Abstract

Materials that demonstrate large magnetoresistance have attracted significant interest for many decades. Recently, extremely large tunnel magnetoresistance (TMR) has been reported by several groups across ultrathin CrI₃ by exploiting the weak antiferromagnetic coupling between adjacent layers. Here, we report a comparative study of TMR in all three chromium trihalides (CrX₃, X= Cl, Br, or I) in the two-dimensional limit. As the materials exhibit different transition temperatures and interlayer magnetic ordering in the ground state, tunneling measurements allow for an easy determination of the field–temperature phase diagram for the three systems. By changing sample thickness and biasing conditions, we then demonstrate how to maximize and further tailor the TMR response at different temperatures for each material. In particular, near the magnetic transition temperature, TMR is non-saturating up to the highest fields measured for all three compounds owing to the large, field-induced exchange coupling.
Materials that show a substantial change in resistance in response to an applied magnetic field, or large magnetoresistance (MR), are generally rare but highly sought-after, both for fundamental interest as well as for potential applications in magnetic sensors and memory\textsuperscript{1-6}. In non-magnetic semimetals, such as WTe\textsubscript{2} or MoTe\textsubscript{2}, extreme positive MR (10\textsuperscript{6}\% at 10T) can be achieved at low temperature due to both a balance of electron and hole carriers\textsuperscript{8-10} as well as their relatively high mobilities\textsuperscript{11,12}. The MR is further non-saturating up to the highest fields measured. In magnetic thin-films or perovskite manganites, respectively, giant (10\textsuperscript{3}\%)\textsuperscript{13} or colossal (10\textsuperscript{6}\%)\textsuperscript{14} negative MR can instead be achieved at higher temperatures. The former effect forms the basis of magnetic memory technology due to the low critical fields needed to saturate the MR.

The recent discoveries of 2D magnets\textsuperscript{15-17}, such as CrI\textsubscript{3}, provide a novel opportunity to explore large MR materials through the use of van der Waals heterostructures. Despite being insulating, electrons can tunnel through the CrI\textsubscript{3} layers in the ultrathin limit. Several groups have previously demonstrated negative tunnel magnetoresistance (TMR) as large as 10\textsuperscript{6}\% in graphene/CrI\textsubscript{3}/graphene junctions under a 2T field at optimized biasing voltage\textsuperscript{18-20}. Here, as the antiferromagnetically coupled CrI\textsubscript{3} layers become polarized by the magnetic field\textsuperscript{21-23}, the tunneling current increases dramatically due to an electron spin-filtering effect\textsuperscript{24}. This result motivates a systematic study of TMR in the entire CrX\textsubscript{3} (X= I, Br, and Cl) family across bias, temperature, sample thickness, as well as contact material. For CrI\textsubscript{3} and CrCl\textsubscript{3} with antiferromagnetic (AFM) interlayer coupling, we observe the largest TMR in slightly thicker samples at low temperature, but which saturates at the critical polarizing field of 2T, while CrBr\textsubscript{3} samples with ferromagnetic (FM) interlayer coupling always show negligible TMR in the ground state. Near the transition temperature, however, all three materials demonstrate non-saturating TMR up to 14T. We interpret this effect as a field-induced splitting of the paramagnetic electron
bandstructure. Surprisingly, this splitting can be over 80% of the value in the ground state. Finally, using NbSe$_2$ with larger work function in place of graphene, we find that exchange splitting is much smaller for hole carriers in the valence band, consistent with theoretical expectations. Our results establish CrX$_3$ as a highly tunable platform to study TMR physics using relatively simple device geometries.

A schematic illustration of our devices is shown in the left panel of Fig. 1a and the detailed fabrication procedure can be found in the Methods section. In short, ultrathin CrI$_3$, CrBr$_3$, or CrCl$_3$ from 2 to 15 layers (L) is exfoliated in a nitrogen-filled glovebox and sandwiched between top and bottom few-layer graphene electrodes (Gr) with full encapsulation by hexagonal boron nitride (hBN) on both sides for sample protection. In the right panel of Fig. 1a, we show an optical image of such a CrI$_3$ device as an example. Our key findings can be summarized as a plot of TMR vs. thickness for each material measured at their “optimal” temperature, as shown in Fig. 1b. While their differences shall be explained in detail in the remaining sections, we note that the largest TMR response is generally observed in samples over 6L, and so we show main measurements on devices in this thickness regime.

We begin with transport behavior without magnetic field in order to confirm the ground-state magnetic properties of CrX$_3$. In Fig. 2, we show temperature-dependent I-V characteristics for few-layer devices incorporating the three different materials (CrI$_3$: 8L, CrBr$_3$: 8L, and CrCl$_3$: 15L). All tunnel junctions exhibit nonlinear current-voltage characteristics due to quantum mechanical tunneling across the insulating layers. At higher bias yielding current above ~1nA, transport is governed by Fowler-Nordheim (FN) tunneling$^{18}$, while for direct tunneling near zero bias, the current is below the noise level (~1pA) for samples of this thickness. A zero-bias conductivity is measurable in thinner samples, however (see Supplementary Fig. S1). For CrI$_3$ and
CrCl$_3$, decreasing temperature lowers the current level for a given voltage, whereas CrBr$_3$ shows the opposite trend. In order to verify this, we additionally measured resistance with continuously changing temperature, and the results are shown in the corresponding insets in the bottom panel of Fig. 2. Here, a marked kink (or peak) was observed at the magnetic transition temperature ($T_{AFM}$ or $T_{FM}$) for each device. By taking the derivative of these curves, we determined the critical temperatures more precisely to be 46K for CrI$_3$, 37K for CrBr$_3$, and 17K for CrCl$_3$ (see Supplementary Fig. S2). These temperatures are consistent with previous reports for bulk CrBr$_3^{25}$ and CrCl$_3^{26}$, although few-layer CrI$_3$ shows a slightly lower value than that for the bulk crystal (61K)$^{27}$, possibly due to different interlayer spin coupling and/or stacking between the two systems$^{28, 29}$. The abrupt change in tunnel resistance at the critical temperature arises from spontaneous exchange splitting of the CrX$_3$ conduction band$^{30, 31}$. We shall later discuss the results for the valence band. Below $T_{AFM}$ ($T_{FM}$), increasing (decreasing) resistance with decreasing temperature for CrI$_3$ and CrCl$_3$ (CrBr$_3$) indicates that the ground-state interlayer magnetic ordering is AFM (FM) between adjacent layers, as tunneling across filters with antiparallel (parallel) spins raises (lowers) the effective barrier height. Schematic illustrations of these effects are shown in the top panel of Fig. 2. These results are consistent with several recent studies of ultrathin CrX$_3$$^{32-34}$. The different ground-state interlayer spin ordering observed in these three materials will yield different phase transitions and TMR behavior upon application of a magnetic field, both of which can be measured in our device geometry. In Fig. 3a-c, we show voltage vs. temperature at constant current for the same three devices at several different fields applied perpendicular to the layers. We chose a small, 0.1nA current level in order to minimize the effects of Joule heating. Nevertheless, we found that measured transition temperatures did not change up to 100nA (Supplementary Fig. S3). In general, increasing magnetic field polarizes spins parallel to the field.
direction. For CrI$_3$ and CrCl$_3$, the field decreases the resistance at low temperature as the interlayer AFM ground state is gradually destroyed, consistent with magneto-optical studies$^{16, 21-23}$. For CrBr$_3$, however, the low-temperature resistance is barely changed, since a spin-parallel, interlayer FM state has already formed in the ground state. Instead, the largest change occurs around the critical temperature. Here, increasing magnetic field stabilizes the parallel spin state, and so the voltage is decreased while the transition temperature into this state, $T_P$, is increased. In CrI$_3$ and CrCl$_3$, we observe that for intermediate magnetic fields, not only is $T_P$ pushed to higher temperatures, but a second transition to an antiparallel interlayer spin state can be seen at temperatures below $T_{AP}$ and decreases for increasing field. In the limit of zero field, $T_P$ and $T_{AP}$ approach $T_{FM}$ and $T_{AFM}$, respectively, critical temperatures for the transition to spontaneous magnetic order. These net results are reproducible over several different samples (see Supplementary Fig. S4). We have additionally performed field-sweep measurements at several different temperatures (see Supplementary Fig. S5). The combined dataset allows us to obtain a field–temperature phase diagram for all three materials, as shown in Fig. 3d-f. In the spin schematics for the ground state, the easy axis is drawn to be out of plane for CrI$_3$ and CrBr$_3$, while it is in-plane for CrCl$_3$, as had been just recently demonstrated$^{32-34}$.

A field-induced transition to the spin-parallel state should be accompanied by substantial TMR. We show I-V plots with and without a 5.5T perpendicular field for CrI$_3$ and CrCl$_3$ (insets of Fig 4a and b) and for CrBr$_3$ (see inset of Supplementary Fig. S6a) at 1.4K. When the field is applied, we generally observe clear TMR as the current is enhanced for any given voltage. For constant voltage biasing $V$, we define the TMR percentage between 0 and 5.5T as $\text{TMR (\%)} = \frac{I(5.5T,V) - I(0T,V)}{I(0T,V)} \times 100\%$,$^{24}$ and have plotted these voltage-dependent values in the main panels of Fig. 4a, Fig. 4b, and Fig. S6a for CrI$_3$, CrCl$_3$, and CrBr$_3$, respectively. First, we notice that the
devices exhibit a noticeable asymmetry between negative and positive voltage. While we are unclear as to the precise origin of this effect, we note that there is an inherent asymmetry built into the device geometry as the top and bottom graphite layers are not identical. Different doping levels between the two will lead to different barrier heights and cause asymmetric I-V as our later analysis will show. Similar behavior was also observed in previous reports\textsuperscript{18, 19}. Nevertheless, at an optimized voltage level, we find that TMR at 1.4K reaches as high as $6\times10^5\%$ in CrI$_3$ and 1490\% in CrCl$_3$ (Fig. 4a and b), whereas a much smaller TMR of $\sim10\%$ was observed in CrBr$_3$ (Fig. S6), owing to the pre-formed, spin-parallel ground state. Overall, we attribute the larger TMR values to the high-quality interfaces naturally formed between the crystalline layers, as well as the sizable spin splitting of the electron bandstructure, which we shall discuss in detail below.

In order to determine the smallest magnetic field necessary to achieve the large TMR, we measured normalized current at the optimal voltage with continuously changing field. These results are shown in main panel of Fig. 4c. We observe that the TMR response for CrI$_3$ and CrCl$_3$ effectively saturates at 2T, the critical polarizing field for these two materials in the ground state\textsuperscript{32}. Up to this field, however, the current for CrI$_3$ increases in discrete steps, while that for CrCl$_3$ increases continuously. This could be understood by the difference in magnetic anisotropy between the two\textsuperscript{31, 32}. Within the layers, CrI$_3$ exhibits the characteristics of a strong Ising ferromagnet with out-of-plane easy axis. A perpendicular field thus acts to flip the layers that are initially polarized in the opposite direction one by one. CrCl$_3$, on the other hand, has an in-plane easy axis, and so the same field smoothly rotates the spins until they are fully aligned. Finally, TMR in the CrBr$_3$ device is small and negligible up to 5.5T. We next repeated these measurements at many different temperatures and have plotted the TMR percentage for all three devices as a function of temperature in Fig. 4d. While both CrI$_3$ and CrCl$_3$ show decreasing TMR with increasing
temperature, CrBr\textsubscript{3} shows the opposite trend up to 40K, at which its maximum TMR is found to be \(~200\%\) (see also Supplementary Fig. S6b). In particular, the values for CrBr\textsubscript{3} and CrCl\textsubscript{3} cross at \(~30\K\).

The contrasting TMR behavior in the three materials could be quantitatively explained by considering spin-dependent tunneling in the FN regime. Here, the current-voltage relation scales as \(\ln\left(\frac{I_{\uparrow\downarrow}}{V^2}\right) \sim \frac{\Phi_{\uparrow\downarrow}(B)^{3/2}}{V}\), where \(\Phi_{\uparrow\downarrow}(B)\) is the tunnel barrier for electrons of different spin in CrX\textsubscript{3} and is tunable by magnetic field. As the work function of few-layer graphene\textsuperscript{35} is expected to be close to the electron affinity of CrX\textsubscript{3}\textsuperscript{36}, the tunneling current is dominated by electron carriers. For CrI\textsubscript{3} and CrCl\textsubscript{3} in the anti-parallel ground state, electrons of both spins encounter a spatially modulated barrier with effective height \(\Phi_{\text{eff,AP}} = \Phi_{\uparrow\downarrow,\text{eff}}\). In the spin-parallel state with \(\gtrsim 2\text{T}\) upward field, the barrier becomes uniform, with \(\Phi_{\text{eff}} < \Phi_{\text{eff,AP}} < \Phi_{\uparrow\downarrow}\).

The lower barrier for spin-up electrons yields an exponential rise in spin-filtered current, which manifests as large TMR. A schematic bandstructure outlining these quantities is shown in the inset of Fig. 4c. The spin-degenerate barrier in the paramagnetic state near the transition temperature, \(\Phi_{\text{PM}}\), is also shown, together with the exchange-induced gap, \(E_{\text{ex}} = \Phi_{\uparrow} - \Phi_{\downarrow} = 2(\Phi_{\text{PM}} - \Phi_{\uparrow})\). By fitting the current-voltage data to the FN formula at different magnetic field levels and temperatures, we are able to extract these various barrier heights. More detailed information about this process can be found in Supplementary Information: Section V. These quantities are summarized in Table 1 for all three compounds. In particular, CrI\textsubscript{3} shows larger TMR than CrCl\textsubscript{3} due to larger \(E_{\text{ex}}\) (lower \(\Phi_{\uparrow}\)) relative to \(\Phi_{\text{eff}}\). The exchange splitting decreases with increasing temperature and gradually disappears above \(T_{\text{AFM}}\textsuperscript{18}\).

In contrast, for CrBr\textsubscript{3} at low temperature, increasing field has a negligible effect on the barriers since they are already split uniformly in the P state. The peak TMR in CrBr\textsubscript{3} starting in
the paramagnetic (PM) state near $T_{FM} \sim 40K$ then suggests a different mechanism. In order to explore this further, we have measured current vs. field at optimal voltage biasing for all three materials at their respective magnetic transition temperatures. In Fig. 5a, we show this dependence with current normalized to that at zero field. In all cases, current increases smoothly without saturation up to 14T, with CrI$_3$ showing the largest change, corresponding to a TMR value of 17000%.

At these temperatures, increasing magnetic field induces the splitting of $\Phi_{PM}$, with $\Phi_{\uparrow}^P < \Phi_{PM} < \Phi_{\downarrow}^P$, also resulting in considerable TMR. We have further extracted $E_{ex}$ as a function of magnetic field by performing full current-voltage measurements, and the results are plotted in Fig. 5b. For comparison, the respective exchange splitting in the ground state is marked as a dashed line. Relative to this value, at 14T the field-induced splitting at the transition temperature is already ~82% in CrI$_3$, ~85% in CrBr$_3$, and ~87% in CrCl$_3$, all two orders of magnitude larger than the Zeeman energy (~1.7meV at 14T). This effect may be analogous to that observed in the colossal MR materials undergoing a PM insulator to FM metal transition, wherein the field suppresses the resistance caused by critical spin fluctuations or phase disorder$^{14}$. This surprising result indicates that large exchange coupling can be induced in these materials at elevated temperatures even with moderate magnetic fields.

Finally, all the analysis of the electron barrier heights so far was carried out on devices using few-layer graphene electrodes with relatively low work function (4.42eV)$^{35}$. We have additionally investigated the spin splitting of the valence band in CrI$_3$ using few-layer NbSe$_2$ contacts with a higher work function (~5.9eV$^{37}$). The results are discussed in Supplementary Information: Section VI. Overall, the critical temperature and field remain similar; however, TMR is $\sim 10^4$ times lower (~70%), from which we estimate $E_{ex}$ to be 2–3meV, consistent with theoretical
expectations

In summary, we have investigated the magnetic properties of all three chromium halides in the atomically thin limit by incorporating them in van der Waals tunnel junctions. We have systematically characterized both the ground state and field-driven phases as well as their TMR behavior with changing bias, temperature, thickness, and metal contact. While thicker samples with smaller work function graphene electrodes generally show higher TMR due to multiple spin filters of tunneling electrons acting in series, we find that the field range of the TMR response can be further tuned with temperature. Our work will have important implications for future devices utilizing these 2D materials.
Methods

Crystal synthesis. CrI$_3$ and CrCl$_3$ single crystals were grown by the chemical vapor transport method. We used a two-zone horizontal tube furnace. The temperature for source (growth) zones was gradually raised to 993 – 873K (823 – 723K) within 24 hours, and then held for 150 hours for actual growth. CrBr$_3$ single crystals was purchased from HQ graphene.

Device fabrication. Graphite (CoorsTek), h-BN (HQ graphene), CrI$_3$, CrBr$_3$, and CrCl$_3$ were exfoliated onto SiO$_2$(285nm)/Si chip within a nitrogen-filled glove box (Inert Pure LabHE, $P_{O_2}, P_{H_2O} < 0.1$ppm). By using a polymer-assisted pickup method reported previously$^{38}$, we sequentially stacked the structure of hBN/graphite/CrX$_3$/graphite/hBN in a home-built transfer setup inside the glove box, followed by transferring whole stack onto pre-patterned Au (40nm)/Ti (5nm) electrodes produced by conventional photolithography & lift-off methods and e-beam deposition. The overlapping area of graphite/CrX$_3$/graphite was set to be ~ 10 µm$^2$ for few-layer devices and ~1 µm$^2$ for bilayer devices. 1.4- to 7- nm-thick CrI$_3$ (2, 4, 8, and 10L), 1.3- to 7.8-nm-thick CrBr$_3$ (2, 8, 10, and 12L), and 1.2- to 9-nm-thick CrCl$_3$ (2, 8, 10, 12 and 15L) were used for fabrication. Graphite flakes were connected to pre-patterned electrodes and h-BN layers were used as protecting layers. Devices were stored inside the glovebox until they were loaded into the cryostat.

I. I-V characteristics for bilayer CrX$_3$ devices

In the main panel of Fig. S1, we show field-dependent I-V characteristics for three bilayer CrX$_3$ devices. The current is measurable down to zero bias. Maximum TMR in these samples is 50% for CrI$_3$, 80% for CrBr$_3$, and 170% for CrCl$_3$, all reduced from their thicker counterparts.

Figure S1. I-V characteristics for 2L (a) CrI$_3$, (b) CrBr$_3$, and (c) CrCl$_3$ devices. CrI$_3$ and CrCl$_3$ devices were measured at 1.4K and CrBr$_3$ device was measured at 40K.
II. Determination of magnetic transition temperature

The magnetic transition temperature of CrX₃ can be more precisely determined by taking the first or second derivatives of voltage vs. temperature (see Fig. S2). At $T_{FM}$, d$V$/dT = 0 in CrBr₃, and at $T_{AFM}$, d²V/dT² is peaked in CrI₃ and CrCl₃.

![Figure S2](image)

**Figure S2.** V vs. T plot and corresponding dV/dT or d²V/dT² of (a) 8L CrI₃, (b) 8L CrBr₃, and (c) 15LCrCl₃ at 0 T.

We measured voltage vs. temperature at several different currents for few-layer CrI₃ to determine the significance of Joule heating on the measured transition temperature (see Fig. S3). $T_{AFM}$ shows little change up to 100nA.

![Figure S3](image)

**Figure S3.** Voltage vs temperature of 8L CrI₃ for several different current biases.
III. Additional magnetotransport measurements for CrCl₃ and CrBr₃ devices

In Fig. S4, we show additional voltage vs. temperature measurements at different perpendicular fields (0, 1, 2, 5.5T) for 10, 12L CrCl₃ devices and 10, 14L CrBr₃ devices. In Fig. S5, we show voltage vs. perpendicular magnetic field at several different temperatures for 8L CrBr₃ and 15L CrCl₃, the same devices shown in Fig. 3. The combined data set allow for the construction of the phase diagrams in Fig. 3d-f.

**Figure S4.** (a) Voltage vs temperature at 1nA for (a) 10L and (b) 12L CrCl₃ at $B_\perp = 0, 1, 2, 5.5T$. Same for (c) 10L CrBr₃.

**Figure S5.** Voltage vs. perpendicular magnetic field at 1 nA for (a) 8L CrBr₃ and (b) 15L CrCl₃ at different temperatures.
IV. Temperature-dependent TMR of CrBr$_3$ device

**Figure S6.** TMR vs. voltage at 5.5T for 12L CrBr$_3$ at (a) 1.4K and (b) 40K. Insets in (a) and (b) show I-V characteristics at 0T and $B_\perp = 5.5T$ for the same devices.

V. Barrier height calculation

We calculated the spin-dependent barrier heights of CrX$_3$ devices using the Fowler-Nordheim (FN) current-voltage relation:

$$I \sim \frac{V^2}{\Phi} \exp\left(-\frac{4d\sqrt{2m}\Phi^3}{3\hbar eV}\right),$$

where $e$ is electronic charge, $d$ is the CrX$_3$ thickness, $m$ is the effective electron mass (estimated to be the free-electron mass), $\hbar$ is the Planck’s constant, and $\Phi$ is the barrier height between the graphene electrode and CrX$_3$. We can linearize this relation by plotting $\ln \left(\frac{I}{V^2}\right)$ vs. $\frac{1}{V}$, and extracting $\Phi$ from the slope. This is shown in Fig. S7 for all three CrX$_3$. The various barrier heights are obtained under different field and temperature conditions.
**Figure S7.** ln (I/V^2) vs. 1/V for (a) 8L CrI₃, (b) 12L CrBr₃, and (c) 12L CrCl₃. Φ is determined by the slope. The magnetic field levels for the traces in (b) are 0, 1, 2, 5.5T from black to gray.
VI. Magnetotransport for CrI$_3$ device using NbSe$_2$ electrodes

We additionally fabricated a CrI$_3$ device with high work function NbSe$_2$ (5.9eV) electrodes to investigate the spin-dependent current for hole transport (h-BN/NbSe$_2$/CrI$_3$/NbSe$_2$/h-BN). The results show that the critical polarizing field remains similar to that for devices using graphene electrodes, but with ~$10^4$ times lower TMR percentage, as shown in Fig. S8.

**Figure S8.** Magnetotransport results for NbSe$_2$/CrI$_3$/NbSe$_2$ tunnel junction device at 1.8K. The thickness for each material was measured to be ~10 nm. (a) Field-dependent voltage measurement at 1nA. (b) I-V plots from 0 to 3T, in sequence from black to grey. (c) voltage-dependent TMR at 3T.
