(Dated: June 3, 2019)

Compact microwave resonators made of superconducting rings containing Josephson junctions (SQUIDs) are attractive candidates for building frequency tunable metamaterials with low losses and pronounced nonlinear properties. We explore the nonlinearity of a SQUID metamaterial by performing a two-tone resonant spectroscopy. The small-amplitude response of the metamaterial under strong driving by a microwave pump tone is investigated experimentally and theoretically. The transmission coefficient $S_{21}$ of a weak probe signal is measured in the presence of the pump tone. Increasing the power of the pump, we observe pronounced oscillations of the SQUID’s resonance frequency $f_{res}$. The shape of these oscillations varies significantly with the frequency of the pump tone $f_{dr}$. The response to the probe signal displays instabilities and sidebands. A state with strong second harmonic generation is observed. We provide a theoretical analysis of these observations, which is in good agreement with the experimental results.

I. INTRODUCTION

Superconducting metamaterials have a number of unique properties that are difficult or impossible to achieve in any other media [1]. A generic element of such a metamaterial, its elementary meta-atom, is a superconducting ring split by a Josephson junction. Each meta-atom thus forms a Superconducting Quantum Interference Device (SQUID), the most relevant circuit element of superconducting electronics. A Josephson junction acts as a nonlinear inductor, the inductance depending on the superconducting current flowing through it. SQUIDs are used in a variety of applications including sensitive measurements of magnetic fields and the detection of very small currents. In the microwave range, the unique properties of SQUIDs include the tunability of their intrinsic resonance frequency $f_{res}$, extremely low losses, and bi- and multistable response [6–10] allowing for a wireless switching between opaque and transparent states of the metamaterial [9–11].

The nonlinear dynamics of Josephson junctions and SQUIDs plays an essential role in the development of parametric amplifiers [12–14] and even evokes interest in fields as remote as biology [15]. Parametric amplifiers are capable of amplifying one of the two quadratures of a signal without adding extra noise. Their performance is fundamentally limited only by quantum noise - an extra-ordinary property making them relevant for applications in various fields ranging from astrophysics to the readout of qubits [16]. Driven beyond the parametric regime by a strong microwave driving, a resonant Josephson Junction circuit exhibits a bifurcation and enters the bi-stable regime with two stable dynamical states, which differ by both amplitude and phase. This behavior has been used to build the so-called Josephson bifurcation amplifier [17].

Here, we study the resonant response of the metamaterial to a weak probe signal, while an additional strong driving (pump) signal pushes the metamaterial into a strongly nonlinear regime. In contrast to studies of intermodulation in SQUID metamaterials [18], where two signals of close frequencies induce sum and difference tones, here we consider signals with remote frequencies and are concerned with the strongly nonlinear behavior induced by the pump. The frequency of the pump is fixed, while the weak signal response is measured over a broad band of frequencies. We note that previously the authors of Refs. [7, 8] presented pioneering studies of the response of a single SQUID to a strong driving focusing on the amplitude-frequency and amplitude-phase characteristics. The analysis given in Refs. [7, 8] resembles that of [9]. Here, by extending the experiment and the theoretical framework to two applied signals and performing a mathematical stability analysis of the solutions, we go beyond these works. We find previously unobserved regions of instability in the response of the SQUIDs. Some of these instabilities are associated with SQUID states that generate harmonics of the driving signal.

The paper is organized as follows: In section II we illustrate the main physical ideas behind our study. Section III describes the experimental setup, details of the measurement procedure, and presents our observations. In Section IV we provide the theoretical analysis of the nonlinear dynamics of an rf-SQUID in the presence of both the weak probe signal and the large amplitude driving tone. We start from revisiting a previously developed analytical approach to the nonlinear SQUID response [9], and then apply it's formalism to the two-tone scenario. Section IV concludes the paper.
II. THE MAIN IDEA

The main idea behind our work is that the large amplitude, steady state response of a nonlinear system to a strong driving can be investigated by a weak probe signal, which is superimposed on the driving (see Fig. 1). The oscillatory response to the the weak probe signal is expected to be small, and hence governed by a linear equation. The parameters of this equation (most relevantly the resonance frequency) will sensitively depend on the amplitude and frequency of the strong driving. Thus, by examining the weak signal response, we gain information about the nonlinear steady state oscillations.

It is known that the response of (non-hysteretic) rf-SQUIDs - our meta-atoms - in a certain range of driving amplitudes and frequencies, has regions with multiple stable steady states, a feature known as multistability [9]. We find that a distinct resonance dip in the response to the probe signal corresponds to each of the stable states, allowing us to map the multistabilities. Furthermore, unstable regions, in which no stable steady-state solutions exist, are seen as gaps within which no resonant response to the weak probe signal is observed.

III. EXPERIMENTAL SETUP AND RESULTS

A. Experimental Setup

The experiments were carried out at a temperature of 4.2 K using a one dimensional array of 54 single junction SQUIDs (rf-SQUIDs). In this setting, each SQUID constitutes a metamaterial atom embedded in a coplanar waveguide (CPW). This is shown in Fig. 2(a). The rf-SQUIDs (see Fig. 2(b)) were fabricated using the well established Nb/AlO$_x$/Nb trilayer process. The SQUID parameters are the same as reported in previous publications and experiments [3]. The value of the Josephson critical current is $I_c = 1.8$ $\mu$A, leading to a zero field Josephson inductance of $L_{J,0} = 82.5$ pH. The geometric loop inductance amounts $L_{geo} = 183$ pH and the shunt capacitance is $C = 2.0$ pF. These characteristics result in a resonance frequency of approximately 14.8 GHz at zero magnetic field. The ratio of zero field Josephson and geometric inductances is $\beta_L = 2\pi I_c L_{geo}/\Phi_0 \approx 0.45$, where $\Phi_0 = h/(2e)$ is the magnetic flux quantum. The value $\beta_L < 0$ indicates that the SQUIDs are in the non-hysteretic regime, thus having each a single stable static state at any magnetic flux.

A strong microwave pump signal generated by a microwave source (the driving tone) was inserted into the CPW to carry out the two-tone spectroscopy of the above described sample. In the presence of this driving tone, we measured the transmission coefficient $S_{21}$ of a weak probe signal propagating through the sample. A vector network analyzer (VNA) (see, Fig. 2(c)) was used for these measurements. Typical frequencies for the two signals were $1 – 10$ GHz and $14 – 20$ GHz for the driving tone and $1 – 16$ GHz for the probe signal. No external magnetic field was applied.

B. Observations

We observed that the frequency dependent transmission coefficient $S_{21}$ of the weak probe signal shows, even in the presence of a strong pump signal, a narrow resonant drop at the resonance frequency $f_{res}$. The resonance frequency $f_{res}$ itself strongly varies with the power of the externally applied pump tone. Typical experimentally measured dependencies of $S_{21}(f_{pr},P)$ on the frequency $f_{pr}$ of the weak probe signal and the power $P$ of the driving tone are presented in Figs. 3-5 for driving tone frequencies of 15 GHz, 6 GHz and 1 GHz, respectively.

For all driving tone frequencies, we observed a substantial decrease of the resonance frequency $f_{res}$ with increas-
FIG. 3. The transmission spectrum of the metamaterial at a driving tone frequency $f_{dr} = 15$ GHz. Driven into a strongly nonlinear regime by a large amplitude driving tone, the SQUID metamaterial shows a resonant response to the weak probe signal of the VNA. The resonance frequency is seen as a minimum in the transmission coefficient $S_{21}$. With increasing driving tone power the resonance frequency drops first, then shows an oscillatory behavior. The blue curve shows the theoretically calculated resonance frequency as given by the harmonic approximation of Eq. (11), while the white curve shows the result obtained by solving Eq. (20).

An additional feature seen in Fig. 3 is the splitting of the resonance curves of different SQUIDs. This splitting is due to the slightly different strength of coupling of each single SQUID to the CPW. If the coupling of a SQUID is comparatively weak, the effect of the driving tone on this particular SQUID also will be smaller. Thus, its resonance curve will be shifted to higher values of the driving tone power.

At lower frequencies of the driving tone ($f_{dr} \leq 7$ GHz) we observe gaps in the probe signal’s resonant response. Such a gap is seen in Fig. 4 at 12 GHz and a driving power of around 0 dBm. It indicates an instability in the response of the strongly driven SQUIDs, as will be explained below. In the vicinity of the gap the resonance curve splits. This is due to the existence of two stable SQUID states in this range of parameters. Both states are occupied by some of the 54 SQUIDs of our metamaterial, allowing us to image the bistability directly.

Lowering the driving frequency even further, we observe resonant sidebands in the probe signal’s transmission coefficient $S_{21}$ (see Fig. 5). These sidebands are located above and below the main resonance curve, at frequencies $f_{res} \pm 2f_{dr}$, where $f_{dr}$ is the frequency of the driving tone and $f_{res}$ is the resonance frequency at a given power of the driving tone.

All above observations can be explained by an analysis of the nonlinear rf-SQUID dynamics in the presence of a large amplitude microwave signal. The oscillations of the resonance frequency with the power of a driving tone are obtained by treating the response to the probe signal as that of a harmonic oscillator with parameters depending on the power of the driving tone. To obtain the resonance gaps and sidebands, we have to go beyond this harmonic model and turn to a more detailed treatment of the generic SQUID nonlinearity.

IV. THEORETICAL DESCRIPTION

A. The nonlinear response of rf-SQUIDs to a harmonic driving

In order to explain the effects reported in the previous section we assume that the interaction between adjacent rf-SQUIDs is negligible, and that therefore the electrodynamical response of the superconducting metamaterial is determined by the response of individual SQUIDs. The dynamics of an rf-SQUID is governed by a simple circuit
model: the resistively and capacitively shunted Josephson junction (RCSJ) model \cite{19} in parallel with the geometric inductance of the SQUID ring $L_{\text{geo}}$ (see Fig. 2(b)). In this model the time-dependent Josephson phase $\varphi(t)$ satisfies the nonlinear equation:

$$\varphi_{\text{ext}} = \varphi + L_{\text{geo}} C \dot{\varphi} + \frac{L_{\text{geo}}}{R} \dot{\varphi} + \beta L \sin \varphi, \quad (1)$$

where $\varphi_{\text{ext}}$ consists of both, an externally applied driving tone and a probe signal, $\beta_L = L_{\text{geo}}/L_1$, $L_1 = \Phi_0/2\pi I_c$ with $I_c$ being the critical current and $R$ the normal resistance of the Josephson junction.

We start by considering the nonlinear dynamics of an rf-SQUID in the presence of a strong driving tone $\varphi_{\text{ext}} = \varphi_d \sin(\omega_{\text{dr}} t)$. Approximate solutions to Eq. (1) are obtained by exploiting the fact that the response of an rf-SQUID to a driving tone of frequency $\omega_{\text{dr}}$ will mostly be dominated by harmonic oscillations at the same frequency $\omega_{\text{dr}}$. This approach has already been successfully applied to a study of dynamic metastable states that can be excited in an rf-SQUID metamaterial \cite{9} and uses the following ansatz

$$\varphi_{\text{ext}} = \varphi_d \sin(\omega_{\text{dr}} t)$$

$$\varphi(t) = \varphi_a \sin((\omega_{\text{dr}} + \delta) t) \quad (2)$$

Notice that $\varphi_a \propto \sqrt{P}$ for the driving tone amplitude holds, where $P$ is the power of the driving tone. Inserting the ansatz of Eq. (2) into Eq. (1) the nonlinear term of Eq. (1), is expanded into a Fourier series with the help of a Jacobi-Anger identity \cite{20}

$$\sin(\varphi_a (\omega_{\text{dr}} t + \delta)) =$$

$$2 \sum_{n=0}^{\infty} J_{2n+1}(\varphi_a) \sin((2n+1)(\omega_{\text{dr}} t + \delta)), \quad (3)$$

where $J_n(x)$ are Bessel functions of $n$th-order. All terms of this expansion except for $n = 0$ are neglected according to our assumptions and Eq. (1) reads

$$\varphi_{\text{dr}} \sin(\omega_{\text{dr}} t) =$$

$$\left(1 - \frac{\omega_{\text{dr}}^2}{\omega_{\text{geo}}^2}\right) \varphi_a \sin(\omega_{\text{dr}} t + \delta)$$

$$+ \frac{\omega_{\text{dr}}}{\omega_c} \varphi_a \cos(\omega_{\text{dr}} t + \delta)$$

$$+ 2\beta_L J_1(\varphi_a) \sin(\omega_{\text{dr}} t + \delta), \quad (4)$$

where $\omega_c = R/L_{\text{geo}}$ and the geometrical frequency is given by $\omega_{\text{geo}} = (L_{\text{geo}} C)^{-1/2}$. Rewriting Eq. (1) in terms of $\sin(\omega_{\text{dr}} t)$ and $\cos(\omega_{\text{dr}} t)$ and comparing the coefficients of these functions we obtain an equation for the amplitude of the driving tone $\varphi_{\text{dr}}$, in terms of the amplitude of the Josephson phase response $\varphi_a$:

$$\varphi_{\text{dr}} =$$

$$\sqrt{\left(1 - \frac{\omega_{\text{dr}}^2}{\omega_{\text{geo}}^2}\right)^2 \varphi_a^2 + 4 \beta_L^2 J_1^2(\varphi_a)} + \frac{\omega_{\text{dr}}^2}{\omega_c^2} \varphi_a^2. \quad (5)$$

For the SQUIDs used here the resistance $R$ is in is of the order of 10 k$\Omega$ and hence $\omega_c \approx 50 \cdot 10^3/\text{s}$. Thus, to a good approximation, the last term in Eq. (5) can be neglected.

From Eq. (5) one can see that if the SQUID is driven at a frequency near the geometric resonance, i.e. $\omega_{\text{dr}} \approx \omega_{\text{geo}}$, we have $\varphi_{\text{dr}} \approx 2 \beta_L J_1(\varphi_a)$. Since $J_1(\varphi_a)$ is an oscillating function, the inverse function $\varphi_a(\varphi_{\text{dr}})$ is multi-valued. This phenomenon is referred to as multi-stability and was experimentally observed by Jung et al. \cite{9} as well as by Refs. \cite{7} \cite{8}, however, without putting an emphasis on it. The response amplitude of a SQUID as a function of the driving amplitude $\varphi_a(\varphi_{\text{dr}})$ for $\omega_{\text{dr}} \approx 0.988 \cdot \omega_{\text{geo}}$ is shown in Fig. 6. Some parts of the curve $\varphi_a(\varphi_{\text{dr}})$ are unstable in the sense, that any small perturbation to the amplitude $\varphi_a$ will cause a change of the state of the SQUID. These parts are marked with red dotted lines in Fig. 6.

To investigate the stability of the solutions of Eq. (5), we followed a standard procedure \cite{21}, where the time evolution of a small perturbation to the phase and amplitude of the SQUID response as given by Eq. (2) is studied. The response is written $\varphi_a \sin(\omega_{\text{dr}} t + \delta) = x \sin \omega_{\text{dr}} t + y \cos \omega_{\text{dr}} t$ with $\varphi_a = \sqrt{x^2 + y^2}$, $\delta = \arctan(y/x)$ and the perturbations $\lambda_1(t)$ are added: $x \to x + \lambda_1(t)$, $y \to y + \lambda_2(t)$, $\lambda(t) \ll 1$. Linear differential equations are then derived for $\lambda_i(t)$ from Eq. (1) assuming the validity of Eq. (5). In unstable regions the perturbations $\lambda_i(t)$ show an exponential growth, while
The response is assumed to be of the form 
\[ \varphi = \varphi_a \sin (\omega_{dr} t + \delta) + \varphi_{pr} \] 
Eq. (1) then takes the following form:

\[ \varphi_{dr} \sin (\omega_{dr} t) + \varphi_{pr,ext} = \varphi_a \sin (\omega_{dr} t + \delta) + \varphi_{pr} \]

\[ - \omega_{dr}^2 \varphi_a \sin (\omega_{dr} t + \delta) + \omega_{geo}^2 \varphi_{pr} \]

\[ + \omega_{dr} \omega_{c} \varphi_a \cos (\omega_{dr} t + \delta) + \omega_{c}^{-1} \varphi_{pr} \]

\[ + \beta_L \sin (\varphi_a \sin (\omega_{dr} t + \delta) + \varphi_{pr}) \]  
Eq. (6)

For a weak probe signal, the response \( \varphi_{pr} \) will be small. Expanding up to the first order in \( \varphi_{pr} \), the nonlinear term of (6) becomes

\[ \sin (\varphi_a \sin (\omega_{dr} t + \delta)) + \cos (\varphi_a \sin (\omega_{dr} t + \delta)) \cdot \varphi_{pr} \] 
Eq. (7)

At this point a key assumption enters the calculation: since the VNA signal is very weak and \(| \varphi_{pr} | \ll \varphi_a \), its presence does not significantly alter the state of the SQUID. It is hence assumed that the Eq. (4) is still valid. Substituting Eqs. (4) and (7) into Eq. (6) we obtain an effective equation for the response \( \varphi_{pr} \) to the VNA signal:

\[ \varphi_{pr,ext} = \varphi_{pr} + \omega_{geo}^{-2} \varphi_{pr} + \omega_{c}^{-1} \varphi_{pr} \]

\[ + \beta_L \cos (\varphi_a \sin (\omega_{dr} t + \delta)) \cdot \varphi_{pr} \] 
Eq. (8)

This equation with a time dependent, periodic coefficient is known as Hill’s equation [22]. Solutions of the homogeneous part of this equation can be unstable in the sense that their amplitude exponentially grows in time [22, 23]. These instabilities, however, only occur for specific values of \( \omega_{dr} \), \( \varphi_a \) and \( \omega_c \) and will be studied in next subsection. Here, solely the special solution to (8) is of interest, and only the time average of \( \cos (\varphi_a \sin (\omega_{dr} t + \delta)) \) over one period, i.e. the zeroth Fourier mode, will be taken into account. We use the Jacobi-Anger identity [20]

\[ \cos (\varphi_a \sin (\omega_{dr} t + \delta)) = \]

\[ J_0(\varphi_a) + 2 \sum_{n=1}^{\infty} J_{2n} (\varphi_a) \cos (2n (\omega_{dr} t + \delta)) \] 
Eq. (9)

And approximate the Eq. (8) by

\[ \varphi_{pr,ext} = [1 + \beta_L J_0(\varphi_a)] \varphi_{pr} + \omega_{c}^{-1} \varphi_{pr} + \omega_{geo}^{-2} \varphi_{pr} \] 
Eq. (10)

The frequency of the resonant drop of the probe signal’s transmission coefficient \( S_{21} \) then is

\[ f_{res} = \frac{\omega_{geo}}{2 \pi} \sqrt{[1 + \beta_L J_0(\varphi_a)] - \frac{\omega_{geo}^2}{2 \omega_c^2}} \] 
Eq. (11)

This result gives the shift of the resonance frequency as a function of the amplitude of the driving response \( \varphi_a \) (see Eq. (5)). In the experimental data, however, the transmission coefficient \( S_{21} \) is plotted against the power of the driving tone, \( P \). We thus introduce a coupling constant \( C \) by means of

\[ \varphi_{dr} = C \sqrt{P} \] 
Eq. (12)
When fitting Eq. (11) to experimental data, $C$ is the only free parameter. It has to be obtained independently for every driving tone frequency, since the transmission through microwave cables and devices is frequency dependent.

In Figs. 3, 5 the SQUID resonance frequency predicted by Eq. (11) is plotted blue. Unsurprisingly, the analysis presented so far describes the experiment best at high driving frequency regions (Fig. 3), since in this regime the time dependent terms in the expansion of Eq. (9) are expected to average out. However, even at low driving tone frequencies the Eq. (11) is in a good accord with experimental results (Figs. 4 and 5).

2. Parametric instabilities of the SQUID response

At certain values of the driving frequency $\omega_{dr}$ and the driving amplitude $\varphi_{dr}$ the solution to the homogeneous part of equation (6) becomes unstable [22]. To describe this phenomenon called parametric instability, or parametric resonance [23], we take into account the driving tone frequencies the Eq. (11) is in a good accord with experimental results (Figs. 4 and 5).

At the same time the frequency of the second harmonic of the response with a frequency of $2f_{dr}$, too, becomes approximately equal to the resonance frequency. The amplitude of the second harmonic can therefore be expected to grow in this regime. In fact, numerics show that the resonant drop in Fig. 4 which is not described by Eqs. (11) or (20), results from a SQUID state where the amplitudes $\varphi_{a1}$, $\varphi_{a2}$, of the first and second harmonics with frequencies $\omega_{dr}$ and $2\omega_{dr}$ have the same order of magnitude. We therefore use the Ansatz

\[ \varphi(t) = \varphi_{a1} \sin (\omega_{dr}t + \delta_1) + \varphi_{a2} \sin (2\omega_{dr}t + \delta_2) \]  

(17)
to describe this state. The frequency of the resonant drop is obtained analogously to (11) and given by

\[ f_{res} = \frac{\omega_{geo}}{2\pi} \left( 1 + \beta_{L} J_{0}(\varphi_{a1}) J_{0}(\varphi_{a2}) \right. \]

\[ \left. + 2 \beta_{L} \sum_{n=1}^{\infty} J_{2n}(\varphi_{a1}) J_{2n}(\varphi_{a2}) \cos (2n(2\delta_1 - \delta_2)) \right)^{1/2}. \]

(18)

The amplitudes $\varphi_{a1}$ and $\varphi_{a2}$ are obtained numerically as Fourier coefficients of the first and second harmonics of the solution to Eq. (1). The green solid line in Fig. 4 shows the resonance as described by Eq. (18) in comparison with experimental results.

This bistability which is characterized by a response at twice the driving frequency for one of the stable states is a
new feature of the SQUID nonlinearity, not yet reported to our knowledge. In fact, the observation of this bistability demonstrates the advantages of the two-tone spectroscopy over frequency-amplitude and frequency-phase measurements, in which it cannot be imaged with such ease. We expect that other irregularities in the weak signal response, like e.g. the ones seen in Fig. 5, can similarly be explained in terms of states with a strong response at harmonics of the driving tone.

4. Sideband resonances

Figure 5 shows the response to the probe signal at a low driving tone frequency \( \omega_{dr} \ll \omega_{pr} \). We observe sideband resonances approximately 2 GHz above and below the main resonance. These sidebands appear due to the term \( J_2(\varphi_t) \cos (2\omega_{dr}t) \) in the probe signal equation (13). The term mixes the oscillation at \( \omega_{pr} \) with modes at frequencies separated from it by a multiple of \( 2\omega_{dr} \). To calculate the positions of the sidebands we therefore use the ansatz

\[
\varphi(t) = a \sin (\omega_{pr}t) + b_1 \sin (\omega_{pr}t + 2\omega_{dr}t) + b_2 \sin (\omega_{pr}t - 2\omega_{dr}t)
\]

and \( \varphi_{pr,ext} = \varphi_{pr} \sin (\omega_{pr}t) \). To describe the sidebands nearest to the main resonance, modes with frequencies further away from \( \omega_{pr} \), i.e. \( \omega_{pr} \pm 4\omega_{dr}, \omega_{pr} \pm 6\omega_{dr} \), and so on can be neglected. Since the dissipation is rather small, one can neglect phase shifts \( \delta \) in the above ansatz.

We substitute (19) into (13) and solve for \( a(\varphi_{pr}) \). With dissipation being neglected, resonances occur at those frequencies \( \omega_{pr} \) at which \( a(\varphi_{pr}) \propto \varphi_{pr} \) diverges, or, equivalently,

\[
\varphi_{pr}(a) = 0 .
\]

Solving Eq. (20) involves finding the roots of a sixth-order polynomial in \( \omega_{pr} \), which is done numerically. For most values of the driving tone frequency \( \omega_{dr} \) and power \( P \), the equation (20) has three positive roots, corresponding to the main resonant response and two sidebands. The resonance and sideband curves predicted by Eq. (20) for the driving tone frequency of 1 GHz are plotted in Fig. 5 (the white solid line) and are in good agreement with the experiment. For higher driving tone frequencies (Fig. 4), the sidebands are outside of the experimentally accessible frequency range. The main resonance curves given by Eq. (20) (white solid line) and Eq. (11) (blue solid line) agree with each other rather well. In unstable regions, the roots found solving Eq. (20) are complex, and hence no resonances can be observed. The region of parametric instability determined in this way is consistent with the region determined by the conditions of Eqs. (15), (16).

V. CONCLUSIONS

We presented the results of a two-tone spectroscopy of an rf-SQUID metamaterial consisting of 54 single SQUIDs placed in a transmission line. The power of the pump (driving) tone was typically much higher than the power of the probe signal used to measure the transmission spectrum.

We observed that the resonance frequency of the metamaterial, seen as a drop in the transmission spectrum of the probe signal at frequencies between 10 and 15 GHz, shows a characteristic oscillatory dependence on the power of a pump tone. The frequency of the pump tone was varied between 1 GHz and 20 GHz, changing the shape of the resonance curve.

For pump tone frequencies below or in the region of the resonance frequencies, i.e. for our parameters \( f_{dir} < 14.5 \) GHz, we observed the gaps in the resonance curves of the transmission spectrum. A bistability in the response was directly observed at an intermediate range of the pump frequency (6 GHz). At a low pump frequencies \( f_{dir} \) sidebands located approximately \( 2f_{dir} \), above and below the main resonance curve were found.

Most of our observations are well described theoretically by an approach based on an approximate analytical model for the response of a SQUID to strong external driving. Whereas the shape of the resonance curves naturally followed from an extension of the model to two tones of different amplitudes, the gaps could be explained as parametric instabilities of the SQUID response. The observed bistability is shown to appear due to the existence of a state with strong second harmonic generation.

To summarize, at high driving power levels SQUID metamaterials exhibit a rich spectrum of features tunable by the power and the frequency of the pump tone. The non-linear two tone spectroscopy is a powerful method to study these features, which can be applied to other systems. The high degree of nonlinearity and the unique multistable behavior make superconducting circuits an exciting playground for studies of tunable metamaterials.
