26 APRIL 2019

Abstract

We develop a fast and accurate algorithm for evaluating $\sqrt{a^2 + b^2}$ for two floating point numbers $a$ and $b$. Library functions that perform this computation are generally named $\text{hypot}(a,b)$. Our approach will leverage the fused multiply-add operation where available. We will compare four closely related approaches that we will develop to the current resident library function that is delivered with Julia 1.1 and to the version that has been distributed with the C math library since circa 1991. We will demonstrate the performance of our algorithms by simulation and settle on a final version that we believe is best.

Given two floating point numbers $a$ and $b$ we wish to compute $\sqrt{a^2 + b^2}$ quickly and accurately. We note that the problem is trivial if either operand is zero and further that the magnitudes of the operands are important but the signs are not. Therefore, we shall confine our in depth analysis to the case where $a \geq b > 0$. Enforcing this condition will be an initialization step when we develop an actual code. This paper will be restricted to the case where all floating point calculations are done in IEEE 754 compliant arithmetic using round-to-nearest rounding, although many of the results can be extended to other formats under proper conditions.

We begin with a few definitions. We shall denote by $F \subset \mathbb{R}$ the set of all strictly positive floating point numbers in the normalized range of the current format. We define $fl(x) : \mathbb{R} \to F$ to be a function such that $fl(x)$ is the element of $F$ that is closest to $x$ provided $x$ lies within the normalized range of the current format. We define \textit{machine epsilon}, which we will denote by $\epsilon$, to be the difference between 1 and the closest larger element of $F$. For example, in IEEE 754 double precision $\epsilon = 2^{-52}$. We define $F_{\text{max}}$ and $F_{\text{min}}$ to be, respectively, the largest and smallest elements of $F$. 

1 Mathematical Preliminaries

We will need a few mathematical preliminaries before proceeding to the core of our analysis. They follow as a series of three lemmas. The first two both relate to floating point computations.

Lemma 1. Let $x \in \mathbb{R}$ lie within the normalized range of the current format. Then

$$fl(x) = x(1 + \delta)$$

for some $\delta$ satisfying $|\delta| < \frac{\epsilon}{2}$.

This lemma is very well known and can be found in [1]. A lesser known but related lemma is:

Lemma 2. Let $x \in \mathbb{F}$ be any normalized floating point number. Then

$$x = fl(x(1 + \delta))$$

for any $\delta$ satisfying $|\delta| < \frac{\epsilon}{4}$.

And finally, this analytical lemma will be useful in what follows and is easily established by examining the Maclaurin series expansion of $\sqrt{1 + x}$:

Lemma 3. If $x > 0$ then $\sqrt{1 + x} < 1 + \frac{x}{2}$

2 Operands with widely differing magnitudes

To see what happens when $a > b$ have widely differing magnitudes observe that

$$\sqrt{a^2 + b^2} = a\sqrt{1 + \frac{(b/a)^2}{2}}$$

where the inequality follows by replacing $x$ with $(b/a)^2$ in lemma [3]. Now, if

$$\frac{(b/a)^2}{2} \leq \frac{\epsilon}{4}$$

then lemma [2] guarantees that $a = fl(\sqrt{a^2 + b^2})$. We can rewrite the inequality and accept $a$ as the correctly rounded answer whenever $b \leq a\sqrt{\epsilon/2}$. Note that this form will also yield the exact answer whenever $b = 0$. If we test for this case first in our code then we will not have to separately check for zero operands in the initialization phase.

\footnote{To see why it’s true simply consider the operation 1.0*(1.0 - eps/3.9).}
3 Operands without widely differing magnitudes

When the operands do not have widely differing magnitudes then our approach will be to compute \( a^2 + b^2 \) with some care and use the built-in \texttt{sqrt()} function. There could be an unnecessary floating point exception if the calculation of \( a^2 + b^2 \) leads to an overflow/underflow/denormalization and we need to avoid that where possible. Clearly, there can be no overflow if \( a \leq \sqrt{F_{\text{max}}/2} \) and there can be no underflow/denormalization provided that \( b \geq \sqrt{F_{\text{min}}} \). If one of these is violated\(^2\) we can avoid the exception by rescaling the operands, doing the calculation, and then scaling back. When such rescaling is necessary, we will use the standard library functions \texttt{frexp()} and \texttt{ldexp()} to do so without rounding errors.

A little rounding error analysis will be very useful at this point. Let \( z \in \mathbb{F} \) be the result of our floating point calculation of \( a^2 + b^2 \). Because this calculation will be done in floating point there must be some \( \delta_1 \), whose value we do not yet know, such that

\[
z = (a^2 + b^2)(1 + \delta_1).
\]

Now let \( h = \texttt{sqrt}(z) \). Since we are assuming that the \texttt{sqrt()} function is correctly rounded lemma 1 implies that \( h = \sqrt{z}(1 + \delta_2) \) for some \( |\delta_2| < \frac{\epsilon}{2} \). Putting this all together and invoking lemma 3 leads to

\[
h = \sqrt{(a^2 + b^2)(1 + \delta_1)(1 + \delta_2)} < \sqrt{a^2 + b^2(1 + \frac{\delta_1}{2})(1 + \delta_2)} < \sqrt{a^2 + b^2(1 + \frac{\delta_1 + 2\delta_2}{2} + \frac{\delta_1\delta_2}{2})}
\]

The first thing we should observe is that if we were able to compute a correctly rounded \( z \) then \( |\delta_1| < \frac{\epsilon}{2} \). Plugging in above we see that the relative error in the computed \( h \) could be as large as

\[
\frac{3\epsilon}{4} + \frac{\epsilon^2}{8}
\]

and hence the computed \( h \), after rounding, could be as much as one \texttt{ulp}(h) different from the correctly rounded true value.

In a similar fashion if \( |\delta_1| < \frac{3\epsilon}{2} \) then the relative error in the computed \( h \) could be as large as

\[
\frac{5\epsilon}{4} + \frac{3\epsilon^2}{8}
\]

and hence the computed \( h \), after rounding, could not be more than one \texttt{ulp}(h) different from the correctly rounded true value. Careful rounding error analysis of the computation \( z = a \ast a + b \ast b \) shows that the computed value satisfies

\[
|z - (a^2 + b^2)| \leq \epsilon z
\]

\(^2\)At this stage of the process it is not possible to violate both because such a pair of operands would have widely differing magnitudes.
and hence our computed answer must be within one ulp of the correctly rounded one. An excellent treatment can be found in section 5.3 of [2].

At this point we propose two algorithms for the computation in the event that the operands are not widely separated. First is the direct calculation

<table>
<thead>
<tr>
<th>Algorithm 1. Unfused</th>
</tr>
</thead>
<tbody>
<tr>
<td>( h = \sqrt{a^2+b^2} )</td>
</tr>
</tbody>
</table>

And the second uses the fused multiply-add operation

<table>
<thead>
<tr>
<th>Algorithm 2. Fused</th>
</tr>
</thead>
<tbody>
<tr>
<td>( h = \sqrt{fma(a,a,b*b)} )</td>
</tr>
</tbody>
</table>

### 3.1 Splitting

There is one other trick that is worth explaining before we get to testing. First of all, if \( b \leq a/2 \) then computing \( fma(a,a,b*b) \) benefits from the fact that \( b^2 < a^2/4 \) and that means that the rounding error we accrued from computing \( b*b \) is farther to the right and should have less influence on the final value.

If the above is not the case then \( a \geq b > a/2 \). Floating point numbers that satisfy this inequality are called *nearly equal numbers* and they have the very useful property that their difference can be computed with no rounding error, that is \( fl(a - b) = a - b \). Let \( d = a - b \) and note that \( 0 < d < a/2 \). Now with a little algebra we can show that

\[
\begin{align*}
a^2 + b^2 &= a^2 + (d - a)^2 \\
&= a^2 + d^2 - 2da + a^2 \\
&= 2a^2 - 2da + d^2 \\
&= 2a(a - d) + d^2 \\
&= 2ab + d^2
\end{align*}
\]

In this case computing \( fma(a,2*b,d*d) \) is a better choice. Both \( d = a - b \) and \( 2*b \) are computed with no rounding error. And so this calculation mimics the first in terms of the magnitudes of the components.

This leads to two variant algorithms

<table>
<thead>
<tr>
<th>Algorithm 3. Unfused and Split</th>
</tr>
</thead>
<tbody>
<tr>
<td>if ( 2*b &gt; a ) then</td>
</tr>
<tr>
<td>( d = a - b )</td>
</tr>
</tbody>
</table>
\[
h = \sqrt{a*2*b+d*d}
\]

\[
\text{else}
\]
\[
h = \sqrt{a*a+b*b}
\]

\text{end if}

and

\textbf{Algorithm 4. Fused and Split}

\textbf{if} 2*b > a \textbf{then}
\[
d = a-b
\]
\[
h = \sqrt{\text{fma}(a,2*b,d*d)}
\]
\text{else}
\[
h = \sqrt{a,a,b*b}
\]
\text{end if}

\textbf{4 Testing}

We will test all four of the above algorithms against two existing approaches. The first is the algorithm \texttt{hypot}(a,b) which is used in Julia 1.1 which is a widely known stable algorithm for this computation. It essentially amounts to

\textbf{Algorithm 5. hypot()}

\textbf{if} a == 0 \textbf{then}
\[
h = 0
\]
\text{else}
\[
r = b/a
\]
\[
h = x*sqrt(1+r*r)
\]
\text{end if}

This approach is constructed to avoid unnecessary overflow/underflow that might occur in an interim calculation when very large/small inputs are squared. In the non-trivial case it accomplishes this by rescaling so that the quantity \( r \) that must be squared is \( 1 \geq r \geq 0 \) and this cannot lead to an overflow/underflow error prior to the calculation of the square root. Overflow is only possible if the true value of \( \sqrt{x^2+y^2} \) is beyond the range of the floating point format.

The downside of this approach is that it rescales even when rescaling is unnecessary and that rescaling generates additional rounding error. We will see that this causes it to sometimes give answers that are as much as two ulps from the correctly rounded answer.

The second existing approach is the code that has been delivered with the standard C math library since at least 1991. The code appears in appendix B
and we shall refer to it as $\text{clib}\_\text{hypot}()$. We will not give any explanation of its inner workings although the interested reader is welcome to examine it.

As a baseline for testing purposes we will use the big float format in Julia to do an arbitrary precision calculation of the hypotenuse and then cast the result to a double precision floating point number to get a correctly rounded value that we shall call $\tilde{h}$. We note that in some exceedingly rare situations this may not be exactly true.

Our tests will consist of creating $10^9$ random pairs of double precision floating point numbers and then running all six algorithms on each pair as well as computing $\tilde{h}$. Then we will note the percentage of times each algorithm differed from $\tilde{h}$ by exactly one ulp and exactly two ulps. This will be summarized in a table along with a description of the probability distribution used to create the test pairs.

Julia code for all four algorithms proposed in this paper and the test function appear in Appendix A.

5 Conclusions

Clearly Algorithm 3 is not viable. It is both less accurate and more work than Algorithm 1. In retrospect, this is not surprising since making the third term in a fused multiply-add as small as possible makes the product of the first two as large as possible. That is a good thing in $\text{fma}()$ since that term is not

rounded until after the third term is added. However, in Algorithm 3 that term is rounded first thus making it possible that the largest rounding error is larger than necessary. Hence, in the absence of a fused multiply-add Algorithm 1 is the clear choice.

The difference between the Algorithms 2 and 4 is almost negligible. Both of them are comparable to the results from the clib_hypot() algorithm. My conclusion is that the best approach is to use the Algorithm 1 if there is no fused multiply-add available and Algorithm 2 otherwise since it is almost as good as Algorithm 4 but requires fewer floating point operations. The convenient thing about this is that in Julia this can be accomplished with the following code since the muladd() function will take advantage of a hardware fused multiply-add where available but will not emulate it in software simulation if not.

```julia
function Hypot(x::T,y::T) where T<:AbstractFloat
    ax,ay = abs(x), abs(y)
    if ay > ax
        ax,ay = ay,ax
    end

    if ay <= ax*sqrt(eps(T)/2) #Note: This also gets ay == 0
        return ax
    end

    if (ax > sqrt(floatmax(T)/2.0)) || (ay < sqrt(floatmin(T)))
        sx,xs = frexp(ax)
        ay = ldexp(ay,-xs)
        return ldexp(sqrt(muladd(sx,sx,ay*ay)),xs)
    else
        return sqrt(muladd(ax,ax,ay*ay))
    end
end
```
Acknowledgments

The author would like to thank Prof. Lucas Wilcox of the Naval Postgraduate School for invaluable help with the subtleties of the Julia programming language, and also Claude-Pierre Jeannerod of INRIA for several very helpful comments on the analysis.

 * Method :
 * If (assume round-to-nearest) z=x*x+y*y
 * has error less than sqrt(2)/2 ulp, than
 * sqrt(z) has error less than 1 ulp (exercise).
 * */
So, compute \(\sqrt{x^2+y^2}\) with some care as follows to get the error below 1 ulp:

1. if \(x > 2y\) use
   \[
   x_1 x_1 + (y y + (x_2 (x + x_1)))\]
   for \(x^2 + y^2\)
   where \(x_1 = x\) with lower 32 bits cleared, \(x_2 = x - x_1\); else
2. if \(x <= 2y\) use
   \[
   t_1 y_1 + ((x - y) (x - y) + (t_1 y_2 + t_2 y))\]
   where \(t_1 = 2x\) with lower 32 bits cleared, \(t_2 = 2x - t_1\),
   \(y_1 = y\) with lower 32 bits chopped, \(y_2 = y - y_1\).

* NOTE: scaling may be necessary if some argument is too large or too tiny

* Special cases:
  * \(\text{hypot}(x, y)\) is INF if \(x\) or \(y\) is +INF or -INF; else
  * \(\text{hypot}(x, y)\) is NAN if \(x\) or \(y\) is NAN.

* Accuracy:
  * \(\text{hypot}(x, y)\) returns \(\sqrt{x^2+y^2}\) with error less than 1 ulps (units in the last place)
