(Dated: 14th May 2019)

The effect of ferroelectric fluctuations on the temperature dependent dielectric constant of SrTiO3 has been long studied. Those fluctuations have been shown in recent years to be quantum critical and SrTiO3 demonstrated to form the archetypal quantum critical paraelectric. The effect of those same fluctuations on the pressure and temperature dependence of the ferroelectric soft phonon mode as the system is tuned away from criticality are reported for the first time in this paper. We show that the mean field approximation is confirmed experimentally. Furthermore, using a self-consistent model of the quantum critical excitations including coupling to the volume strain and without adjustable parameters, we determine logarithmic corrections that would be observable only very close to the quantum critical point. Thus, the mean-field character of the pressure dependence is much more robust to the fluctuations than is the temperature dependence. We predict stronger corrections for lower dimensionalities however. The same calculation confirms that the Lydanne-Sachs-Teller relation is valid over the whole pressure and temperature range considered. Therefore, the measured dielectric constant can be used to extract the frequency of the soft mode down to 1.5 K and up to 20 kbar of applied pressure. The soft mode is observed to stiffen further, raising the low-temperature energy gap and returning towards the expected shallow temperature dependence of an optical mode. This behavior is consistent with the existence of a ferroelectric quantum critical point on the pressure-temperature phase diagram of SrTiO3, which applied pressure tunes the system away from. We additionally compare the soft mode frequencies in ambient KTaO3 and show they correspond to SrTiO3 at around 2 kbar. This work represents the first experimental measurement of the stiffening of a soft phonon mode as a system is tuned away from criticality, a potentially universal phenomenon across a variety of phase transitions and systems in condensed matter physics.

I. INTRODUCTION

The incipient ferroelectric SrTiO3 has been studied in great detail and is used as a dielectric or an insulating substrate in many applications [1-7] as it possess an anomalously high dielectric constant at low temperatures. SrTiO3 is the clearest example of a quantum paraelectric known. The nature of the quantum paraelectric state has been an open question since Barrett [1] first attempted to describe the deviation from Curie-Weiss behavior observed in SrTiO3. Recently, progress has been made [8] in describing this state but the effect of fluctuations on the pressure dependence has not been considered until this work.

SrTiO3 has a cubic perovskite structure at room temperature with a well-documented antiferrodistortive transition at around 110 K [10], below which the unit cell is tetragonal. The dielectric constant, $\varepsilon_r$, of SrTiO3 exhibits a classical Curie-Weiss temperature dependence at high temperatures [4], but departs from the Curie-Weiss behavior as the polarization is modified by quantum fluctuations below 50 K, and no ferroelectric ordering is observed. The system remains close to long-range order through a displacive ferroelectric transition, but the transition does not occur in pristine SrTiO3. The polarization is due to the ionic motion of a transverse optical phonon mode, which softens to approach zero energy at low temperature at the zone center $\Gamma$ point. This mode, commonly described as the ‘soft mode’ or ‘ferroelectric mode’ corresponds to opposing motion of the oxygen octahedra and titanium ions along the c-axis [2, 11]. Inelastic neutron scattering experiments by Yamada et al. [12] have shown however that the soft mode is ‘frozen out’ at low temperatures - instead of falling to zero the phonon energy flattens out to a fixed value or gap $\Delta$ as temperature is decreased below 50 K. This means that spontaneous long-range ferroelectricity does not form, but a low-energy excitation into short range charge ordering is available to the system, leading to the very large polarizability and departures from classical predictions seen at low temperatures [5]. These phenomena have been linked to a postulated ferroelectric quantum critical point (QCP) at the equivalent of a small ‘negative pressure’ on SrTiO3’s pressure-temperature phase diagram (Fig. 1) - quantum critical fluctuations of the polarization in the vicinity of this point lead to a modified dependence of the dielectric properties. The application of strain [13], or the substitution of a heavier oxy-
gen isotope to form SrTi\textsuperscript{18}O\textsubscript{3} [14, 15], which both have the opposite effect on the system to applying pressure, lead to a ferroelectric phase, consistent with this QCP. Our recent work [8] has shown through detailed measurements of the dielectric constant under pressure that SrTiO\textsubscript{3} is driven away from its quantum critical regime by the application of pressure. The dielectric response was in addition seen to match that seen in KTaO\textsubscript{3} at elevated pressures, in agreement with the position on the pressure/doping phase diagram postulated for this material (Fig. 1). Additionally, the dielectric loss in SrTiO\textsubscript{3} is dominated by a series of peaks at characteristic temperatures. The largest of these peaks, at approximately 10 K, is associated with quantum fluctuations. Recent work [16] suggests that this peak reflects a localized excitation formed of quantum fluctuations of domain walls.

Critical exponents in the temperature dependence of susceptibility, resistivity and heat capacity have been used extensively to identify and characterize the various states discovered in the heavy fermion systems and incipient transition metal itinerant magnets [17]. There are good reasons for this. In particular the power of the temperature critical exponents lies in the incredible precision good reasons for this. In particular the power of the temperature critical exponents lies in the incredible precision good reasons for this. In particular the power of the temperature critical exponents lies in the incredible precision good reasons for this. In particular the power of the temperature critical exponents lies in the incredible precision
the two are linked by the LST - the phonon frequencies directly determine the dielectric response. Eq. 2 was used to extract the temperature and pressure dependence of the frequency \( \omega_{TO} \) of the ferroelectric soft mode \( \omega^2_{TO} = \frac{\epsilon_r^2 \omega^2_{LO}}{\omega^2_{TO}} \)

where \( \omega_{TO} \) and \( \omega_{LO} \) denote the ferroelectric soft mode and its longitudinal equivalent, which is denoted as \( E_g \) and of energy \( 148 \text{ cm}^{-1} \) by Ishidate et al. [24].

II. EXPERIMENTS

A. Methods

High precision capacitance measurements were carried out on single crystal samples of SrTiO\(_3\) from Crystal GmbH with gold electrodes vacuum evaporated onto the surfaces in a parallel-plate capacitor geometry. Measurements under extremely hydrostatic pressure conditions were made possible by the development, in collaboration with CamCool Research Ltd, of a piston-cylinder clamp cell with miniature shielded coaxial cables running into the sample region and electrically isolated from the cell body. This eliminates stray capacitances from the wiring and allows pF capacitance signals to be measured with stabilities of one part in a million. The shield conductors of the coaxial cables were joined together at the sample position and at the measurement instrument in the standard 2-point capacitance setup. The pressures in the measurements reported were 0/ambient, 2.4, 3.3, 4.6, 5.2, 6.9, 8.6, 9.6, 11.9, 14.1, 15.7, 17.1, 18.6 and 20.0 kbar, with a typical uncertainty of ±0.2 kbar. An Andeen-Hagerling 2550A 1 kHz capacitance bridge was used, at a voltage of 0.1 V. Sample thickness, corresponding to capacitor plate separation, was 0.5 mm. Measurements were taken on a modified 1K Dipper cryostat from ICE Oxford, allowing continuous stable temperature control down to 1.2 K, and an adiabatic demagnetization refrigerator developed in house capable of reaching 200 mK. Typical heating or cooling rates were held at 0.01 K per minute to allow the large thermal mass of the pressure cell to thermally equilibrate.

B. Results

Measurements were carried out of the dielectric constant of SrTiO\(_3\) from room temperature down to 1.5 K at fixed hydrostatic pressures up to 20.0 kbar. The effect of pressure, as discussed in more detail in our recent paper [8], is to drastically reduce the magnitude of the low-temperature dielectric constant from \( \sim 18,000 \) at ambient pressure to \( \sim 500 \) at 20.0 kbar as the system is tuned away from a ferroelectric transition and associated quantum critical behavior.

Such a drastic change in the dielectric properties must reflect a change in the phonon spectrum of the system as the LST relation cancel, leading to

\[
\frac{\epsilon_r}{\epsilon_\infty} = \frac{\omega^2_{LO}}{\omega^2_{TO}},
\]

where \( \omega_{TO} \) and \( \omega_{LO} \) denote the ferroelectric soft mode and its longitudinal equivalent, which is denoted as \( E_g \) and of energy \( 148 \text{ cm}^{-1} \) by Ishidate et al. [24].
Figure 2. a) Zone-center soft mode phonon energy of SrTiO$_3$ extracted from the dielectric constant via the Lydanne-Sachs-Teller relation, plotted against temperature for applied pressures from ambient (blue, lowest) to 20 kbar (red, topmost). The variation of the frequencies of other phonon branches and the refractive index with temperature and pressure were modeled as described in the text. Neutron scattering data from Yamada et al. [12] are shown as open circles and the corresponding data for KTaO$_3$ from Shirane et. al. [26] as crosses. b) Calculated temperature dependence of the TO phonon energy for several pressures.

(pressures in kbar, temperature in K) which was used to extract the values for $\omega_{TO}$ shown in Fig. 2(a). As pressure is increased the phonon frequency markedly flattens off and returns towards the flat temperature dependence of an archetypal optical mode. The low-temperature gap, $\Delta$, is doubled from 2 meV by even 2.4 kbar, the smallest pressure applicable with this setup. The small phonon energy gap is directly linked to the ferroelectric quantum critical fluctuations observed in this material, so the gap widening as seen and becoming energetically inaccessible as the system is tuned away from criticality is an expected result. The prediction that pressure will tune the system towards the behavior seen in KTaO$_3$ overlayed on Fig. 2(a) lie by inspection at where SrTiO$_3$ values at around 2 kbar would be found.

Fig. 3(a) shows the pressure dependence of $\omega_{TO}$ at fixed temperatures, taken directly from the data of Fig. 2(a). The data at 1.5 K, 2 K, 5 K and those extrapolated to 0 K all overlap as the dielectric response flattens off as temperature approaches zero, so any data in this range can be taken as the zero-temperature value. The inset of Fig. 3(a) shows the square of the phonon energy at 2 K, equivalent to the zero-temperature gap, $\Delta$, plotted against pressure. This shows very good agreement to a linear fit, giving the behavior expected from Landau theory $\omega = \omega_0(p - p_c)^{0.5}$ with the critical pressure $p_c$ at which the ferroelectric quantum critical point occurs equal to -0.7(1) kbar. This is in agreement with the analysis in our earlier paper [8] and with observations that strain or oxygen-18 substitution (both equivalent to ‘negative pressure’ in SrTiO$_3$) drive the system to a ferroelectric state [13–15].

III. THEORY

A. Model

We consider a standard model Hamiltonian for displacive ferroelectrics with normal mode coordinates that describe local displacements $\phi_{i\alpha}$, with $\alpha = 1, 2, ..., n = d$ in the unit cell $i = 1, 2, ..., N$ that are associated with the soft TO mode, the condensation of which is driven by the dipolar force and leads to the ferroelectric transition. We also consider the coupling to volume strain $\eta_i$. The Hamiltonian is as follows, [19]

$$H = H_\phi + H_\eta + H_{\phi\eta},$$

where $H_\phi$ is the Hamiltonian of the polar degrees of freedom alone,

$$H_\phi = \frac{1}{2} \sum_{i,\alpha} \Pi_{i\alpha}^2 + \frac{\omega_0^2}{2} \sum_{i,\alpha} \phi_{i\alpha}^2 + \sum_{i,\alpha\beta} \left[ u + v\delta_{\alpha\beta} \right] \phi_{i\alpha}^2 \phi_{i\beta}^2$$
$$+ \frac{1}{2} \sum_{i,j,\alpha\beta} F_{\alpha\beta} (i - j) \phi_{i\alpha} \phi_{j\beta},$$

$H_\eta$ is the elastic energy,

$$H_\eta = \frac{K}{2} \sum_i \eta_i^2 + P \sum_i \eta_i,$$
and $H_{\phi \eta}$ is a linear-quadratic coupling between $\phi_{i\alpha}$ and $\eta_i$,

$$H_{\phi \eta} = -\lambda \sum_{i,\alpha} \eta_i \phi^2_{i\alpha}.$$  

Here, $\Pi_{i\alpha}$ is the conjugate momentum of $\phi_{i\alpha}$; and $F_{\alpha \beta}$ ($i-j$) is the dipolar interaction with Fourier transform $F_{\alpha \beta} (q) = q^2 \delta_{\alpha \beta} + g_0 q_\alpha q_\beta / q^2$, where $g_0$ is a constant that depends on the lattice structure. $\omega_0$ is the frequency of the purely harmonic model; $u$ and $v$ are coefficients of the isotropic and anisotropic cubic anharmonicities, respectively; $\lambda$ is the coupling constant between the polarization and volume strain; and $K$ and $P$ are, respectively, the bulk modulus and applied hydrostatic stress (e.g. biaxial stress for $d = 2$ and pressure for $d = 3$).

Though the low temperature paraelectric lattice structure of SrTiO$_3$ is tetragonal, we will follow previous work [9] and assume cubic symmetry for simplicity. The TO excitations of (3) are thus doubly degenerate,

$$\Omega_q^2 = r(T, P) + q^2,$$

where $r(T, P) \equiv \Delta^2(T, P)$ is the square of the phonon gap at the zone-center. In addition to (4), there is a singlet LO mode which we will neglect as it is gapped out by the large depolarizing field of order $O (g)$. Within the SCPA, [18, 19] $r(T, P)$ is given as follows,

$$r(T, P) = \omega_0^2 + 4(d + 2) u + 12 v \left< |\phi|^2 \right> - 2\lambda \langle \eta \rangle,$$  

where $\left< |\phi|^2 \right>$ are the fluctuations of polarization,

$$\left< |\phi|^2 \right> = \frac{1}{N} \sum_q \frac{1}{\Omega_q} \left[ n (\Omega_q/k_B T) + \frac{1}{2} \right],$$  

with $n(\xi) = (e^\xi - 1)^{-1}$ a Bose factor and $\langle \eta \rangle$ is the average volume strain,

$$\langle \eta \rangle = \frac{\lambda}{K} \left< |\phi|^2 \right> - \frac{P}{K}.$$  

By substituting Eqs. (6) and (7) into Eq. (5), we separate the contributions from thermal and quantum fluctuations as follows [33],

$$r(T, P) = \frac{2\lambda}{K} (P - P_c)$$

$$+ \Gamma \left( \frac{T}{T_D} \right)^{d-1} \Phi \left[ r(T, P) / (k_B T)^2 \right]$$

$$+ \frac{2\lambda}{K} P_c = -[r(0, 0) + \Gamma \{ Z_0 [0] - Z_0 [r(0, 0)] \}],$$

where $P_c$ is the critical pressure at $T = 0$ K,

$$\Phi [R] = \frac{(k_B T_D)^{d-1}}{2 (2\pi)^d} \int_0^{T_D/T} \frac{1}{\sqrt{R + x^2}} n \left( \sqrt{R + x^2} \right),$$  

$$Z_0(r) = \frac{(k_B T_D)^{d-1}}{2 (2\pi)^d} \int_0^{T_D/T} \frac{1}{\sqrt{r / (k_B T_D)^2 + x^2}},$$

where $r(0, 0) = \omega_0^2 + \Gamma Z_0 [r(0, 0)]$, $\Gamma = 4(d + 2) u + 12 v - 2\lambda^2 / K$, and $T_D = \Lambda / k_B$ is the Debye temperature. Eqs. (8), (9), and (10) self-consistently determine the temperature and pressure dependence of $r(T, P)$.

Figure 3. a) Zone-center soft mode phonon energy of SrTiO$_3$, plotted against pressure at fixed temperatures. The solid lines show fits to $\omega_0(p - p_c)^{0.5}$ with $\omega_0$ and $p_c$ free fitting parameters to guide the eye. The inset gives the square of the zero-temperature extrapolated phonon gap, $\Delta$, against pressure, with a linear fit shown as a solid line. b) Calculated pressure dependence of the TO phonon energy for several temperatures. Inset. Calculated pressure dependence of the TO phonon gap.
B. Results

The non-adjustable model parameters are $\omega_0, \Gamma, \lambda, K,$ and $\Lambda$ which we fit experimental data reported for SrTiO$_3$ as follows: $\omega_0$ and $\Gamma$ are determined from the temperature dependence of the transverse optic phonon gap measured by neutron scattering, [12]; $\lambda/K$ is obtained from the slope of $\Delta^2$ versus $P$ measured here (see inset of Fig. 3(b)); and $\Lambda$ from specific heat data ($T_D = \Lambda/k_B = 400 K$) [34]. The resulting parameters are $\omega_0 = 10.2 i \text{meV}, \Gamma = 90.0 \text{meV}^3, \lambda/K = 0.054 \text{meV}^2,$ and $\Lambda = 34.5 \text{meV}$. The calculated temperature and pressure dependence of $\Delta(T,P)$ is in good qualitative and quantitative agreement with experiments, as shown in Figs. 2 and 3.

To further explore the behavior of the excitations, we study the pressure dependence of the fluctuations near the QCP. At $T = 0 K$, Eq. (8) gives,

$$r(0, P) = \frac{2\lambda}{K} (P - P_c) + \Gamma \{ Z_0[r(0, P)] - Z_0[0] \} . \quad (11)$$

For $r \to 0,$

$$Z_0[r] - Z_0[0] \simeq \begin{cases} -b \ln r + cr, & d = 1, \\ -br^{1/2} + cr, & d = 2, \\ -br + cr \ln r, & d = 3, \\ -br + cr^{3/2}, & d = 4, \end{cases} \quad (12)$$

with $b, c$ positive constants. Thus the lower (upper) critical dimension is $d_{cL} = 1$ ($d_{cU} = 4$). While there are strong deviations from mean field behavior for $d = 2,$ the corrections are only logarithmic for $d = 3.$ Equation. (11) then gives,

$$r(0, P) \propto \begin{cases} \frac{(P - P_c)^2}{(P - P_c)}, & d = 2, \\ (P - P_c), & d \geq 3, \end{cases} \quad (13)$$

with weak logarithmic corrections for $d = 3.$ Such corrections should be observable only when extremely close to the QCP ($((P - P_c)/P_c \ll 1)$ and a renormalization group analysis would be required for a quantitative description. For the present experiments, $|(P - P_c)/P_c| \gtrsim 1,$ and thus are not observable.

Quantum critical excitations in uniaxial and $XY$ ferroelectrics are generally expected to differ from those of cubic systems. We briefly consider such cases in Appendix A.

IV. CONCLUSIONS

The Lydanne-Sachs-Teller relation was used to extract the pressure and temperature dependence of the transverse optical soft mode frequency in SrTiO$_3$ from precision measurements of the dielectric constant under pressure. The mode was seen to stiffen as pressure was applied, moving towards a more typical flat optical mode. The low-temperature phonon gap $\Delta$ widened with increasing pressure, showing excellent agreement to the $\Delta \propto (P - P_c)^{0.5}$ predicted by Landau theory and with an extrapolated critical pressure $P_c$ of -0.7(1) kbar.

By treating the pressure within a self-consistent model for the quantum ferroelectric excitations, we have shown that the pressure dependence is robustly mean-field like. There are logarithmic corrections very close to absolute zero but these extend only to very low pressures (much less than 1 kbar). At the same time we verify the applicability of the LST over the whole of the phase space considered.

SrTiO$_3$ forms an ideal model system for the study of the physics of soft phonon modes and of quantum criticality, and pressure allows direct and clean tuning of the phonons - the driving mechanism of the whole system. Our results provide the first measurement of the stiffening of a soft phonon mode as a system is tuned away from criticality in a clean and direct manner by the application of hydrostatic pressure - a potentially universal phenomenon across a variety of phase transitions and systems in condensed matter physics.

Work at the University of Costa Rica is supported by the Vice-rectory for Research under the project no. 816-B7-601 and the Office of International Affairs.

Appendix A: Uniaxial and $XY$ ferroelectrics

For uniaxial ferroelectrics, there is an preferred polarization direction which we choose to be the $x_3$-axis. The Hamiltonian is similar to that of Eq. (3) except that $\alpha = \beta = 3, v = 0,$ and $F(q) = q^2 + g(qs/q)^2.$ The phonon excitations are $\Omega_q = \sqrt{r + q^2 + g(s q/q)^2}, \quad (35)$ which give

$$Z_0[r] - Z_0[0] = \begin{cases} br + cr \ln r + O(r^2), & d = 2, \\ br + O(r^{3/2}), & d = 3. \end{cases} \quad (A1)$$
The upper critical dimension is thus $d_{uc} = 3$ and there are weak logarithmic corrections in $d = 2$.

For $XY$ ferroelectrics, there is an easy plane of polarization and the Hamiltonian is again similar to that of Eq. (3) except that $\alpha = \beta = 1, 2$. The excitations are $\Omega_q = \sqrt{r + q^2}$ and $\Omega_q = \sqrt{r + q^2 + g (q_1^2 + q_2^2) / q^2}$. The former isotropic dispersion dominates the critical behavior and the corrections to mean-field behavior are thus the same as those given in Eq. (12).
