We investigate the competition of coherent and dissipative dynamics in many-body systems at continuous quantum transitions. We consider dissipative mechanisms that can be effectively described by Lindblad equations for the density matrix of the system. The interplay between the critical coherent dynamics and dissipation is addressed within a dynamic finite-size scaling theory, which allows us to identify the regime where they develop a nontrivial competition. We put forward general scaling behaviors involving the Hamiltonian parameters and the coupling associated with the dissipation. This scaling scenario is supported by a numerical study of the dynamic behavior of a one-dimensional lattice fermion gas undergoing a quantum Ising transition, in the presence of dissipative mechanisms such as local pumping, decaying and dephasing.

Understanding the quantum dynamics of many-body systems is one of the greatest challenges of modern physics. The recent progress in atomic physics and quantum optical technologies has provided a great opportunity for a thorough investigation of the interplay between the coherent quantum dynamics and the (practically unavoidable) dissipative effects, due to the interaction with the environment [1–4]. Likely, the most intricate regime is the one characterized by an actual competition of both dynamic mechanisms, which may develop a nontrivial interplay. This can be responsible for the emergence of further interesting phenomena in many-body systems, in particular when they are close to a quantum phase transition, where quantum critical fluctuations emerge and correlations develop a diverging length scale [5].

In this paper we study the dynamic behavior of a many-body system close to a continuous quantum transition, in the presence of dissipation. We consider a class of dissipative mechanisms that can be effectively described by Lindblad equations for the density matrix of the system [6–7]. We address the interplay between the critical coherent dynamics and dissipative mechanisms within a dynamic finite-size scaling (FSS) framework, which allows us to identify the dynamic regime where a nontrivial competition develops. General scaling behaviors are put forward, involving both the Hamiltonian parameters and the couplings associated with the dissipative terms of the Lindblad equation. To verify the emerging scaling scenario, we consider the paradigmatic one-dimensional Kitaev fermion model [8]. We study its dynamic behavior close to its quantum Ising transition, in the presence of local incoherent pumping, decay and dephasing. The numerical results reported below nicely support the general dynamic FSS theory addressing the competition between critical coherent dynamics and dissipation.

Our considerations apply to a generic \(d\)-dimensional many-body system with Hamiltonian \(\hat{H}\), close to a zero-temperature transition driven by quantum fluctuations [9]. A quantum transition is generally characterized by few relevant perturbations, whose tuning gives rise to quantum critical behaviors, characterized by a diverging length scale, and universal power laws. We assume that the many-body system is also subject to dissipative interactions with the environment, so that the time dependence of its density matrix \(\rho\) is described by the Lindblad master equation [6]

\[
\frac{\partial \rho}{\partial t} = -\frac{i}{\hbar} [\hat{H}, \rho] + u \sum_o D_o [\rho],
\]

where the first term provides the coherent driving, while the second term accounts for the coupling to the environment. Its form depends on the nature of the dissipation arising from the interaction with the bath, which is effectively described by a set of dissipators \(D_o\), and a global coupling \(u > 0\). In the case of systems weakly coupled to Markovian baths, the trace-preserving superoperator \(D_o [\rho]\) can be generally written as [10–11]

\[
D_o [\rho] = \hat{L}_o \rho \hat{L}_o^\dagger - \frac{1}{2} \left< \rho \hat{L}_o^\dagger \hat{L}_o + \hat{L}_o \hat{L}_o^\dagger \rho \right>,
\]

where \(\hat{L}_o\) is the Lindblad jump operator associated to the system-bath coupling scheme. In the following we will restrict to homogeneous dissipation mechanisms, preserving translational invariance, as depicted, for example, in Fig. 1. In quantum optical implementations, the conditions leading to Eqs. (1)–(2) are typically satisfied [12], therefore this formalism constitutes the standard choice for theoretical investigations of this kind of systems.

The dissipator \(\mathbb{D} \equiv \sum_o D_o\) typically drives the system to a steady state, which in general is noncritical, even when the Hamiltonian parameters are critical. However,
one may identify a dynamic regime where the dissipation is sufficiently small to compete with the coherent evolution driven by the critical Hamiltonian, leading to potentially novel dynamic behaviors. This is the target of the present article. As discussed below, such low-dissipation regime naturally emerges within a dynamic FSS framework, assuming many-body systems of linear size $L$ (i.e., of dimension $L^0$), where the effects of the coherent and dissipative driving terms are somehow of dimension $L$.

The dynamic FSS framework that we consider is an extension of the FSS theory at quantum transitions, already developed at equilibrium [1,13,14] and in out-of-equilibrium conditions [15,16] for closed systems. Let us assume that the Hamiltonian Hamiltonian has one relevant parameter $\mu$, whose tuning toward the point $\mu_c$ develops a quantum critical behavior. The critical power laws are generally characterized by the renormalization-group (RG) dimension $y_\mu$ of the relevant parameter $\mu \equiv \mu - \mu_c$ and the dynamic exponent $z$, so that the diverging length scale behaves as $\xi \approx |\mu|^{-\nu}$ with $\nu = 1/y_\mu$ and the suppression of the gap (difference of the two lowest energy levels) as $\Delta \approx \xi^{-\frac{1}{2}}$. The finite size $L$ of the system provides a further relevant length scale. FSS is defined by taking the large-$L$ limit, keeping appropriate scaling variables fixed, such as $\xi/L$ and $\Delta L^z$ (thus $\Delta \sim L^{-z}$).

Moreover, to describe out-of-equilibrium dynamic protocols, for example arising from a quench of the Hamiltonian control parameter $\mu$, a further time scaling variable $\theta \propto t\Delta$ has to be introduced [15]. For example, let us consider a sudden quench of $\mu$ at $t = 0$, from $\mu_i$ to $\mu_f$, starting from the ground state associated with the initial value $\mu_i$. We expect that the coherent evolution of a generic observable $G_O$, such as the fixed-time correlation of two local operators $\hat{O}$ at a distance $x$, undergoes the asymptotic FSS behavior [15]:

$$G_O(x,t,\mu_i,\mu_f,L) \approx L^{-2y_\theta} G_O(X,\theta,\kappa_i,\kappa_f), \quad (3)$$

$$X \equiv x/L, \quad \theta \equiv t L^{-\frac{1}{2}}, \quad \kappa_i/\kappa_f \equiv \mu_i/\mu_f L^\nu, \quad (4)$$

where $y_\theta$ is the RG exponent associated with $\hat{O}$. This scaling behavior is expected to be universal, i.e., largely independent of the microscopic properties of the system.

To account for the effects of the dissipators [2], we need to extend the above dynamic FSS theory. We assume that at $t = 0$, beside quenching the Hamiltonian parameter $\mu$, the dissipation is also turned on, by effectively, and suddenly, switching the corresponding effective coupling from zero to some finite value $u > 0$. We argue that the effects of a sufficiently low dissipation can be taken into account by adding a further dependence on a FSS variable associated with $u$ in the dynamic FSS ansatz [3], i.e., $\gamma \equiv u L^\zeta$ where $\zeta$ is a suitable exponent, to ensure the substantial balance, thus competition, with the critical coherent driving. Since dissipation is predicted to give rise to a relevant perturbation at the quantum transition, we expect $\zeta > 0$. Thus, the low-dissipation regime, where the critical coherent dynamics and dissipation compete, should be characterized by $u \sim L^{-\zeta}$.

We conjecture that the exponent $\zeta$ coincides with the dynamic exponent $z$. Indeed, we note that the parameter $u$ of the dissipator in Eq. (1) plays the role of decay rate, i.e., of an inverse relaxation time, of the associated dissipative process [6]. Since any relevant time scale $t_s$ at a quantum transition behaves as $t_s \sim \Delta^{-1}$ [15], we identify the dissipation scaling variable as

$$\gamma \equiv u L^\zeta. \quad (5)$$

In other words, to observe a nontrivial competition between critical coherent dynamics and dissipation, one should consider a sufficiently small coupling $u \sim L^{-z}$, so that its size is comparable with the energy difference $\Delta \sim L^{-z}$ of the lowest energy levels of the critical Hamiltonian. Under the combined effect of coherent and dissipative driving, the dynamic FSS ansatz should read

$$G_O(x,t,\mu_i,\mu_f,u,L) \approx L^{-2y_\theta} G_O(X,\theta,\kappa_i,\kappa_f,\gamma). \quad (6)$$

We conjecture that this scaling ansatz describes the low-dissipation regime of quenching protocols for many-body systems at quantum transitions [17]. The main features of such dynamic regime are expected to depend only on the universality class of the transition and the general properties of the dissipative mechanism.

We now present numerical evidence of the above conjecture. To this purpose, we consider a Kitaev quantum wire defined by the Hamiltonian [8]

$$\hat{H}_K = -t \sum_{j=1}^L \left( c_j^\dagger c_{j+1} + \delta c_j^\dagger \sigma_j \right) + h.c. - \mu \sum_{j=1}^L \tilde{n}_j, \quad (7)$$

where $c_j$ is the fermionic annihilation operator on the $j$th site of the chain, $\tilde{n}_j \equiv c_j^\dagger c_j$ is the density operator, and $\delta > 0$. We consider antiperiodic boundary conditions, $\tilde{c}_{L+1} = -\tilde{c}_1$, [15] set $\hbar = 1$, and $t = 1$ as the energy scale.

The Hamiltonian (7) can be mapped into a spin-1/2 XY chain, by means of a Jordan-Wigner transformation [5]. It undergoes a continuous quantum transition at $\mu = \mu_c = -2$, independently of $\delta$, between a disordered ($\mu < \mu_c$) and an ordered quantum phase ($|\mu| > |\mu_c|$). This transition belongs to the two-dimensional Ising universality class [3], characterized by the length-scale critical exponent $\nu = 1$, related to the RG dimension $y_\mu = 1/\nu = 1$ of the Hamiltonian parameter $\mu$ (more precisely of the difference $\mu \equiv \mu - \mu_c$). The dynamic exponent associated with the unitary quantum dynamics is $z = 1$.

Moreover, the RG dimension of the fermionic operator $c_j$ is $y_c = 1/2$, and that of the density operator $\tilde{n}_j$ is $y_n = 1$ [5]. In the following we set $\delta = 1$ (without loss of generality), such that the corresponding spin model is the quantum Ising chain $\hat{H}_{IS} = -\sum_j \delta_j^{(3)} \sigma_j^{(3)} - g \sum_j \delta_j^{(1)}$, where $\delta_j^{(k)}$ are the Pauli matrices and $g = -\mu/2$ [19].
We focus on the dynamic behavior of the Fermi lattice gas close to its quantum transition, in the presence of homogeneous dissipation mechanisms following the Lindblad equation \[ \dot{\rho} = -i[H, \rho] + \sum_j \mathbb{D}_j[\rho] \] with site-dependent dissipators \( \mathbb{D}_j[\rho] \). The onsite Lindblad operators \( L_j \) describe the coupling of each site with an independent bath \( \mathbb{B} \), and are associated with particle loss (\( L_j c_j \)), pumping (\( L_{\text{p}j} c_j^\dagger \)), and dephasing (\( L_{\text{d}j} n_j \)), respectively:

\[
\hat{L}_{\text{a}j} = \hat{c}_j, \quad \hat{L}_{\text{p}j} = \hat{c}_j^\dagger, \quad \hat{L}_{\text{d}j} = \hat{n}_j. \tag{8}
\]

With this choice of dissipators, the full open-system many-body fermionic master equation enjoys a particularly simple treatment, which enables a direct solvability for systems with up to thousands of sites \([24, 25]\). The uniqueness of the eventual steady state has been proven for the above decay and pumping operators \([27–30]\). The lar-}

![FIG. 2: Upper panel: connected density-density correlation function \( G(x,t) \) for \( X = x/L = 1/4 \), as a function of the rescaled time \( \theta = t/L \), after a quench from the ground state at the critical point \( \mu_c = 0 \) to \( \mu_f \) such that \( \kappa_f = \mu_f/L = 2 \). Continuous curves are for pure unitary dynamics \((u = 0)\), where the dynamic FSS is verified; dotted curves are in the presence of incoherent particle losses, with the dissipative coupling \( u \) such that \( u L^{1.25} = 1 \). Lower panel: temporal decay of \( G(x,t) \) for a dissipative dynamics with \( u = 1 \), at criticality \((\mu_c = \mu_f = 0)\). A much faster decay to an uncorrelated state emerges, with a slope that asymptotically depends only on \( x \). All curves are sufficiently accurate to be considered as practically exact, on the scale of this and of all next figures.](image1)

![FIG. 3: The correlation functions \( C(x,t) \) (upper panel), \( P(x,t) \) (central panel), and \( G(x,t) \) (lower panel), for \( X = 1/4 \), versus \( \theta = t/L \). The system has been driven out of equilibrium through a quench from the critical point \( \mu_c = 0 \) to \( \kappa_f = 2 \), and by the dissipation induced by incoherent particle losses, for \( \gamma = u L = 1 \). The curves approach a scaling function with increasing \( L \), thus supporting the dynamic FSS in Eq. (6). Results for other values of \( X, \kappa, \gamma \) and \( \gamma \) confirm it.](image2)

\[ u = 0 \]. We consider the fixed-time correlations:

\[ C(x,t) = \text{Tr}[\rho(t) \{ \hat{c}_j^\dagger \hat{c}_{j+x} + \hat{c}_{j+x}^\dagger \hat{c}_j \}], \tag{9a} \]

\[ P(x,t) = \text{Tr}[\rho(t) \{ \hat{c}_j^\dagger \hat{c}_{j+x} + \hat{c}_{j+x}^\dagger \hat{c}_j \}], \tag{9b} \]

\[ G(x,t) = \text{Tr}[\rho(t) \{ \hat{n}_j \hat{n}_{j+x} - \text{Tr}[\rho(t) \hat{n}_j] \text{Tr}[\rho(t) \hat{n}_{j+x}] \}], \tag{9c} \]

where \( j, x \in [1, L/2] \) and \( \rho(t) \) is the density matrix of the system. The dynamic FSS behavior of the observables \([9a, 9b, 9c]\) is expected to be given by Eq. (6), with \( y_{\mu} = 1, z = 1, y_C = y_P = 1/2 \), and \( y_G = 1 \). This scaling scenario should hold for all the considered dissipation mechanisms, cf. Eq. (8). Of course, the corresponding scaling functions are expected to differ.

Before discussing the emerging scenario from the full model, let us neglect the bath coupling and only consider the unitary dynamics \((u = 0)\). As is visible from the upper panel of Fig. 2 for the density-density correlation \( G(x,t) \) (continuous curves), the scaling behavior emerges in the large-\( L \) limit after the proper rescaling of the pre- and post-quench control parameter and of time as in Eq. (4). An analogous scenario emerges when \( u \ll L^{-2} \); for example for \( u \sim L^{-\zeta} \) with \( \zeta > 0 \), the asymptotic behavior converges to the dynamic FSS scenario with \( u = 0 \) (dotted curves in the upper panel), and thus the coherent dynamics prevails. Conversely, if the coupling \( u \) is switched on and kept fixed with \( L \), the dissipative dynamics overcomes the coherent coherence. Indeed the system exponentially collapses to an uncorrelated state, in a much shorter time scale (bottom panel.
FIG. 4: The integrated correlations $A_P$ and $A_C$, for $Z = z/L = 1/4$, versus $\theta = t/L$. The system is quenched from $\kappa_i = 0$ to $\kappa_f = 2$, and dissipation is induced either by the presence of incoherent particle losses ($\hat{L}_{ij}$, left panels) or by an incoherent dephasing mechanism ($\hat{L}_{di,j}$, right panels), with $\gamma = 1$. The results nicely support Eq. (11), since curves appear to converge to a scaling function with increasing $L$.

---

Since at a quantum transition $\Delta \sim L^{-z}$, this is a low-dissipation regime. This reflects the fact that at a quantum transition the perturbation arising from dissipation is always relevant, such the temperature at equilibrium $|5, 9, 13|$. Therefore, when $u \gg \Delta$, critical coherent fluctuations do not survive dissipation. These arguments should also apply to non-Markovian system-bath couplings $|33|$ (not described by Lindblad equations), replacing $u$ with the parameter controlling the decay rate.

This dynamic scenario has been checked within fermion wires, cf. Eq. (7), in the presence of local dissipation mechanisms associated with the Lindblad operators $|8|$. Further studies would serve to achieve a conclusive validation of our competition theory, for other many-body systems and/or dissipation mechanisms, including nonlocal ones $|34–36|$. Further interesting issues may concern quantum thermodynamic properties $|37|$ arising in the competition regime. The dynamic FSS framework can be also exploited to study other protocols in the presence of dissipation, for example when slowly changing the Hamiltonian parameters across a quantum transition.

Other issues worth being investigated concern the emergence, and characterization, of analogous competition scaling phenomena in many-body systems at first-order quantum transitions, for which dynamic FSS frameworks have been also developed $|15|$, and new features may arise, like a particular sensitivity on the type of boundary conditions $|14, 38|$. We finally mention that some experimental breakthroughs have been recently achieved in the control of dissipative quantum many-body dynamics, through different platforms, such as Rydberg atoms or circuit-QED technology. For example, a quantum critical behavior in such out-of-equilibrium context has been reported $|39–41|$. These studies encourage the verification of our competition theory, using a limited (relatively small) amount...
of controlled objects, which may already suffice to highlight some signatures of the dynamic scaling.

[17] We may derive an analogous scaling ansatz in the infinite volume limit $L \to \infty$, keeping the length scale of the correlations finite. In particular, assuming $\tilde{\mu}_L$ and $\tilde{\mu}_f$ within the disordered phase side (thus the quench protocol does not cross the critical point $\tilde{\mu} = 0$), for which the ground-state length scales $\xi_{\tilde{\mu},f}$ are large but finite, behaving as $\xi_{\tilde{\mu},f} \sim |\tilde{\mu}_f|^{\nu}$, the thermodynamic $L/\xi_{\tilde{\mu},f} \to \infty$ limit of the dynamic FSS ansatz \ref{eq:3-4} can be written as $G_0 \approx \xi_{\tilde{\mu},f}^{-2\nu} \tilde{G}_0(x/\xi_{\tilde{\mu},f}, \xi_{\tilde{\mu},f}/t)^{1-\nu}/t^{\nu}$.

[18] Antiperiodic boundary conditions turn out to be convenient for the calculations presented here. However, the dynamic scaling scenario applies to general boundary conditions as well.

[19] Note however that the non-local Jordan-Wigner transformation of the Ising chain with periodic or antiperiodic boundary conditions does not map into the fermionic model \ref{eq:3} with periodic or antiperiodic boundary conditions. Indeed further considerations apply \ref{20,21}, leading to a less straightforward correspondence, depending on the parity of the particle number eigenvalue. Therefore, although their bulk behaviors in the infinite volume limit, and thus their phase diagram, are analogous, the resulting FSS functions differ, since they depend on the choice of the boundary conditions.

[26] The dynamics of the dissipative fermionic Kitaev chain (Fig. 1) can be written in terms of coupled linear differential equations, whose number scales linearly with $L$. We employ a fourth-order Runge-Kutta method to numerically integrate them. Further details on the computation of the time trajectories from the Lindblad Eq. \ref{eq:1} will be reported elsewhere.

[31] This definition cannot be extended to $z \to 0$ (more precisely $Z \to 0$), because the integral of the two-point function is singular, in that the critical continuum limit at equilibrium $C(x) \sim P(x) \sim 1/x$ at small distance $[5]$.
