We report a comprehensive study of the noncentrosymmetric superconductor Mo₃P. Its bulk superconductivity, with $T_c = 5.5$ K, was characterized via electrical resistivity, magnetization, and heat-capacity measurements, while its microscopic electronic properties were investigated by means of muon-spin rotation/relaxation (µSR) and nuclear magnetic resonance (NMR) techniques. In the normal state, NMR relaxation data indicate an almost ideal metallic behavior, confirmed by band-structure calculations, which suggest a relatively high electron density of states, dominated by the Mo 4d-orbitals. The low-temperature superfluid density, determined via transverse-field µSR and electronic specific heat, suggest a fully-gapped superconducting state in Mo₃P with $\Delta_0 = 0.83$ meV, the same as the BCS gap value in the weak-coupling case, and a zero-temperature magnetic penetration depth $\lambda_0 = 126$ nm. The absence of spontaneous magnetic fields below the onset of superconductivity, as determined from zero-field µSR measurements, indicates a preserved time-reversal symmetry in the superconducting state of Mo₃P and, hence, spin-singlet pairing.

I. INTRODUCTION

Noncentrosymmetric superconductors (NCSCs) belong to a class of materials that miss a key symmetry, such as parity. In NCSCs the lack of inversion symmetry of the crystal lattice often induces an antisymmetric spin-orbit coupling (ASOC), which lifts the degeneracy of the conduction-band energy levels and splits the Fermi surface. Consequently, both intra- and inter-band Cooper pairs can be formed. The admixture of spin-singlet and spin-triplet pairing in NCSCs is determined by the strength of the ASOC and by other microscopic parameters. Cooper pairs with a spin-triplet pairing have a nonzero spin, which implies a weak moment in the superconducting state and a breaking of the time-reversal-symmetry (TRS). This is the case of, e.g., Sr₂RuO₄ and UPt₃, known to exhibit triplet superconductivity, and where TRS breaking in the SC state has been confirmed by measurements of both zero-field muon-spin relaxation/rotation (µSR) and polar Kerr effect.

Some NCSCs are known to show a broken TRS upon the onset of superconductivity. Examples include LaNiC₂, La₇Ir₃, and some Re-based binary alloys ReT (T = transition metal, e.g., Ti, Zr, Nb, Hf) in the weak SOC limit. TRS breaking can be achieved via nonunitary triplet pairing, such as in non-centrosymmetric LaNiC₂ and centrosymmetric LaNiGa. In case of ReT alloys, where a strong SOC is present, the $T_f$ point group has several irreducible representations with dimension larger than 1. Therefore, they can support TRS breaking with singlet-, triplet-, or admixed pairing. For ReT, there are a number of possible TRS-breaking states, however, all such states have symmetry-constrained point- or line nodes in the gap, inconsistent with the experimentally observed nodeless-gap. To explain a fully-gapped superconducting state exhibiting broken TRS, a model employing loop-Josephson currents (LJC) was recently proposed. This model is based on an on-site-, intra-orbital-, singlet-pairing SC state, where a phase shift among the on-site singlet pairs gives rise to the LJC within a unit cell. Such currents can produce weak internal magnetic fields, which break the TRS and can, in principle, be detected experimentally.

Despite numerous examples of NCSCs, to date only a few of them are known to break TRS in their superconducting state. The causes of such a selective TRS breaking remain largely unknown. Consequently, comprehensive studies of other NCSCs, such as Mo₃P, reported here, may help to identify the origin of this behavior. Superconductivity in Mo₃P was first reported in 1954 and confirmed ten years later. In that same year, also the Mo₃P crystal structure was determined. To our knowledge, none of these early works had a follow-up regarding the characterization of the superconducting properties of Mo₃P.

In this paper, we report on an extensive study of the Mo₃P physical properties, in the normal and superconducting state, by means of electrical resistivity, magnetization, thermodynamic, muon-spin relaxation (µSR) and nuclear magnetic resonance (NMR) methods. In addition, we also present theoretical density functional theory (DFT) band-structure calculations. Despite a noncentrosymmetric crystal structure, Mo₃P is shown to be a moderately correlated electron material, which adopts a fully-gapped, spin-singlet superconducting state with preserved TRS.

II. EXPERIMENTAL DETAILS

Polycrystalline samples of Mo₃P were prepared via solid-state reaction, where high-purity (99.999%) Mo powders and P pieces were mixed in a stoichiometric ratio and made to react at 1100 °C for 48 hours. The resulting powders were thoroughly ground and pressed into pellets and then sintered at 1100 °C for over 48 hours. The final product had a silvery color, indicative of good metallicity. Room-temperature x-ray powder diffraction (XRD) measurements were performed by using a Bruker D8 diffractometer with Cu Kα radiation. The magnetic susceptibility, electrical resistivity, and specific-heat measurements were performed on a 7-T Quantum Design Magnetic Property Measurement System (MPMS-7) and a 14-T Physical Property Measure-
mment System (PPMS-14) equipped with a dilution refrigerator (DR). The μSR measurements were carried out at the GPS and HAL-9500 spectrometers of the Swiss muon source at Paul Scherrer Institut, Villigen, Switzerland. For the low-temperature HAL measurements, the samples were mounted on a silver plate using diluted GE varnish. The μSR data were analysed by means of the musrfit software package.

The 31P NMR measurements, including lineshapes and spin-lattice relaxation times were performed on Mo3P powder in two external magnetic fields, 0.503 and 7.067 T. This allowed us to compare the NMR parameters in the superconducting and the normal state, respectively. The NMR signals were monitored by means of standard spin-echo sequences, with a substantially improved accuracy. According to the temperature-dependent electrical resistivity in the low-temperature region is shown in the inset. FIG. 1. Room-temperature x-ray powder diffraction pattern and Rietveld refinement for Mo3P. The open red circles and the solid black line represent the experimental pattern and the Rietveld-refinement profile, respectively. The blue lines at the bottom show the residuals, i.e., the difference between calculated and experimental data. The vertical bars mark the calculated Bragg-peak positions for Mo3P (green), MoO2 (blue), and MoO2 (purple).

The electronic structure of Mo3P was calculated by using the full-potential linearized augmented plane-wave (LAPW) method, as implemented in the WIEN2k package. In particular, we employed the generalized gradient approximation (GGA). The Brillouin zone integration was performed on a regular mesh of 10×10×10 points. Muffin-tin radii (rmt) of 2.41 and 2.06 fmohr were chosen for Mo and P atoms, respectively. The largest plane-wave vector was defined by rmtkmax = 8. The SOC was treated by using a second-order variational procedure.

III. RESULTS AND DISCUSSION

A. Crystal structure

The crystal structure and the purity of Mo3P polycrystalline samples were checked via XRD at room temperature. Figure 1 shows a representative XRD pattern, analyzed by means of the FullProf Rietveld-analysis suite. As previously reported, we confirm that Mo3P crystallizes in the tetragonal noncentrosymmetric a-V, S-type structure with space group I42m (No. 121). The refined lattice parameters, a = b = 9.79094(2) Å and c = 4.826099(13) Å, are consistent with the reported values, but here established with a substantially improved accuracy. According to the refinements in Fig. 1, tiny amounts of Mo4P3 (3.46%) and MoO3 (4.28%) phases were also identified. The refined Mo3P crystal structure, shown in the inset, comprises three different Mo sites and a single P site in the unit cell. Table I summarizes the atomic positions and the lattice parameters.

B. Electrical resistivity

The temperature-dependent electrical resistivity ρ(T) of Mo3P was measured from room temperature down to 2 K. As shown in Fig. 2, the resistivity data reveal a metallic behavior down to the superconducting transition at Tc. No anomalies associated with structural, magnetic, or charge-density-wave transitions could be detected. The electrical resistivity in the low-temperature region is shown in the inset, where the superconducting transition (with Tc onset = 5.7 K and Tc0 = 5.5 K) is clearly seen. The ρ(T) curve below 300 K can be described by the Bloch-Grüneisen-Mott (BGM) formula:

\[
ρ(T) = ρ_0 + 4A \left( \frac{T}{θ_B^K} \right)^5 \int_0^{θ_B^K} \frac{z^2 dz}{(e^z - 1)(1 - e^{-z})} - αT^3. \tag{1}
\]

Here the first term ρ0 is the residual resistivity due to the scattering of conduction electrons on the static defects of the crystal lattice, while the second term describes the electron-phonon scattering, with θ_B^K being the characteristic (Debye) temperature and A a coupling constant. The third term represents a contribution due to s-d interband scattering, α being the Mott coefficient. The fit in Fig. 2 (red-line) results in ρ0 = 5.92(5) μΩcm, θ_B^K = 251(3) K, and A = 3.4(1)×10^{-6} μΩcmK^{-3}. The fairly large residual electrical resistivity ratio (RRR), i.e., ρ(300 K)/ρ0 ≈ 45, and the sharp superconducting transition temperature (∆Tc = 0.2 K) both indicate a good sample quality.
The superconductivity of Mo₃P was also probed by magnetic susceptibility measurements. The temperature dependence of the magnetic susceptibility $\chi(T)$ was determined using both field-cooled (FC) and zero-field-cooled (ZFC) protocols in an applied field of 1 mT. As shown in Fig. 3, $\chi(T)$ data show a superconducting transition at $T_c = 5.5$ K, consistent with the values determined from electrical resistivity (Fig. 2) and heat capacity (see below). The splitting of the FC- and ZFC-susceptibilities is a typical feature of type-II superconductors with moderate to strong pinning, where the magnetic-field flux is pinned upon cooling the material in an applied field. Below $T_c$, a ZFC-susceptibility value of $\chi_s \sim -1$ (after accounting for demagnetization factor, powder compactness, etc.) indicates bulk superconductivity.

D. Lower and upper critical fields

To determine the lower critical field $\mu_0H_{c1}$ of Mo₃P, its field-dependent magnetization $M(H)$ was measured at various temperatures up to $T_c$, as shown in Fig. 4(a). The $M(H)$ curves, recorded using a ZFC-protocol, show the typical response of a type-II superconductor. The estimated $\mu_0H_{c1}$ values at different temperatures, determined from the deviation of $M(H)$ from linearity, are plotted in Fig. 4(b). The solid line is a fit to $\mu_0H_{c1}(T) = \mu_0H_{c1}(0)[1 - (T/T_c)]^2$. This provides a lower critical field $\mu_0H_{c1}(0) = 29.4(2)$ mT, consistent with 24.9(5) mT, the value calculated from the magnetic penetration depth $\lambda(0)$ (see below).

To investigate the behavior of the upper critical field $\mu_0H_{c2}$, we measured the temperature-dependent electrical resistivity $\rho(T)$ and specific heat $C(T)/T$ at various applied magnetic fields, as well as the field-dependent magnetization $M(H)$ at various temperatures up to $T_c$. As shown in Figs. 5(a) and (b), the superconducting transition, determined from $\rho(T)$ and specific heat $C(T)/T$ data, shifts towards lower temperature upon increasing the magnetic field. In zero magnetic field, $T_c = 5.5$ K determined from $C(T)/T$ is consistent with the $T_c$ values determined from $\rho(T)$ (Fig. 2) and $\chi(T)$ (Fig. 3) data. In the latter case, as shown in Fig. 5(c), the diamagnetic signal disappears once the applied magnetic field exceeds the upper critical field. Figure 5(d) summarizes the upper critical fields vs. the superconducting transition temperatures $T_c$, as derived from $\rho(T,H)$, $C(T,H)/T$, and $M(H,T)$ data, respectively. The temperature dependence of $\mu_0H_{c2}(T)$ was analyzed by means of the semi-empirical model $\mu_0H_{c2}(T) = \mu_0H_{c2}(0)(1 - t^2)/(1 + t^2)$, where $t = T/T_c$ is the normalized temperature (see, e.g., 33). This model follows from the Ginzburg-Landau (GL) relation between $H_{c2}$ and the coherence length $\xi$ (see below), by assuming $\xi(t) \propto \sqrt{(1 + t^2)/(1 - t^2)}$. Although the GL theory is strictly valid near $T_c$, the above form of $H_{c2}(T)$ has been shown to be
satisfied in a wider temperature range. The solid lines in Fig. 5(d) are fits to the GL model, which gives $\mu_0H_{c2}(0) = 0.94(1)$ T and $1.09$ T for specific heat and magnetization, and for electrical resistivity data, respectively. For a comparison, we estimated the upper critical field also by means of the Werthamer-Helfand-Hohenberg (WHH) model (d). The dashed lines in Fig. 5(d) are fits to a WHH model without spin-orbital scattering and give $\mu_0H_{c2}^{\text{WHH}}(0) = 0.76(1)$ T and $0.83(1)$ T for specific heat and magnetization, and for electrical resistivity data, respectively.

At low fields, both GL and WHH models describe the experimental data very well. At higher applied fields, however, the WHH-type fits deviate significantly from the data, clearly providing underestimated critical-field values. The remarkable agreement of the less elaborate GL model with experimental data is clearly seen in Fig. 5(d). We note that, while the specific-heat-, magnetization-, and electrical-resistivity datasets agree well at low fields ($<0.25$ T), at higher fields, the transition temperatures determined from $\rho(T,H)$ are systematically higher than those derived from $C(T,H)/T$ and $M(H,T)$ data. A similar behavior has also been found in other NCSCs, e.g., LaPtSi, BiPd, or La$T$Si$_5$ ($T = \text{Pd}, \text{Pt},$ and Ir$^{35-39}$, as well as in standard superconductors. Generally, the surface/filamentary superconductivity above bulk $T_c$, or a strong anisotropy of the upper critical field, are proposed as the cause of the differing $T_c$ values. In order to clarify this issue, studies of single-crystal specimen are highly desirable.

In the GL theory of superconductivity, the coherence length $\xi$ can be calculated from $\xi = \sqrt{\Phi_0/2\pi\mu_0H_c}$, where $\Phi_0 = 2.07 \times 10^{-3}$ T $\mu$m$^2$ is the quantum of magnetic flux. With a bulk $\mu_0H_{c2}(0) = 0.94(1)$ T, the calculated $\xi(0)$ is $18.7(1)$ nm. The magnetic penetration depth $\lambda$ is related to the coherence length $\xi$ and the lower critical field $\mu_0H_{c1}$ via $\mu_0H_{c1} = (\Phi_0/4\pi\lambda^2)[\ln(\kappa) + 0.5]$, where $\kappa = \lambda/\xi$ is the GL parameter$^{40}$. By using $\mu_0H_{c2} = 29.4$ mT and $\xi = 18.7$, nm, the resulting magnetic penetration depth $\lambda_{\text{GL}} = 113(1)$ nm, is consistent with 126(1) (zero-field extrapolation) and 121(2) nm (50 mT), the experimental values from TF-$\mu$SR data (see Sec. III F and Table I). A GL parameter $\kappa \sim 7$, almost ten times larger than the $1/\sqrt{2}$ threshold value, clearly confirms that Mo$_3$P is a type-II superconductor.

E. Zero-field specific heat

Specific-heat data offer valuable insight into the superconducting properties, including the gap value and its symmetry. Therefore, the Mo$_3$P specific heat was measured down to 0.1 K in zero field. As shown in Fig. 6, there is a clear specific-heat jump at $T_c$, indicating a bulk superconducting transition. The electronic specific heat $C_e/T$ was obtained by subtracting the phonon contribution from the experimental data. As shown in the inset of Fig. 6, the normal-state specific heat of Mo$_3$P is fitted to $C_e(T) = C_0 + CT$, where $C_0$ is the electronic specific-heat coefficient and $\beta T^2$ is the phonon contribution to the specific heat. The derived values are $C_0 = 10.3(4)$ mJ/mol-K$^2$ and $\beta = 0.67(3)$ mJ/mol-K$^3$. The Debye temperature $\Theta_D^0$ can be calculated by using $\Theta_D^0 = (12\pi^4 Rn/5\beta)^{1/3}$, where $R = 8.314$ J/mol-K is the molar gas constant and $n = 4$ is the number of atoms per formula unit. The resulting $\Theta_D^0 = 225(3)$ K (extracted from low-T data) is consistent with the value derived from electrical-resistivity data (see Fig. 2). The density of states (DOS) at the Fermi level $N(\epsilon_F)$ was evaluated from the expression $N(\epsilon_F) = 3\gamma_n/(2\pi^2 k_B^2) = 2.2(1)$ states/e-f.u. (accounting for spin degeneracy$^{41}$), where $k_B$ is the Boltzmann constant. The electron-phonon coupling constant $\lambda_{\text{ep}}$, a measure of the attractive interaction between electrons due to phonons, was estimated from $\Theta_D^0$ and $T_c$ values by applying the semi-empirical McMillan formula$^{42}$:

$$\lambda_{\text{ep}} = \frac{1.04 + \mu^* \ln(\Theta_D/1.45 T_c)}{(1 - 0.62 \mu^*) \ln(\Theta_D/1.45 T_c) - 1.04}. \quad (2)$$

The Coulomb pseudopotential $\mu^*$, usually lying in the

![FIG. 5. Temperature-dependent electrical resistivity $\rho(T,H)$ (a) and specific heat $C/T(T,H)$ (b) for different applied magnetic fields, up to 1.4 T. In the first case, $T_c$ was defined as the onset of zero resistance. (c) Field-dependent magnetization $M(H,T)$ measured at various temperatures and in applied magnetic fields up to 1.0 T. From $\rho(T,H), C(T,H)/T$, and $M(H, T)$ one can derive the upper critical field $\mu_0H_{c2}$, as shown in (d). The solid lines represent fits to an effective Ginzburg-Landau (GL) model, whereas the dash-dotted lines are fits based on a WHH model.](image)

![FIG. 6. Normalized electronic specific heat $C_e/T$ for Mo$_3$P versus $T/T_c$. Inset: the measured specific heat $C/T$ as a function of $T^2$. The dashed line in the inset is a fit to $C_e/T = C_0 + \beta T^2$, while the solid line in the main panel is the electronic specific heat calculated by considering a fully-gapped $s$-wave model.](image)
0.09–0.18 range, was here fixed to 0.13, a commonly used value for transition metals. From Eq. (2) we obtain \( \lambda_{\text{ep}} = 0.72(1) \) for MoP almost twice the reported value for the elemental Mo (0.41)\(^{43,44} \). Finally, the band-structure density of states \( N_{\text{band}}(\epsilon_F) \) can be estimated from the relation \( N_{\text{band}}(\epsilon_F) = N(\epsilon_F)/(1 + \lambda_{\text{ep}})^{43} \), which gives \( N_{\text{band}}(\epsilon_F) = 1.28(1) \) states/eV-f.u.

The electronic specific heat divided by the electronic specific-heat coefficient, i.e., \( C_e/T_0 \), is shown in the main panel of Fig. 6 as a function of the reduced temperature. The temperature-independent behavior of \( C_e/T_0 \) at low-\( T \) suggests a fully-gapped superconducting state in MoO\(_3\)P. The temperature-dependent superconducting-phase contribution to the entropy was calculated by means of\(^{45} \):

\[
S(T) = -\frac{6y_n}{\pi^2 k_B} \int_0^\infty \left[ f \ln f + (1-f) \ln (1-f) \right] e^\epsilon d\epsilon,
\]

where \( f = (1 + e^{E/h_\text{TF}})^{-1} \) is the Fermi function, \( \Delta_0 \), is the SC gap value at 0 K, and \( E(\epsilon) = \sqrt{\epsilon^2 + \Delta^2(T)} \), the excitation energy of quasiparticles, with \( \epsilon \) the electron energies measured relative to the chemical potential (Fermi energy)\(^{45,46} \). \( \Delta(T) \) is the same as in Sec. III F. T temperature-dependent electronic specific heat in the superconducting state can be calculated from \( C_e = T \frac{dS}{dT} \). T solid line in Fig. 6 represents a fit with a fully-gapped wave model. The resulting superconducting gap \( \Delta_0 = 0.82(1) \) meV is consistent with the \( \mu\text{SR} \) results (see Fig. 1). The MoO\(_3\)P gap value \( \Delta_0 \), as derived from both specific-heat and TF-\( \mu\text{SR} \) data, is comparable to the expected weak-coupling BCS value 0.80 meV, thus indicating weakly-coupled superconducting pairs in MoO\(_3\)P. Furthermore, all the specific-heat discontinuity at \( T_\text{c} \), i.e., \( \Delta C/\gamma T_\text{c} \approx 1.4 \), is fully consistent with the conventional BCS value of 1.4.

**E Transverse-field \( \mu\text{SR} \)**

To investigate the superconducting properties of MoO\(_3\)P at a microscopic level, we carried out \( \mu\text{SR} \) measurements applied transverse fields (TF). The optimal field value \( H_\text{TF} \) such experiments was determined via a preliminary field-dependent \( \mu\text{SR} \) depolarization-rate measurement at 1.5 T. To track the additional field-distribution broadening due to the flux-line-lattice (FLL) in the mixed superconducting state, a magnetic field (up to 500 mT) was applied in the normal state and then the sample was cooled down to 1.5 K. Figure 7(a) shows the TF-spectra in an applied field of 50 and 300 mT, respectively. The solid lines represent fits using the same model as described in Eq. (4) below. The resulting effective Gaussian relaxation rate \( \sigma_{\text{TF}}(H) \) is summarized in Fig. 7(b). Above the lower critical field \( \mu_{\text{TF}}H_\text{c1} \) (29.4 mT), the relaxation rate decreases continuously. By considering the decrease of the inter vortex distance with the field and the vortex-core effects, a field of 50 mT was chosen for the temperature-dependent TF-\( \mu\text{SR} \) studies. For a comparison, the TF-\( \mu\text{SR} \) relaxation was also measured in a field of 500 mT. The field dependence of the Gaussian relaxation rate was analyzed following Eq. (8) (see details below). The derived zero-temperature \( \mu_{\text{TF}}H_{\text{c2}} = 0.96(1) \) T and magnetic penetration depth \( \lambda_0 = 126(1) \) nm are consistent with the temperature-dependent 50-mT results (see Table II).

The TF-\( \mu\text{SR} \) time spectra were collected at 1.5 K (a) and 7.5 K (b) in an applied field of 50 mT. Fourier transforms of the above time spectra at 1.5 K (c) and 7.5 K (d). The solid lines are fits to Eq. (4) using two oscillations, while the dash-dotted line in (c) represents a fit with a single oscillation. The vertical dashed line indicates the applied magnetic field. Note the clear diamagnetic shift below \( T_\text{c} \) in (c).

**FIG. 7.** (a) Time-domain TF-\( \mu\text{SR} \) spectra of MoO\(_3\)P measured in its superconducting state (at \( T = 1.5 \) K) at 50 and 300 mT. (b) Field-dependent Gaussian relaxation rate \( \sigma_{\text{TF}}(H) \). The arrows indicate the field values (50 and 500 mT) used in the temperature-dependent TF-\( \mu\text{SR} \) studies. The solid line is a fit to Eq. (8).

**FIG. 8.** TF-\( \mu\text{SR} \) time-dependent spectra, collected at 1.5 K (a) and 7.5 K (b) in an applied field of 50 mT. Fourier transforms of the above time spectra at 1.5 K (c) and 7.5 K (d). The solid lines are fits to Eq. (4) using two oscillations, while the dash-dotted line in (c) represents a fit with a single oscillation. The vertical dashed line indicates the applied magnetic field. Note the clear diamagnetic shift below \( T_\text{c} \) in (c).
respectively, with the latter not undergoing any depolarization. \( B_i \) and \( B_{bg} \) are the local fields sensed by implanted muons in the sample and sample holder, \( \gamma_{\mu} = 2\pi \times 135.53 \text{MHz/T} \) is the muon gyromagnetic ratio, \( \phi \) is the shared initial phase, and \( \sigma_i \) is a Gaussian relaxation rate of the \( i \)th component. The number of required components is material dependent, generally in the \( 1 \leq n \leq 5 \) range. For superconductors with a large \( \kappa (\gg 1) \) value, the magnetic penetration depth is much larger than the coherence length. Hence, the field distribution is narrow and a single-oscillating component is sufficient to describe \( A(t) \). In case of a small \( \kappa (\lesssim 1/\sqrt{2}) \) value, the magnetic penetration depth is comparable to the coherence length. This implies a broad field distribution, in turn requiring multiple oscillations to describe \( A(t) \).

Figures 8(c) and (d) show the FFT spectra of the TF-\( \mu \)SR time-domain asymmetries at 1.5 K and 7.5 K. Solid lines represent fits to Eq. (4) using two oscillations (i.e., \( n = 2 \)) in the superconducting phase and one oscillation in the normal phase. In the 1.5 K case, a single-component oscillation [dash-dotted line in panel (c)] is clearly unable to fit the \( T < T_c \) data. The derived Gaussian relaxation rates as a function of temperature are summarized in the insets of Fig. 9. Above \( T_c \), the relaxation rate is small and temperature-independent, but below \( T_c \) it starts to increase due to the onset of the FLL and the increase in superfluid density. Unlike the TF-\( \mu \)SR spectra collected at 50 mT, the 500-mT datasets can be described by a single oscillation. This reflects the narrower internal-field distribution for applied fields comparable to \( H_{c2} \). In case of multi-component oscillations (at 50 mT), the first-term in Eq. (4) describes the field distribution as the sum of \( n \) Gaussian relaxations:

\[
P(B) = \gamma_{\mu} \frac{2}{\sigma_i} \sum_{i=1}^{2} \frac{A_i}{A_{\text{tot}}} \exp \left[ -\frac{\gamma_{\mu}^2 (B - B_i)^2}{2\sigma_i^2} \right].
\]  

Then, the first and second moments of the field distribution in the sample were calculated by:

\[
\langle B \rangle = \frac{\sum_{i=1}^{2} A_i B_i}{A_{\text{tot}}}, \quad \text{and}
\]  

\[
\langle B^2 \rangle = \frac{\sigma_{\text{eff}}^2}{\gamma_{\mu}^2} = \frac{\sum_{i=1}^{2} A_i}{A_{\text{tot}}} \left[ \frac{\sigma_{\text{eff}}^2}{\gamma_{\mu}^2} - \langle B_i - \langle B \rangle \rangle^2 \right],
\]

where \( A_{\text{tot}} = \sum_{i=1}^{2} A_i \). In the superconducting state, the measured Gaussian relaxation rate includes contributions from both a temperature-independent relaxation due to nuclear moments (\( \sigma_n \)) and the FLL (\( \sigma_{\text{FLL}} \)). The FLL-related relaxation can be extracted by subtracting the nuclear contribution according to \( \sigma_{\text{FLL}} = \sqrt{\sigma_{\text{eff}}^2 - \sigma_n^2} \). Since \( \sigma_{\text{FLL}} \) is directly related to the magnetic penetration depth and the superfluid density (\( \sigma_{\text{FLL}} \propto 1/\lambda^2 \)), the superconducting gap value and its symmetry can be determined from the measured \( \sigma_{\text{FLL}}(T) \).

For small applied magnetic fields (\( H_{\text{appl}}/H_{c2} \ll 1 \)) and large \( \kappa \) values (\( \kappa \gg 1 \)), \( \sigma_{\text{FLL}} \) is field-independent and proportional to \( \lambda^{-2} \). In the Mo-P case, however, the upper critical field \( \mu H_{c2} \) is relatively small (0.94 T) compared to the applied TF-field (50 and 500 mT). Therefore, to extract the penetration depth from the measured \( \sigma_{\text{FLL}} \), the effects of overlapping vortex cores with increasing field have to be considered, requiring the following expression for calculating the magnetic penetration depth [40,48]:

\[
\sigma_{\text{FLL}} = 0.172 \frac{\gamma_{\mu} \Phi_0}{2 \pi} (1 - h) \left[ 1 + 1.21 \left( 1 - \sqrt{h} \right)^2 \right] \lambda^{-2},
\]

where \( h = H_{\text{appl}}/H_{c2} \), with \( H_{\text{appl}} \) the applied magnetic field. The above expression is valid for type-II superconductors with \( \kappa \geq 5 \) in the 0.25/\( k^1/3 \) \( h \leq 1 \) field range. With \( \kappa \approx 6 \) and \( h = 0.053 \) (TF-50 mT) and 0.53 (TF-500 mT), Mo-P fulfills the above conditions.

By using Eq. (8), we could calculate the inverse-square of the magnetic penetration depth, whose temperature dependence is shown in Fig. 9. To gain insight into the superconducting pairing symmetry in Mo-P, the temperature-dependent superfluid density \( \rho_{\text{sc}}(T) \) \( \lambda^{-2}(T) \propto \rho_{\text{sc}}(T) \) was further analyzed by means of different models, generally described by:

\[
\rho_{\text{sc}}(T) = 1 + 2 \left[ \int_{\Delta_b}^\infty \frac{f}{\sqrt{E^2 - \Delta_k^2}} \frac{dE}{E} \right]_{\text{FS}},
\]

where \( \Delta_b \) is an angle-dependent gap function, \( f = 1 + e^{E/k_{\text{B}}T} \) is the Fermi function, and \( \langle \psi \rangle_{\text{FS}} \) represents an average over the Fermi surface. The gap function can be written as \( \Delta_b(T) = \Delta(T) \psi \), where \( \Delta \) is the maximum gap value and \( \psi \) is the angular dependence of the gap, equal to 1, \( \cos 2\psi \), and \( \sin \theta \) for an s-, d-, and p-wave model, respectively. Here \( \psi \) and \( \theta \) are azimuthal angles. The temperature dependence of the gap is assumed to follow \( \Delta(T) = \Delta_0 \tanh \{1.82[1.018(T/T_c - 1)]^{0.51}\} \), where \( \Delta_0 \).
the gap value at zero temperature, is the only adjustable parameter. Note that the function $\Delta(T)$ is practically model-independent.

Three different models, including $s$-, $d$-, and $p$ waves, were used to describe the temperature-dependent superfluid density $\lambda^{-2}(T)$ measured in an applied field of 50 mT [Fig. 9(a)], with the first two being singlet-pairing and the last one triplet-pairing. For the $s$- and $p$-wave model, the estimated gap values are 0.83(1) and 1.12(1) meV, respectively; with the shared zero-temperature magnetic penetration depth $\lambda_0 = 121(2)$ nm; while for the $d$-wave model, the estimated $\lambda_0$ and gap values are 109(2) nm and 1.10(1) meV. As can be seen in Fig. 9(a), the temperature-independent behavior of $\lambda^{-2}(T)$ below $1/3 T_c$ strongly suggests a nodeless superconductivity in Mo$_3$P. Therefore, $\lambda^{-2}(T)$ is clearly more consistent with a single fully-gapped $s$-wave model. In case of $d$- or $p$-wave models, a less-good agreement with the measured $\lambda^{-2}$ values is found, especially at low temperature. Such conclusions are further supported by the low-specific-heat data shown in Fig. 5.

A gap value $d$ more consistent with a single fully-gapped $s$-wave model. In polycrystalline samples, the $1/3$-relaxing and $2/3$-relaxing components of the asymmetry $A_{ZF}$ were obtained using the $Dmfit$ software, with the best-fit parameters being $\delta_{iso} = 285$ ppm, $\Omega = 35$ KHz, and $\eta_{CS} = 0.38$. Here, $\delta_{iso} = (\delta_{11} + \delta_{22} + \delta_{33})/3$ is the isotropic component of the shift tensor, i.e., the average of its diagonal components in the principal axes system (PAS), the linewidth is $\Omega = [\delta_{11} - \delta_{22}]$, and $\eta_{CS} = (\delta_{22} - \delta_{11})/(\delta_{11} - \delta_{iso})$. The temperature evolution of the line widths and shifts (normalized to the field value and the reference frequency, respectively) is shown in Fig. 10. The

G. Zero-field $\mu$SR

We performed also ZF-$\mu$SR measurements, in order to search for a possible TRS breaking in the superconducting state of Mo$_3$P. The large muon gyromagnetic ratio, combined with the availability of 100% spin-polarized muon beams, make ZF-$\mu$SR a very sensitive probe for detecting small spontaneous magnetic fields. This technique has been successfully used to detect the TRS breaking in the superconducting states of different types of materials. Normally, in the absence of external fields, the onset of SC does not imply changes in the ZF muon-spin relaxation rate. However, if the TRS is broken, the onset of tiny spontaneous currents gives rise to associated (weak) magnetic fields, readily detected by ZF-$\mu$SR as an increase in muon-spin relaxation rate. Representative ZF-$\mu$SR spectra collected above (8 K) and below $T_c$ (1.5 and 4 K) are shown in Fig. 10. For non-magnetic materials, in the absence of applied fields, the relaxation is mainly determined by the randomly oriented nuclear moments. Consequently, the ZF-$\mu$SR spectra of Mo$_3$P could be modelled by means of a combined Lorentzian and Gaussian Kubo-Toyabe relaxation function

$$A_{ZF} = A_s \left[ \frac{1}{3} \frac{2}{3} \left( 1 - \sigma_{ZF}^2 m^2 - A_{ZF} \right) e^{-\frac{\Delta_0^2}{m_T^2}} A_{hK} \right] + A_{hK}.$$  

(10)

Here $A_s$ and $A_{hK}$ represent the initial muon-spin asymmetries for muons implanted in the sample and sample holder, respectively. In polycrystalline samples, the 1/3-nonrelaxing and 2/3-relaxing components of the asymmetry correspond to the powder average of the local internal fields with respect to the initial muon-spin orientation. After fixing $A_s$ to its average value of 0.215, the resulting fit parameters are shown in Fig. 10(b)-(c). The weak Gaussian and Lorentzian relaxation rates reflect the absence of electronic magnetic moments and the small value of the Mo$_3$P nuclear moments. Although the ZF-$\mu$SR spectra in Fig. 10(a) show tiny differences between the normal and the superconducting state, the resulting $A_{ZF}(T)$ and $\sigma_{ZF}(T)$ parameters show no distinct changes across $T_c$. Note that the tiny increase of $A_{ZF}$ between the normal and superconducting state [Fig. 10(b)] is not related to a TRS-breaking effect, but to the correlated decrease of $\sigma_{ZF}$ [Fig. 10(c)]. The clear lack of an additional relaxation below $T_c$ implies that the TRS is preserved in the superconducting state of Mo$_3$P.

H. $^{31}$P NMR in the normal phase

NMR is a versatile technique for investigating the electronic properties of materials, in particular, their electron correlations, complementary to $\mu$SR with respect to probe location. Considering the rather low $T_c$- and $H_{iso}(0)$ values of Mo$_3$P as well as the detailed $\mu$SR study of its superconducting properties (see previous section), we mostly employed NMR to investigate the normal-state electronic properties of Mo$_3$P. To this aim, $^{31}$P NMR measurements were performed at 7 and 0.5 T, i.e., above and below $H_{iso}(0)$ (0.94 T). For both fields, the $^{31}$P NMR reference frequency $\nu_0$ was determined by using a solid-state NH$_4$H$_2$PO$_4$ sample, whose Larmor frequency coincides with that of phosphoric acid. The $^{31}$P NMR shifts were then calculated with respect to this reference.

Typical $^{31}$P NMR lineshapes are shown in Fig. 15 in the Appendix. As expected, the NMR lines at 0.5 T show a significant broadening and frequency shift below $T_c$ in the superconducting phase. The 7-T lines, instead, are practically temperature independent, with typical shapes reflecting the Knight shift anisotropy. The Knight shift, peak position, and linewidth were obtained using the $Dmfit$ software, with the best-fit parameters being $\delta_{iso} = 285$ ppm, $\Omega = 35$ KHz, and $\eta_{CS} = 0.38$. Here, $\delta_{iso} = (\delta_{11} + \delta_{22} + \delta_{33})/3$ is the isotropic component of the shift tensor, i.e., the average of its diagonal components in the principal axes system (PAS), the linewidth is $\Omega = [\delta_{11} - \delta_{22}]$, and $\eta_{CS} = (\delta_{22} - \delta_{11})/(\delta_{11} - \delta_{iso})$. The temperature evolution of the line widths and shifts (normalized to the field value and the reference frequency, respectively) is shown in Fig. 11. The
almost temperature- and field-independent line widths and frequencies, suggest a behavior close to that expected for weak- to moderately-correlated metal. The above picture changes only close to \(T_c\), below which we detect a significant drop in frequency and increase of line width, reflecting the electron pairing and the development of the flux-line lattice in the superconducting phase, respectively.

The temperature-dependent NMR relaxation rate \(1/T_1\) provides useful insight into the dynamics of conduction electrons and their degree of correlation. The \(1/T_1\) data, shown in Fig. 12(a) (inset), indicate an almost linear behavior with slightly different slopes in the regime above and below \(T^* \sim 103\) K. While the change in slope might reflect a change in the electron-nuclei coupling, the linearity of \(1/T_1(T)\) is once more a clear indication of weak- to moderate electron correlations. This conclusion is confirmed by the \(1/T_1\) data shown in Fig. 12(a) (main panel), where the reported product, at a first approximation considered as constant, is \(0.054\) s\(^{-1}\)K\(^{-1}\). Compared to other metallic superconductors, such as MgB\(_2\), AlB\(_2\), and ZrB\(_2\) (see Fig. 5 in Ref. 54), such a value indicates a good metallicity, i.e., a relatively high electron density of states at the Fermi level. Upon closer inspection we note that, after a minimum at \(10\) K, \(1/T_1\) increases slightly with temperature. The origin of this minimum is currently unknown to us.

The Korringa relation\(^{55}\) states the proportionality between the spin relaxation rate divided by the square of the gyromagnetic ratio for a free electron, and \(\gamma_N\) the gyromagnetic ratio of the probe nucleus. Here, \(\alpha\) is a coefficient of correlation which, in the ideal case of uncorrelated related electrons, should be 1. As shown in Fig. 12(b), in Mo\(_3\)P\(_2\) the Korringa product is nearly constant down to \(T_c\). An average \(\alpha^2\) value much lower than 1 (here shown by a dashed line) suggests ferromagnetic electronic correlations in Mo\(_3\)P\(_2\).

\[
\frac{1}{T_1} \propto K_s^2 = \alpha S_0, \quad S_0 = \frac{\gamma_e^2}{\gamma_N^2} \frac{\hbar}{4\pi k_B},
\]

where \(\gamma_e\) is the gyromagnetic ratio for a free electron, and \(\gamma_N\) the gyromagnetic ratio of the probe nucleus. Here, \(\alpha\) is a coefficient of correlation which, in the ideal case of uncorrelated related electrons, should be 1. As shown in Fig. 12(b), in Mo\(_3\)P\(_2\) the Korringa product is nearly constant down to \(T_c\).

\[\frac{1}{T_1} \propto K_s^2 = \alpha S_0, \quad S_0 = \frac{\gamma_e^2}{\gamma_N^2} \frac{\hbar}{4\pi k_B},\]

The resulting \(\alpha\) value is 5.8, i.e., much higher than unity. Since the \(^{31}\)P NMR \(K_s\) shift is mostly due to 4d-type conduction electrons (Mo), a high \(\alpha\) value is not unusual (see Ref.\(^{57}\)) and suggests at most moderate ferromagnetic correlations.

I. Electronic band structure and discussion

To further understand the properties of the normal- and superconducting states of Mo\(_3\)P\(_2\), we performed DFT band-structure calculations, whose main results are summarized in Fig. 13. As shown in panels (a)-(c), close to Fermi level the DOS is dominated by the Mo 4d-electrons, while the low-lying states near \(-6\) eV are dominated by contributions...
from both Mo-4d and P-3p electrons. The estimated DOS at Fermi level is about 1.56 states/eV-f.u. (12.5 states/eV-cell/Z, with Z = 8 the number of Mo₂P formula units per unit cell), which is comparable to the experimental results in Sec. III E and Table II. The relatively high DOS hints at a good metallic behavior in Mo₂P confirmed by both electrical resistivity data and the fast NMR relaxation rates. The electronic band structure calculated without considering the SOC is shown in panel (d), while that including SOC in panel (e). In the former case, there are two almost overlapping bands at the Z point, about ~0.05 eV below the Fermi level. After including the SOC the bands separate, since SOC breaks the band degeneracy and brings one of the bands closer to the Fermi level [see Fig. 13(e)]. The dispersion of the Mo 4d bands, which cross the Fermi level, is rather small with a bandwidth of about ∼0.3 – 0.4 eV. The band splitting due to the ASOC is about ~90 meV a value comparable to that of other NCSCs, e.g., Y₃C₁₅ (∼15 meV)⁵⁸ and (Sr,Ba)(Ni,Pd)₁₃₁₃ (< 20 meV)⁵⁹, but much smaller than that of CePt₃Si (∼200 meV)⁶₀ and Li₂Pt₃B (∼200 meV)⁶¹. It is accepted that the band splitting at Fermi level is of primary importance for the superconducting properties⁶. Indeed, because of the large ASOC-induced band splitting, Li₂Pt₃B shows nodal superconductivity⁶², while the upper critical field in CePt₃Si exceeds the Pauli limit⁶³. Conversely, in Y₃C₁₅ and (Sr,Ba)(Ni,Pd)₁₃₁₃, the upper-critical-field is relatively small and they are fully-gapped superconductors⁵⁹,⁶⁴. The latter seems also to be the case of Mo₂P, which shows a small band splitting, a low Hₘ value, and a singlet-pairing superconducting state.

We also compare the superconductivity of Mo₂P with other NCSCs. As shown in Fig. 14, the different families of superconductors can be classified according to the ratio of the superconducting transition temperature Tc to the effective Fermi temperature T_F, in a so-called Uemura plot⁶⁶. Several types of unconventional superconductors, including heavy-fermions, organics, fullerenes, pnictides, and high-Tc cuprates. Selected noncentrosymmetric and elementary superconductors are shown as symbols (adopted from Refs. 16, 65, and 66). The dotted line corresponds to Tc = T_F (here T_F is the temperature associated with the Fermi energy, E_F = k_BT_F), while the dash-dotted line indicates Tc/T_F = 3.09 × 10⁻⁸ for Mo₂P.

FIG. 13. Calculated electronic band structure for Mo₂P Total and partial (Mo and P) density of states (a). Orbital-resolved density of states for the Mo- (b) and P atoms (c). Band structure of Mo₂P without- (d) and with SOC interactions (e), calculated within ±1 eV from the Fermi energy level.

FIG. 14. Uemura plot for different types of superconductors. With 1/100 < Tc/T_F < 1/10, the grey region indicates the band of unconventional superconductors, including heavy fermions, organics, fullerenes, pnictides, and high-Tc cuprates. Selected noncentrosymmetric and elementary superconductors are shown as symbols (adopted from Refs. 16, 65, and 66). The dotted line corresponds to Tc = T_F (here T_F is the temperature associated with the Fermi energy, E_F = k_BT_F), while the dash-dotted line indicates Tc/T_F = 3.09 × 10⁻⁸ for Mo₂P.

IV CONCLUSION

To summarize, we studied the normal- and superconducting state properties of the Mo₂P NCSC by means of bulk- (electrical resistivity, magnetization, and heat capacity), local-probe (μSR and NMR) techniques, and numerical band-structure calculations. The superconducting state of Mo₂P is characterized by Tc = 5.5 K, a relatively low H_c²(0) = 0.94 T, and κ ~ 6. The temperature dependence of the superfluid density and zero-field electronic specific heat reveal a nodeless superconducting state, which is well described by an isotropic s-wave model and is consistent with spin-singlet pairing. The lack of spontaneous magnetic fields below Tc indicates that time-reversal symmetry is preserved in the superconducting state of Mo₂P. Electronic band-structure calculations suggest a small band splitting due the...
Table II. Normal- and superconducting state properties of Mo₃P as determined from electrical resistivity, magnetic susceptibility, specific-heat, NMR, and µSR measurements. The London penetration depth \( \lambda_L \), the effective mass \( m^* \), bare band-structure effective mass \( m^*_{\text{bare}} \), carrier density \( n_c \), BCS coherence length \( \xi_0 \), electronic mean-free path \( l_e \), Fermi velocity \( v_F \), and effective Fermi temperature \( T_F \) were estimated following the Eqs. (40)–(50) in Ref. 65.

\( ^4 \) Similar values were determined via electrical resistivity, magnetic susceptibility, and heat-capacity measurements.

\( ^b \) Derived from a fit to Eq. (8).

ASOC and a sizable density of states at Fermi level, confirmed also by NMR, which shows Mo₃P to be a metal with a rather high \( N(\epsilon_F) \) and moderate ferromagnetic electron correlations.

Appendix: NMR line shapes and relaxation rates

A selection of \(^{31}\)P NMR line shapes for both magnetic fields (0.5 and 7 T) is shown in Fig. 15. At low field (a), the transition to the superconducting phase at low temperature is indicated by a broadening of the line and by its qualitative change of shape. Above \( T_c \), the line shape is described by a Gaussian (analysis performed by DMfit), whereas below \( T_c \), the line shapes can be fitted by means of a convolution of a Gaussian with a Lorentzian. At high field (b), the SC phase transition is suppressed by the applied magnetic field, which also enhances the anisotropy of the line shapes. The black line on top of the 295-K data represents a fit using a Knight-shift anisotropy model (see main text).

The offset may indicate the presence of other temperature-independent components. The coupling constant \( g_A \) (i.e., the coefficient in Eq. (4.1)) may become temperature-dependent for \( \chi < 0.5 \times 10^{-4} \text{emu/mol} \). From the slope \( dK / d\chi \) of the \( K-\chi \) plot for \( T < 50 \text{ K} \), by assuming a standard electronic g-factor of 2.0, the relation \( K = g_A \mu_B \chi + K_{\text{offset}} \) gives a hyperfine coupling constant \( \lambda_{\text{hf}} = -0.082 \text{T} / \mu_B \) and a zero intercept of 0.025%.

As shown in Fig. 16, both the \( K-\chi \) plot behavior and the temperature dependence of the NMR shift are rather complicated. This is not unusual for \( d \)-type electron systems, known for their nonlinear \( K(T) \) dependencies (see, e.g., Ref. 66). In our case, between approximately 30 and 200 K, the Knight shift deviates markedly from linearity to exhibit a shallow minimum around 100 K. At 30 K, \( 1/(T_1 T) \) exhibits a minimum [see Fig. 12(a)], while around 100 K, \( 1/T_1 \) changes slope. Since these anomalies appear in rather independent types of measurements (\( K \) and \( T_1 \)), they may represent true modifications of the Mo₃P electronic properties. Although, currently an explanation concerning their nature is missing, future studies of the Hall coefficient vs. temperature might help to better determine their origin.
