla S(x_t) = 0. \quad (24)$$

Solving for $\alpha$ yields

$$\alpha = \frac{\nabla S(x_t)^T (\tau_t^2 H_t + 2\tau_t I) \nabla S(x_t)}{2\nabla S(x_t)^T (I + \tau_t H_t) v_t} \cdot \frac{2}{1 + \sqrt{1 - v_t^T H_t v_t \nabla S(x_t)^T (\tau_t^2 H_t + 2\tau_t I) \nabla S(x_t) / (\nabla S(x_t)^T (I + \tau_t H_t) v_t)^2}}. \quad (25)$$

In order to simplify the notation, define $\nabla_t := \nabla S(x_t)$ and $d_t := x_t - x^*$, which leads to

$$\alpha \geq \frac{\nabla_t^T (\frac{1}{2} \tau_t^2 H + \tau_t I) \nabla_t}{\nabla_t^T (I + \tau_t H_t)(d_t + \tau_t \nabla_t)}. \quad (26)$$
Hence, we have

\[(1 - \alpha)^2 \leq \left(1 - \frac{\nabla^T f\left(\frac{r_t}{2}\nabla H_t + \tau_t \nabla \right)}{\nabla^T (I + \tau_t H_t)(d_t + \tau_t \nabla)}\right)^2
\]

\[= \left(\frac{\frac{r_t}{2}\nabla^T I + \tau_t \nabla H_t + \nabla^T d_t + \tau_t \nabla^T H_t d_t}{\tau_t \nabla^T \nabla + \tau_t \nabla^T H_t + \nabla^T d_t + \tau_t \nabla^T H_t d_t}\right)^2
\]

\[\leq \left(\frac{\frac{r_t}{2}L\|\nabla\|^2 + \nabla^T d_t + \tau_t L\|d_t\|\|\nabla\|}{\tau_t \nabla^T \nabla + \tau_t \nabla^T H_t + \nabla^T d_t + \tau_t \nabla^T H_t d_t}\right)^2
\]

\[\leq \left(\frac{r_t + (\frac{1}{\alpha} - 1)\eta_t}{\eta_t + \eta_t \cdot (1 + \frac{\alpha}{\tau_t} L |d_t| \|d_t\|_2)}\right)^2.
\]

where

\[r_t = \frac{(x_t - x^*, \nabla S(x_t))}{\|x_t - x^*\|_2\|\nabla S(x_t)\|_2} = \frac{(d_t, \nabla)}{\|d_t\|_2\|\nabla\|_2}.
\]

Let \(\kappa_t := \frac{3}{2} L \|d_t\|_2 \|\nabla\|_2^{-1}.\) Then we have \(\kappa_t\) is bounded:

\[\kappa_t \leq \frac{3}{2} L \|x_0 - x^*\|_2.
\]

Equation (21) and the bound on \((1 - \alpha)^2\) yield

\[\frac{\|x_{t+1} - x^*\|^2}{\|x_t - x^*\|^2} = (1 - \alpha)^2 \cdot \left(\frac{\tau_t^2\|\nabla S(x_t)\|^2 + 2\tau_t\langle \nabla S(x_t), x_t - x^* \rangle + 1}{\|x_t - x^*\|^2} + 1\right)
\]

\[= (1 - \alpha)^2 \cdot (\eta_t^2 + 2\eta_t r_t + 1)
\]

\[\leq \left(\frac{r_t + \eta_t \kappa_t}{r_t + \eta_t (1 + \kappa_t)}\right)^2 \cdot (\eta_t^2 + 2\eta_t r_t + 1).
\]

We will show the convergence of \(r_t\) to 1 in two steps. In the first step, we show \(\lambda_t := \frac{3}{2} \eta_t \rightarrow 0\) by contradiction. In the second step, we establish the convergence rate of \(r_t\) to 1 based on the result of the first step.

Assume there exists a subsequence \(\lambda_t\) of \(\lambda_t\) that is bounded away from 0, such that \(\lambda_{t_k} > c_1\) for some constant \(c_1\). (Note that we always have \(r_t > 0\) as \(x_t\) is on the target side of the boundary for any \(t\).)

Define \(\theta_t := \left(\frac{r_t + \eta_t \kappa_t}{r_t + \eta_t (1 + \kappa_t)}\right)^2 \cdot (\eta_t^2 + 2\eta_t r_t + 1).\) Then we have

\[\theta_t \leq \left(\frac{1 + c_1 \kappa_t}{1 + c_1 (1 + \kappa_t)}\right)^2 \cdot (\eta_t^2 + 2\eta_t, + 1).
\]

As \(\eta_t \rightarrow 0\), there exists a constant \(c_2 > 0\) such that \(\theta_t < 1 - c_2\) for \(i\) large enough.

Because \(\theta_t\) is an increasing function of \(r_t\), we have

\[\theta_t \leq \left(\frac{1 + \eta_t \kappa_t}{1 + \eta_t (1 + \kappa_t)}\right)^2 \cdot (\eta_t^2 + 2\eta_t + 1)
\]

\[= 1 + 2\eta_t + 2\kappa_t \eta_t + \mathcal{O}(\eta_t^2)
\]

\[= 1 + 2\kappa_t \eta_t + \mathcal{O}(\eta_t^2)
\]

\[= 1 + \mathcal{O}(\tau^{-2\eta}).
\]
The product of $1 + t^{-2q}$ over $t$ from 1 to $\infty$ is finite when $q > \frac{1}{4}$:

$$\Pi_{i=1}^{\infty}(1 + t^{-2q}) = \exp\left\{\sum_{t=1}^{\infty} \log(1 + t^{-2q})\right\}$$

$$\leq \exp\left\{\sum_{t=1}^{\infty} t^{-2q}\right\} < \infty.$$  \hspace{1cm} (36)

Therefore, we have

$$\Pi_{i=1}^{\infty} \theta_t \leq \Pi_{i=1}^{\infty} \theta_{t_i} \cdot \Pi_{i=1}^{\infty} (1 + O(t^{-2q})) = 0,$$  \hspace{1cm} (38)

which implies $x_t$ converges to $x^*$, a contradiction. Therefore, $\lambda_t \to 0$ as $t \to \infty$.

Now we can establish the convergence of $r_t$ to 1. We expand $\theta_t$ as

$$\theta_t = \frac{(1 + 2\lambda_t \kappa_t + \lambda_t^2 \kappa_t^2) (\eta_t^2 + 2\eta_t r_t + 1)}{1 + 2\lambda_t (1 + \kappa_t) + \lambda_t^2 (1 + \kappa_t)^2}$$

$$= \frac{1 + 2\lambda_t \kappa_t + \lambda_t^2 \kappa_t^2 + 2\lambda_t r_t^2}{1 + 2\lambda_t \kappa_t + \lambda_t^2 (1 + \kappa_t)^2 + 2\lambda_t} + \eta_t^2 (4\kappa_t + (1 + \lambda_t \kappa_t)^2 + 2\kappa_t^2)$$

$$\leq \frac{1 + 2\lambda_t \kappa_t + \lambda_t^2 \kappa_t^2 + 2\lambda_t r_t^2}{1 + 2\lambda_t \kappa_t + \lambda_t^2 \kappa_t^2 + 2\lambda_t} + \eta_t^2 (4\kappa_t + (1 + \lambda_t \kappa_t)^2 + 2\kappa_t^2)$$

$$\leq 1 - \frac{2\lambda_t (1 - r_t^2)}{1 + 2\lambda_t \kappa_t + \lambda_t^2 \kappa_t^2 + 2\lambda_t} + \eta_t^2 (4\kappa_t + 2)$$

$$\leq 1 - \lambda_t (1 - r_t^2) + \eta_t^2 (4\kappa_t + 2),$$  \hspace{1cm} (40)

where Inequality (40) holds for large enough $t$. As the product of $\theta_t$ over $t$ is positive, we have

$$\sum_{t=1}^{\infty} \log \theta_t = \log \Pi_{t=1}^{\infty} \theta_t > -\infty.$$  \hspace{1cm} (42)

Given that $\eta_t^2 (4\kappa_t + 2) = \Theta(t^{-2q})$, Equation (42) is equivalent to

$$\sum_{t=1}^{\infty} \lambda_t (1 - r_t^2) < \infty,$$  \hspace{1cm} (43)

which implies $\lambda_t (1 - r_t^2) = o(t^{-\frac{1}{2}})$. As $r_t \leq 1$ and $\eta_t = t^{-q}$, we have $\lambda_t = O(t^{-q})$ and hence we have $1 - r_t = o(t^{-\frac{1}{2} + q})$.

### A.2 Proof of Theorem 2

The idea of the proof is to divide the unit sphere into three components: the upper cap along the direction of gradient, the lower cap opposite to the direction of gradient, and the annulus in between.

Let $u$ be a random vector uniformly distributed on the sphere. By Taylor’s theorem, for any $\delta \in (0, 1)$, we have

$$S(x_t + \delta u) = \delta \nabla S(x_t)^T u + \frac{1}{2} \delta^2 u^T \nabla^2 S(x_t) u.$$  \hspace{1cm} (44)

for some $x'$ on the line between $x_t$ and $x_t + \delta u$, where we have made use of the fact that $S(x_t) = 0$. As the function $S$ has Lipschitz gradients, we can bound the second-order term as

$$\left| \frac{1}{2} \delta^2 u^T \nabla^2 S(x') u \right| \leq \frac{1}{2} L \delta^2.$$  \hspace{1cm} (45)
Let \( w := \frac{1}{2}L\delta \). By the Taylor expansion and the bound on the second order term by eigenvalues, when \( \nabla S(x_t)^T u > w \), we have
\[
S(x_t + \delta u) \geq \delta \nabla S(x_t)^T u + \frac{1}{2} \delta^2 u^T \nabla^2 S(x') u \\
\geq \delta (\nabla S(x_t)^T u - \frac{1}{2} L \delta) > 0.
\]
Similarly, we have \( S(x_t + \delta u) < 0 \) when \( \nabla S(x_t)^T u < -w \). Therefore, we have
\[
\phi_x(x_t + \delta u) = \begin{cases} 
1 & \text{if } \nabla S(x_t)^T u > w, \\
-1 & \text{if } \nabla S(x_t)^T u < -w.
\end{cases}
\]
We expand the vector \( \nabla S(x_t) \) to an orthogonal bases in \( \mathbb{R}^d \): \( v_1 = \nabla S(x_t)/\|\nabla S(x_t)\|_2, v_2, \ldots, v_d \). The random vector \( u \) can be expressed as
\[
u = \sum_{i=1}^d \beta_i v_i,
\]
where \( \beta \) is uniformly distributed on the sphere. Denote the upper cap as \( E_1 := \{ \nabla S(x_t)^T u > w \} \), the annulus as \( E_2 := \{ |\nabla S(x_t)^T u| < w \} \), and the lower cap as \( E_3 := \{ \nabla S(x_t)^T u < -w \} \). Let \( p := \mathbb{P}(E_2) \) be the probability of event \( E_2 \). Thus we have \( \mathbb{P}(E_1) = \mathbb{P}(E_3) = (1 - p)/2 \). By symmetry, for any \( i \neq 1 \), we have
\[
\mathbb{E}[\beta_i \mid E_1] = \mathbb{E}[\beta_i \mid E_3] = 0.
\]
Therefore, the expected value of the estimator is
\[
\mathbb{E}[\phi_x(x_t + \delta u)u] = \left( \mathbb{E}[\phi_x(x_t + \delta u)u \mid E_1] + \mathbb{E}[\phi_x(x_t + \delta u)u \mid E_3] \right) \cdot (1 - p)/2 + \mathbb{E}[\phi_x(x_t + \delta u)u \mid E_2] \cdot p.
\]
Exploiting the above derivation, we bound the difference between \( \mathbb{E}[\beta_1 v_1] = \mathbb{E}[\beta_1] / \|\nabla S(x_t)\|_2 \nabla S(x_t) \) and \( \mathbb{E}[\phi_x(x_t + \delta u)u] \). In fact, we have
\[
\|\mathbb{E}[\phi_x(x_t + \delta u)u] - \mathbb{E}[\beta_1 v_1]\|_2 \leq p \left( \mathbb{E}[\phi_x(x_t + \delta u)u \mid E_2] - \frac{1}{2} \mathbb{E}[\beta_1 v_1 \mid E_1] - \frac{1}{2} \mathbb{E}[\beta_1 v_1 \mid E_3] \right)^2 + \mathbb{E}[\|\beta_1 v_1 \mid E_1\|] + \mathbb{E}[\|\beta_1 v_1 \mid E_3\| - \mathbb{E}[\|\beta_1 v_1\|]_2 \leq 2p + p = 3p,
\]
which yields
\[
\cos \angle \left( \mathbb{E}[\phi_x(x_t + \delta u)u], \nabla S(x_t) \right) \geq 1 - \frac{1}{2} \left( \frac{3p}{\mathbb{E}[\beta_1]} \right)^2.
\]
We can bound \( p \) by observing that \( \frac{\mathbb{P}(\|\nabla S(x_t)\|_2, u)^2}{\mathbb{P}(\|\nabla S(x_t)\|_2)^2} \) is a Beta distribution \( B \left( \frac{1}{2}, \frac{d-1}{2} \right) \):
\[
p = \mathbb{P}(\|\nabla S(x_t)\|_2 < w) = \mathbb{P} \left( \frac{\mathbb{P}(\|\nabla S(x_t)\|_2, u)^2}{\mathbb{P}(\|\nabla S(x_t)\|_2)^2} \leq \frac{w^2}{\|\nabla S(x_t)\|_2^2} \right) \leq \mathbb{E} \left( \frac{w^2}{\|\nabla S(x_t)\|_2^2} \right).
\]

(46)
Plugging into Equation [46], we get
\[
\cos \angle (\mathbb{E}[\phi_x(x_t + \delta u)u], \nabla S(x_t)) \\
\geq 1 - \frac{18w^2}{(\mathbb{E}[\delta_1])^2 B(1, d - 1)^2 \|\nabla S(x_t)\|_2^2} \\
\geq 1 - \frac{2(2/(d - 1))^2 \|\nabla S(x_t)\|_2^2}{9L^2d^2} \\
= 1 - \frac{9L^2d^2(d - 1)^2}{8\|\nabla S(x_t)\|_2^2}
\]
We also observe that
\[\mathbb{E}\nabla S(x_t, \delta) = \mathbb{E}[\phi_x(x_t + \delta u)u].\]
As a consequence, we have established
\[\cos \angle \left(\mathbb{E}[\nabla S(x_t, \delta)], \nabla S(x_t)\right) \geq 1 - \frac{9L^2d^2(d - 1)^2}{8\|\nabla S(x_t)\|_2^2}.
\]
Taking \(\delta \to 0\), we get
\[\lim_{\delta \to 0} \cos \angle \left(\mathbb{E}[\nabla S(x_t, \delta)], \nabla S(x_t)\right) = 1.
\]

**A.3 Proof of Theorem 3**

**Proof.** For notational simplicity, we denote \(\xi_b := \phi_x(x_t + \delta u_b)\), and \(\xi = \frac{1}{B} \sum_{b=1}^{B} \xi_b = \bar{\phi}_x\). We use \(\xi, u\) to denote i.i.d. copies of \(\xi_b\) and \(u_b\) respectively. The variance of the estimate with the baseline is
\[
\text{Var}(\nabla S(x_t, \delta)) = \mathbb{E}\left\langle \nabla S(x_t, \delta) - \mathbb{E}\nabla S(x_t, \delta), \nabla S(x_t, \delta) - \mathbb{E}\nabla S(x_t, \delta) \right\rangle \\
= \frac{1}{(B - 1)^2} \sum_{b=1}^{B} \xi_b u_b - B - 1 \mathbb{E}[\xi u] - \xi u_b, \sum_{b=1}^{B} \xi_b u_b - B - 1 \mathbb{E}[\xi u] - \xi u_b \\
= \frac{1}{(B - 1)^2} \sum_{a,b=1}^{B} \left\langle \xi_a u_a - \mathbb{E}[\xi u] - (\xi_a - \frac{1}{B} \mathbb{E}[\xi u]), \xi_b u_b - \mathbb{E}[\xi u] - (\xi_b - \frac{1}{B} \mathbb{E}[\xi u]) \right\rangle
\]
When \(a \neq b\), the summand can be simplified by independence of \(u_a, u_b\) and independence of \(\xi_a u_a, \xi_b u_b\). In fact,
\[
\mathbb{E}\left\langle \xi_a u_a - \mathbb{E}[\xi u] - (\xi_a - \frac{1}{B} \mathbb{E}[\xi u]), \xi_b u_b - \mathbb{E}[\xi u] - (\xi b - \frac{1}{B} \mathbb{E}[\xi u]) \right\rangle \\
= -2\mathbb{E}\left\langle \xi_a u_a - \mathbb{E}[\xi u], \xi_b u_b - \frac{1}{B} \mathbb{E}[\xi u] \right\rangle + \mathbb{E}\left\langle \xi_a u_a - \frac{1}{B} \mathbb{E}[\xi u], \xi_b u_b - \frac{1}{B} \mathbb{E}[\xi u] \right\rangle \\
= -2\mathbb{E}\left\langle \xi_a u_a - \mathbb{E}[\xi u], \frac{\xi_a + \xi_b}{B} u_b - \frac{1}{B} \mathbb{E}[\xi u] \right\rangle + \mathbb{E}\left\langle \xi_a u_a - \frac{1}{B} \mathbb{E}[\xi u], \frac{\xi_a + \xi_b}{B} u_b - \frac{1}{B} \mathbb{E}[\xi u] \right\rangle \\
= -2\mathbb{E}\left\langle \xi_a u_a - \mathbb{E}[\xi u], \xi_b u_b - \frac{1}{B} \mathbb{E}[\xi u] \right\rangle + \mathbb{E}\left\langle \xi_a u_a - \frac{1}{B} \mathbb{E}[\xi u], \frac{\xi_a + \xi_b}{B} u_b - \frac{1}{B} \mathbb{E}[\xi u] \right\rangle \\
= 0 + \left( \frac{2}{B^2} - \frac{2}{B^2} + \frac{1}{B^2} \right) \|\mathbb{E}[\xi u]\|_2^2 \\
= \frac{1}{B^2} \|\mathbb{E}[\xi u]\|_2^2.
\]
When \( a = b \), each summand becomes:
\[
\begin{align*}
\mathbb{E}\left[\left\|\xi_a u_a - \mathbb{E}[\xi u] - (\xi u_a - \frac{1}{B} \mathbb{E}[\xi u])\right\|^2\right] \\
= \mathbb{E}\left[\left\|\xi_a u_a - \mathbb{E}[\xi u]\right\|^2\right] - 2 \mathbb{E}\left[\xi_a u_a - \mathbb{E}[\xi u], \xi u_a - \frac{1}{B} \mathbb{E}[\xi u]\right] + \mathbb{E}\left[\|\xi u_a - \frac{1}{B} \mathbb{E}[\xi u]\|^2\right]
\end{align*}
\]
\[
\begin{align*}
= \mathbb{E}\left[\left\|\xi_a u_a - \mathbb{E}[\xi u]\right\|^2\right] - 2 \mathbb{E}\left[\xi_a u_a, \xi u_a\right] + \frac{2}{B} \mathbb{E}[\|\xi u\|^2] + \mathbb{E}\left[\|\xi u_a\|^2\right] - \frac{2}{B} \mathbb{E}[\xi u_a, \mathbb{E}[\xi u]] + \frac{1}{B^2} \mathbb{E}[\|\xi u\|^2]
\end{align*}
\]
\[
= \mathbb{E}\left[\left\|\xi_a u_a - \mathbb{E}[\xi u]\right\|^2\right] - 2 \mathbb{E}[\xi_a] + \mathbb{E}[\xi^2] + \frac{2B - 1}{B^2} \mathbb{E}[\|\xi u\|^2].
\]

Therefore, the variance can be written as
\[
\text{Var}(\nabla S(x_t, \delta)) = \frac{1}{(B - 1)^2} \sum_{a=1}^{B} \left( \mathbb{E}\left[\left\|\xi_a u_a - \mathbb{E}[\xi u]\right\|^2\right] - 2 \mathbb{E}[\xi_a] + \mathbb{E}[\xi^2] + \frac{2B - 1}{B^2} \mathbb{E}[\|\xi u\|^2]\right) + \frac{||\mathbb{E}[\xi u]||_2^2}{B(B - 1)}.
\]
\[
= \frac{B^2 \text{Var}(\nabla S(x_t, \delta))}{(B - 1)^2} - \frac{B \mathbb{E}[\xi^2]}{(B - 1)^2} + \frac{(3B - 2)||\mathbb{E}[\xi u]||_2^2}{B(B - 1)^2}
\]
\[
\leq \frac{B^2 \text{Var}(\nabla S(x_t, \delta))}{(B - 1)^2} - \frac{B \mathbb{E}[\xi^2]}{(B - 1)^2} + \frac{3B - 2}{B(B - 1)^2}. \tag{47}
\]

The middle term can be expanded as
\[
- \frac{B}{(B - 1)^2} \mathbb{E}[\xi^2]
\]
\[
= - \frac{B}{(B - 1)^2} \sum_{a,b=1}^{B} \mathbb{E}[\xi_a \xi_b]
\]
\[
= - \frac{1}{(B - 1)^2 B} (B \cdot 1 + B(B - 1) \cdot (2\mathbb{E}[\xi] - 1)^2)
\]
\[
= - \frac{1}{(B - 1)^2} - \frac{4}{B - 1} (\mathbb{E}[\xi] - \frac{1}{2})^2.
\]

Plugging into Equation (47), we get
\[
\text{Var}(\nabla S(x_t, \delta)) \leq \frac{B^2}{(B - 1)^2} \text{Var}(\nabla S(x_t, \delta)) + \frac{2}{B(B - 1)} (1 - 2B(\mathbb{E}[\xi] - \frac{1}{2})^2)
\]
\[
= \text{Var}(\nabla S(x_t, \delta)) \left\{ 1 + \frac{2B - 1}{(B - 1)^2} - \frac{2}{\sigma^2(B - 1)} (2B(\mathbb{E}[\xi] - \frac{1}{2})^2 - 1) \right\}.
\]

When \( \mathbb{E}[\xi] \) satisfies \( (\mathbb{E}[\xi] - \frac{1}{2})^2 > \frac{1}{100} (1 + \frac{2B-1}{2B\sigma^2}) \), we have
\[
\frac{2B - 1}{(B - 1)^2} < \frac{2}{\sigma^2(B - 1)} (2B(\mathbb{E}[\xi] - \frac{1}{2})^2 - 1),
\]
which implies \( \text{Var}(\nabla S(x_t, \delta)) < \text{Var}(\nabla S(x_t, \delta)) \).

\[
\square
\]
