We study the spectral function and quasiparticle scattering in Li-decorated graphene (Li@graphene) with an atomistic $T$-matrix formalism and uncover adatom-induced spectral effects which shed light on experimentally observed ARPES features. From transport studies, alkali adatoms are known to introduce charged-impurity scattering limiting the carrier mobility. Here, we demonstrate that Li adatoms furthermore give rise to a low-energy impurity band centered at the $\Gamma$ point which originates from the hybridization between the atomic 2s state of the Li adatoms and graphene “surface” states. We show that the impurity band is strongly dependent on the concentration $c_{\text{Li}}$ of Li adatoms, and aligns with the Li-induced Fermi level on the Dirac cone at $c_{\text{Li}} \sim 8\%$ ($E_F \approx 1.1$ eV). Finally, we show that adatom-induced quasiparticle scattering increases dramatically at energies above $\sim 1$ eV, giving rise to a large linewidth broadening on the Dirac cone with a concomitant downshift and a characteristic kink in the conduction band. Our findings are highly relevant for future studies of ARPES, transport and superconductivity in adatom-doped graphene.

**Introduction.**—Graphene decorated with metallic adatoms has emerged as an interesting platform for engineering graphene’s electronic properties and realizing novel electronic phases such as, e.g., the quantum spin Hall phase [11,3] and superconductivity [4,6]. In addition, doping with adatoms opens the opportunity to probe the electronic properties of graphene at high energies with, e.g., Fermi levels in excess of 1 eV in alkali-doped graphene [7,12]. However, metallic adatoms at the same time introduce charged-impurity scattering, thus limiting the transport in adatom-doped graphene [12,15].

The spectral properties of adatom-doped graphene have been studied with angle-resolved photoemission spectroscopy (ARPES) [16] in several works [7,11,17–19], demonstrating many-body effects such as, e.g., electron-electron and electron-phonon (el-ph) interactions [20,25], while the effect of adatom-induced impurity scattering [12,15] in ARPES is not well understood [19]. In addition, signatures of superconductivity have been observed in ARPES on Li@graphene at Li concentrations corresponding to a Fermi level of $E_F \approx 1$ eV [11]. They appeared alongside with a spectral feature at the $\Gamma$ point which in the ordered LiC$_x$ structure [35] and alkali metal-graphite intercalation compounds [26,28] corresponds to a metal-atom dominated band predicted to promote superconductivity [5].

In this work, we study the spectral properties of disordered Li@graphene, i.e., graphene with a random configuration of Li adatoms as illustrated in Fig. 1(a), using an atomistic first-principles $T$-matrix formalism based on a parameter-free description of the impurity potential [29,30] (see Ref. [31] for recent related developments). This allows for a detailed description of (i) the spectral $\Gamma$-point feature including its hitherto unexplored concentration dependence as well as (ii) the renormalization and linewidth broadening of the bands due to adatom-induced quasiparticle (QP) scattering.

We find that in disordered Li@graphene, the $\Gamma$-point feature corresponds to the hybrid impurity band shown in Fig. 1(b), which originates from the coupling between free-electron like “surface” states localized in proximity to the graphene layer and the atomic Li 2s state as sketched in Fig. 1(a). The impurity band evolves downwards in energy from the position of the Li 2s state with increasing $c_{\text{Li}}$ and aligns with the Fermi level on the Dirac cone at $c_{\text{Li}} \sim 8\%$ ($E_F \approx 1.1$ eV). In agreement with experiments [11], this suggests that conditions favorable for superconductivity may be realized in disordered Li@graphene at concentrations well below the concentration ($c_{\text{Li}} = 33\%$) in LiC$_6$ [5].

We furthermore analyze the effect of adatom scattering on the Dirac cone states, and find that charged-impurity scattering dominates the linewidth broadening, while resonant scattering [32,34] by the atomic Li 2s state is neg-

![FIG. 1. (a) Atomic illustration of disordered Li@graphene with a random configuration of Li adatoms giving rise to (i) a hybrid impurity band, and (ii) pronounced charged-impurity scattering as sketched in the top part. (b) Spectral function of Li@graphene at a Li concentration of $c_{\text{Li}} = 10\%$ showing the appearance of the $\Gamma$-point centered hybrid impurity band $\sim 0.9$ eV above the Dirac point ($E = 0$). The dashed horizontal line indicates the Li-induced Fermi level $E_F$. The unperturbed Dirac-cone bands (red dashed lines) are renormalized (solid blue lines) and broadened by Li-induced impurity scattering.](image-url)
ligible. Near the M point, the linewidth broadening in Fig. 1(b) increases dramatically due to strong charged-impurity scattering with a concomitant downshift and a kink in the QP band [Fig. 1(b) blue line]. Similar features have been observed at high Fermi energies in alkali-doped graphene [27, 29, 30], and may yield an artificially high and anisotropic el-ph coupling if attributed entirely to el-ph scattering as pointed out in Refs. 26 and 31. As we demonstrate, adatom-induced impurity scattering presents a nonnegligible "intrinsic" contribution to the band renormalization in adatom-doped graphene.

Theory and methods.—For a random distribution of Li adatoms as illustrated in Fig. 1(a), the spectral properties probed in ARPES are given by the impurity-averaged Green’s function (GF). Here, we apply the atomistic DFT-based T-matrix formalism described in Refs. 29 and 30 to calculate the GF for disordered Li@graphene.

The impurity-averaged Green’s function is given by the Dyson equation [38, 39]

\[ G^{-1}_k(\varepsilon) = G^0_k^{-1}(\varepsilon) - \Sigma_k(\varepsilon), \]

where \( k \) ∈ 1st Brillouin zone (BZ) and the carets indicate a matrix structure in the band index \( n \). Impurity effects enter via the self-energy \( \Sigma_k(\varepsilon) \), which modifies the pristine band structure \( \varepsilon_{nk} \) of graphene described by the non-interacting Green’s function, \( G^0_{nk}(\varepsilon) = (\varepsilon - \varepsilon_{nk} + i\eta)^{-1} \). While \( G^0_{nk} \) is diagonal in the band index, the disorder self-energy in \( \Sigma_k(\varepsilon) \) is, in general, not diagonal and Eq. (1) must be solved by matrix inversion.

In the T-matrix approximation [39, 40], the impurity self-energy is given by \( \Sigma_k(\varepsilon) = c_i T_{kk}(\varepsilon) \) where \( c_i = N_i/N \) is the impurity concentration (impurities per unit cell), and \( T_{kk}(\varepsilon) \) denotes the \( k \)-diagonal elements of the T matrix. The T matrix takes into account multiple scattering off the individual impurities, and is given by the integral equation

\[ T_{kk'}(\varepsilon) = \hat{T}_{kk'} + \sum_{kk''} \hat{V}_{kk''} G^0_{kk''}(\varepsilon) \hat{T}_{kk'''}(\varepsilon), \]

where \( \hat{V}_{kk'} \) are the impurity matrix elements. The T-matrix self-energy is exact to leading order in the impurity concentration \( c_i \), and is therefore a good approximation for low impurity concentrations, i.e. \( c_i \ll 1 \).

In the following, we obtain the GF and spectral function of Li@graphene based on atomistic DFT (LCAO) calculations [41] of the band structure and impurity matrix elements sampled in the full BZ using the atomistic method described in Refs. 29, 30.

Li-adatom impurity potential.—For the initial characterization of the Li adatoms, we have carried out standard DFT calculations [41], finding that the hollow site at the center of the hexagon of the graphene lattice is the favored adsorption site at a distance of \( d = 1.78 \) Å above the graphene layer, and a net charge of \( Q = -eZ_{Li} \) donated to the graphene lattice per Li adatom (\( Z_{Li} = +0.9 \)), consistent with previous works [43, 44].

In our DFT calculated impurity matrix elements \( V''_{kk'} \) = \( \langle \psi_{nk'} | \hat{V}_{Li} | \psi_{nk} \rangle \) [41], where \( | \psi_{nk} \rangle \) is the Bloch state of the pristine system, the microscopic details of the graphene-Li interaction are encoded in the DFT Li-adatom impurity potential \( \hat{V}_{Li} \).

For the sake of simplicity we here express it as

\[ \hat{V}_{Li} = V_C(\mathbf{r}) + \sum_{nk,n'k'} | \psi_{nk} \rangle V''_{2sz,kk'} | \psi_{n'k'} \rangle, \]

where the two dominant contributions come from: 1) The Coulomb potential \( V_C(\mathbf{r}) \) from the charged Li adatoms (\( Q = +Ze_{Li} \)) which corresponds approximately to a screened point-charge potential given by \( V_C(q,d) = e^2Z_{Li} e^{-qd}/[2\epsilon_0q\varepsilon(q)] \) in Fourier space where \( \varepsilon(q) \) is the 2D static dielectric function of graphene [27, 32]. 2) The atomic Li 2s state with energy \( E_{2s} \) which can be reduced to an effective potential \( V''_{2s,kk'} \) described by the DFT pseudopotential [30] (see, e.g., Refs. 33 and 39 for tight-binding examples).

For an accurate description of the atomic 2s state in the T matrix, we use a Bloch-state basis \( \{|\psi_{nk}\rangle\} \) which describes both the graphene layer and the vacuum region where the Li atoms reside. In our DFT-LCAO based method, this is achieved by introducing so-called "ghost" atoms in the surface region which enlarge the standard LCAO basis for graphene. In the graphene band structure shown in Fig. 2, this gives rise to the two Γ-point centered parabolic bands (labelled \( n = 1, 2 \)) located \( \sim 3.5-5 \) eV above the Dirac point (\( E = 0 \)) which are absent in standard tight-binding and DFT-LCAO calculations [40, 41]. The two bands correspond to free-electron like surface states located predominantly outside the graphene plane with, respectively, even (\( n = 1 \)) and odd (\( n = 2 \)) parity with respect to graphene’s mirror symmetry plane [51], and they are instrumental for the occurrence of the impurity band in Fig. 1(b).

![Graphene bandstructure featuring two parabolic bands labelled n = 1, 2 which are associated with free-electron like surface states.](image-url)

FIG. 2. (a) Graphene bandstructure featuring two parabolic bands labelled \( n = 1, 2 \) which are associated with free-electron like surface states [43]. (b) Diagonal elements of the real and imaginary parts of the effective self-energy in Eq. (5) for the \( n = 1, 2 \) surface states at \( \mathbf{k} = \Gamma \) and \( c_{Li} = 10\% \). The circles indicate the solutions to the QP equation corresponding to the hybrid impurity band in Li@graphene [cf. text below Eq. (4)].
**Li@graphene spectral function.**—In Fig. 1(b) we show the calculated spectral function $A_k(\varepsilon) = \sum_n A_{nk}(\varepsilon)$ for $c_{Li} = 10 \%$, where $A_{nk}(\varepsilon) = -2\text{Im} G_{nn}^{\text{eff}}(\varepsilon)$ is given by the imaginary part of the diagonal elements of the GF. The dashed horizontal line shows the Fermi level $E_F$ assuming a Li-induced carrier density of $n = Z_{Li}n_{Li}$, where $n_{Li}$ is the areal density of Li atoms, and zero residual doping often present experimentally [11]. The spectral function exhibits two distinct features which are absent in the pristine band structure of graphene.

The first is the appearance of a prominent $\Gamma$-centered parabolic impurity band which starts $\sim 0.9$ eV above the Dirac point and extends up to $\sim 2.5$ eV where it vanishes. As indicated by the Fermi level, this band is populated at the considered $c_{Li}$ and is hence important for the electronic and transport properties of Li@graphene, including its potential superconducting state [11]. The second feature is a pronounced renormalization and broadening of the conduction band near the $M$ point which is an indication of strong OP scattering.

As justified below, these features can be analyzed using a diagonal form of the impurity-averaged GF, $G_{nk}(\varepsilon) = [\varepsilon - \varepsilon_{nk} - \Sigma_{nk}(\varepsilon)]^{-1}$. Thus, the renormalized QP bands $\tilde{\varepsilon}_{nk}$ follow from the solution to the QP equation $\varepsilon - \varepsilon_{nk} - \text{Re} \Sigma_{nk}(\varepsilon) = 0$. In the vicinity of $\tilde{\varepsilon}_{nk}$, the spectral function takes the form

$$A_{nk}(\varepsilon) = Z_{nk} \frac{\gamma_{nk}}{[\varepsilon - \tilde{\varepsilon}_{nk}]^2 + (\gamma_{nk}/2)^2},$$

where the wave-function renormalization, or QP weight, is given by $Z_{nk} = [1 - \partial_\varepsilon \text{Re} \Sigma_{nk}(\varepsilon)]^{-1}$, and $\gamma_{nk} = -2Z_{nk} \text{Im} \Sigma_{nk}(\varepsilon) \tilde{\varepsilon}_{nk} \equiv \text{linewidth}$ is the linewidth broadening due to impurity scattering.

Besides renormalization of the pristine band structure, impurities with resonant atomic levels may introduce new spectral features as is the case here. Such features stem from additional solutions $\tilde{\varepsilon}_{\text{imp},k}$ to the QP equation, and the spectral function acquires an additional impurity component, $A_{nk}(\varepsilon) \approx 2\pi Z_{nk} \delta(\varepsilon - \tilde{\varepsilon}_{nk}) + A_{nk}^{\text{imp}}(\varepsilon)$, where well-defined QPs are assumed and $A_{nk}^{\text{imp}}$ is given by Eq. (4) with $\tilde{\varepsilon}_{nk} \rightarrow \tilde{\varepsilon}_{\text{imp},k}$. By virtue of the sum rule $\int \frac{d\varepsilon}{\pi} A_{nk}(\varepsilon) = 1$, this results in a reduction of the QP weights of the pristine bands from their unperturbed value $Z_{nk} = 1$.

In the rest of the paper, we clarify the microscopic origin of the adatom-related features in Fig. 1(b) as well as their dependence on the concentration of Li adatoms.

**Hybrid impurity band.**—The origin of the $\Gamma$-centered impurity band can be traced back to the coupling between the $n=1,2$ surface states in Fig. 2 and the atomic Li 2s state via the last term in Eq. (3). This introduces a pole in the $T$ matrix at the renormalized energy $E_{2s} \approx 2.55$ eV of the 2s state. At $k = \Gamma$, the pole together with the broken mirror plane symmetry in Li@graphene gives rise to large diagonal and off-diagonal $T$-matrix elements between the $n = 1,2$ surface states [52], which dominate all other elements. To facilitate a simple analysis, we thus approximate the GF in the $n=1,2$ surface-state subspace by the inverse of its $2 \times 2$ subblock on the right-hand side of Eq. (4). The diagonal elements of the GF take the form $G_{nk}(\varepsilon) = [\varepsilon - \tilde{\varepsilon}_{nk} - \Sigma_{nk}^{\text{eff}}(\varepsilon)]^{-1}$ where the effective self-energy,

$$\Sigma_{nk}^{\text{eff}}(\varepsilon) = \Sigma_{nk}^n(\varepsilon) + \Sigma_{nk}^{\bar{n}}(\varepsilon)\Sigma_{nk}^{\bar{n}}(\varepsilon) \frac{\Sigma_{nk}^{\bar{n}}(\varepsilon)}{\varepsilon - \tilde{\varepsilon}_{nk} - \Sigma_{nk}^{\bar{n}}(\varepsilon)}, \quad \bar{n} \neq n,$$

describes virtual transitions between the surface state $n$ and the Li 2s state either (i) directly (first term), or (ii) via the other surface state $\bar{n}$ (second term).

With this form of the diagonal elements of the GF, the analysis in Eq. (4) applies. In Fig. 2(b) we show the real (green lines) and imaginary parts (red lines) of the diagonal elements of the effective self-energy, $\Sigma_{nk}^{\text{eff}}$, together with the calculated QP weight $Z_{nk}^{\text{eff}}$ (blue lines) and $\varepsilon - \tilde{\varepsilon}_{nk}$ (black dashed). The intersection of the latter with $\text{Re} \Sigma_{nk}^{\text{eff}}$ (marked with circles) signifies the emergence of the $\Gamma$-centered hybrid impurity band in Fig. 1(b). The QP weights at the $\Gamma$ point are, respectively, $Z_{1\Gamma} \approx 0.3$ and $Z_{2\Gamma} \approx 0.2$, yielding a total QP weight of $Z_{\text{imp},\Gamma} \sim 0.5$ for the impurity band.

We have thus identified the spectral $\Gamma$-point feature observed in ARPES [11] as a low-energy hybridized impurity band arising from the coherent coupling between...
the surface states and the Li 2s state as described by Eq. (5). In the periodic LiC₆ structure, the analogue of this band plays a pivotal role for the predicted superconductivity by enhancing the el-ph coupling at the Fermi level [5].

It is interesting to investigate the concentration dependence of the impurity band and its alignment with the Fermi level in Li@graphene. In Fig. 3(a) and (b), we show the DOS (per unit cell) $\rho(\varepsilon) = -\frac{1}{\pi} \text{Im} [\text{Tr} \Gamma_0(\varepsilon)]$ for, respectively, (i) pristine graphene ($\rho_0$), and (ii) the $\Gamma$-centered bands in Li@graphene ($\rho_L$) obtained by restricting $\mathbf{k}$ sum in the trace to a region around the $\Gamma$ point enclosing the relevant bands. The dashed line in Fig. 3(b) marks the position of the Fermi level corresponding to the Li-induced carrier density $n = Z_{\text{Li}}n_{\text{Li}}$. In the Dirac model the Fermi energy scales as $E_F = \hbar v_F \sqrt{\pi Z_{\text{Li}}n_{\text{Li}}} \approx 120 \sqrt{n}/(10^{12} \text{cm}^{-2})$ meV, whereas the Fermi energy in Fig. 3(b) deviates from this square-root dependence at high $c_{\text{Li}}$, where it flattens out due to the population of the hybrid band and the non-linear part of the Dirac cone. The figure illustrates the development of the hybrid impurity band which starts from the position of the Li 2s state $E_{2s}$ and moves down towards the Dirac cone with increasing Li concentration. Interestingly, our calculations show that the hybrid impurity band aligns with the Fermi level on the Dirac cone at Li concentrations as low as $c_{\text{Li}} \approx 8\%$ ($E_F \approx 1.1$ eV) where the DOS $\rho_F$ of the impurity band and the Dirac-cone DOS $\rho_0$ are comparable. In the presence of a residual doping of graphene [11], this situation is realized at even lower $c_{\text{Li}}$.

**Dirac-cone QP properties.**—Finally, we consider the effect of adatom-induced QP scattering on the renormalization and linewidth broadening of the Dirac-cone bands in Fig. 1(b) and Figs. 3(c)-(d). As the self-energy on the Dirac cone is diagonal [52], the renormalized QP bands $\tilde{\varepsilon}_{\mathbf{k} \mathbf{q}}$ and linewidth broadening $\gamma_{\mathbf{k} \mathbf{q}}$ can be obtained as explained above and below Eq. (4).

In Fig. 4 we show the energy dependence of the linewidth broadening of the conduction band along the $K$-$\Gamma$ and $K$-$M$ paths for a fixed Li concentration of $c_{\text{Li}} = 1\%$ at which the impurity band is absent [cf. Fig. 3(a)]. For clarity, we have separated out the contributions from intra (left) and intervalley (right) scattering using the optical theorem [52] [52]. At energies below $\sim 1$ eV, the intervalley rate exceeds the intravalley rate by far. This is consistent with charged-impurity scattering where intervalley scattering with $q \approx |\mathbf{K} - \mathbf{K}'|$ is weak due to the $q$ dependence of the 2D Coulomb potential $V_C(q, d)$. We find no indications of resonant scattering [52] [53] which is suppressed by the remote energy $E_{2s}$ of the Li 2s state as well as the invisibility of short-range impurity potentials due to adatoms in the hollow site [53] [54] [55]. At higher energies, both the intra and intervalley rates increase dramatically and peak at the energy $\varepsilon \approx 1.75$ eV of the van Hove singularity (VHS) in the DOS in Fig. 3(a). Whereas the increasing DOS and the VHS are the main reasons for the increasing intervalley rate, the increase in the intervalley rate is instead related to the strong trigonal warping of the Dirac cones seen in Figs. 3(c)-3(d). As illustrated in Fig. 3(d), this reduces the intervalley scattering wave vector markedly and thereby enhances the scattering probability due to the $q$ dependence of Coulomb potential. This effect is most pronounced on the $K$-$M$ path, where the reduction in the $K \rightarrow K'$ intervalley wave vector is strongest, and results in an anisotropic linewidth broadening also visible on the $\varepsilon = 1.5$ eV constant-energy contours in Fig. 3(d). In Figs. 3(c) and 3(d), $c_{\text{Li}} = 10\%$, and $K \leftrightarrow K'$ scattering between the overlapping impurity band and Dirac cones may also contribute to the broadening. However, the narrow linewidth of the impurity band shows that this scattering channel is weak because of a small impurity matrix element between the spatially separated surface and Dirac-cone states. Dirac-cone QP scattering is thus not affected markedly by the impurity band.

Interestingly, the strong peak in the linewidth broadening at the VHS is accompanied by a pronounced renormalization of the conduction band in the same energy range as demonstrated by the calculated QP band in Fig. 3(b) (solid blue line). Along the $K$-$M$ path, the conduction band exhibits a pronounced downshift and a kink $\sim 100$–200 meV below the VHS, resembling experimental ARPES features in highly adatom-doped graphene [8, 10]. At high doping levels [7, 8, 10], this adatom-induced kink may interfere with el-ph related kinks located at the optical phonon energy $\sim 200$ meV below the Fermi level [20] [22] [23], thus obscuring the analysis of the el-ph interaction [36] [37] in the regime relevant for superconductivity.

**Conclusions.**—We have studied the spectral function and quasiparticle scattering in disordered Li-decorated graphene with an atomic $T$-matrix method. We demonstrate that (i) the experimentally observed low-
energy spectral feature at the Γ point originates from a Li-induced hybrid impurity band which aligns with the Li-induced Fermi level at $c_{\text{Li}} \approx 8\%$, and (ii) Li-induced charged-impurity scattering produces a strong linewidth broadening and a concomitant downshift and kink in the conduction band in the vicinity of the van Hove singularity in the graphene DOS. Our findings are highly relevant for future studies of transport as well as the el-ph interaction and superconductivity in adatom-doped graphene.

* kkan@dtu.dk

All DFT calculations have been performed with the electronic structure code GPAW [12][43] within the projector augmented-wave method, using the LDA xc functional and a LCAO double-zeta polarized (DZP) basis set. The ground-state calculation of the optimized structure and Bloch functions was performed using a 21 x 21 k-point sampling of the BZ. The Li impurity potential was obtained using a 11 x 11 supercell and a 3 x 3 k-point sampling. All calculations include 10 Å of vacuum between graphene and the cell boundaries in the vertical direction imposed with Dirichlet boundary conditions. The impurity matrix elements, T-matrix self-energy and GF were obtained on a 54 x 54 BZ grid, including the 12 lowest bands and using a numerical broadening of η = 100 meV.

Supplemental material which includes plots of the T-matrix self-energy and details on the extraction of the intra- and intervalley contributions to the linewidth broadening using the optical theorem.

S1. T-MATRIX SELF-ENERGY

Here, we include plots in Fig. S1 of the calculated $T$-matrix self-energy,

$$\tilde{\Sigma}_k(\varepsilon) = c_i\tilde{T}_{kk}(\varepsilon),$$

(S1)

to show that it indeed has the properties mentioned in the main text.

A. Surface-state subspace: Li 2s state

The left panel in Fig. S1 shows the $T$-matrix self-energy in the subspace of the two surface states corresponding to the $n = 1, 2$ bands in Fig. 2(a) of the main text. In this subspace, the self-energy is a dense matrix with almost identical diagonal and off-diagonal elements, and the structure with a pole at $\sim 2.55$ eV due to the coupling to the Li 2s state clearly emerges.

B. Dirac-cone subspace: Li-induced impurity scattering

The left panel in Fig. S1 shows the $T$-matrix self-energy in the subspace of the valence ($v$) and conduction ($c$) bands on the Dirac cone. Here, the self-energy is dominated by impurity scattering off the Coulomb potential which results in a diagonal matrix structure and a pronounced increase in the imaginary part at the van Hove singularities in the DOS.

The wiggles on curves visible at low and high energies are due to the discrete $k$-point sampling of the Brillouin zone and demonstrate the necessity of using a numerical broadening $\eta$ which matches the energy spacing in the band structure between neighboring $k$ points.

In both of the above cases, there are small matrix elements to other remote bands. However, due to the large separation in energy they can safely be neglected in our simplified analysis of the spectral features. The excellent
agreement between the spectral function in Fig. 1(b) of the main manuscript obtained from the full matrix GF and our simplified analysis [Fig. 1(b) solid blue lines + Fig. 2(b)] confirms this.

**S2. OPTICAL THEOREM**

The individual contributions to the linewidth broadening from intra- and intervalley scattering can be obtained by taking advantage of the optical theorem by which the diagonal elements of the imaginary part of the $T$ matrix can be expressed as

$$-2 \text{Im} T_{kk}(\varepsilon) = -2 \text{Im} \sum_{n'k' \leftarrow nk} \frac{|T_{nn'}^{kk}(\varepsilon)|^2}{\varepsilon - \varepsilon_{n'n'} + i\eta}$$

$$= 2\pi \sum_{n'k'} |T_{nn'}^{kk}(\varepsilon)|^2 \delta(\varepsilon - \varepsilon_{n'n'}). \quad (S2)$$

Here, the sums run over possible transitions $nk \rightarrow n'k'$ with the scattering amplitude given by the off-diagonal elements $T_{nn'}^{kk}$ of the $T$ matrix. By splitting the $k'$ sum into sums over intra- and intervalley processes, $\sum_{k'} \rightarrow \sum_{k' \in \text{intra}} + \sum_{k' \in \text{inter}}$, the contributions to the lifetime broadening from intra- and intervalley scattering can be extracted.
