The scaling limit of a critical random directed graph

Christina Goldschmidt* & Robin Stephenson†

Abstract

We consider the random directed graph $\vec{G}(n,p)$ with vertex set $\{1, 2, \ldots, n\}$ in which each of the $n(n-1)$ possible directed edges is present independently with probability $p$. We are interested in the strongly connected components of this directed graph. A phase transition for the emergence of a giant strongly connected component is known to occur at $p = 1/n$, with critical window $p = 1/n + \lambda n^{-4/3}$ for $\lambda \in \mathbb{R}$. We show that, within this critical window, the strongly connected components of $\vec{G}(n,p)$, ranked in decreasing order of size and rescaled by $n^{-1/3}$, converge in distribution to a sequence $(C_1, C_2, \ldots)$ of finite strongly connected directed multigraphs with edge lengths which are either 3-regular or loops. The convergence occurs in the sense of an $\ell^1$ sequence metric for which two directed multigraphs are close if there are compatible isomorphisms between their vertex and edge sets which roughly preserve the edge-lengths. Our proofs rely on a depth-first exploration of the graph which enables us to relate the strongly connected components to a particular spanning forest of the undirected Erdős–Rényi random graph $G(n,p)$, whose scaling limit is well understood. We show that the limiting sequence $(C_1, C_2, \ldots)$ contains only finitely many components which are not loops. If we ignore the edge lengths, any fixed finite sequence of 3-regular strongly connected directed multigraphs occurs with positive probability.

1 Introduction and main result

Let $\vec{G}(n,p)$ be a random directed graph with vertex set $[n] := \{1, \ldots, n\}$ and random edge set where each of the $n(n-1)$ possible edges $(i, j)$, $i \neq j$, is present independently with probability $p$. We are interested in the strongly connected components of $\vec{G}(n,p)$, that is the maximal subgraphs for which there exists a directed path from a vertex to any other.

The usual Erdős–Rényi random graph, $G(n,p)$, in which each of the $n(n-1)/2$ possible undirected edges is present independently with probability $p$, will play an important role in our results. It is well known that $G(n,p)$ undergoes a phase transition [6]: if $np \to c > 1$ as $n \to \infty$ then $G(n,p)$ has a unique giant component with high probability, while if $np \to c < 1$ as $n \to \infty$ then the components of $G(n,p)$ are of size $O_{\mathbb{P}}(\log n)$. In the so-called critical window, where $p = 1/n + \lambda n^{-4/3}$, Aldous [3] proved that the sequence of sizes of the largest components possesses a distributional limit when renormalised by $n^{-2/3}$.

Previous work by Karp [12] and Łuczak [15] has shown that $\vec{G}(n,p)$ undergoes a similar phase transition to that of $G(n,p)$: if $np \to c > 1$ as $n \to \infty$, then $\vec{G}(n,p)$ has a unique giant strongly connected component with high probability, while if $np \to c < 1$ as $n \to \infty$, then all the strongly connected components are $o_{\mathbb{P}}(n)$ in size. These results were strengthened by Łuczak and Seierstad [16], who showed that $\vec{G}(n,p)$ has, in fact, the same critical window as $G(n,p)$.

*Department of Statistics and Lady Margaret Hall, University of Oxford, goldschm@stats.ox.ac.uk
†Department of Statistics, University of Oxford, robin.stephenson@normalesup.org
Theorem 1.1 (Luczak and Seierstad [16]). Let $\gamma_n = (np - 1)n^{1/3}$.

(i) If $\gamma_n \to \infty$ then the largest strongly connected component of $\vec{G}(n, p)$ has size $(4 + o_p(1))\gamma_n^2 n^{1/3}$ and the second largest has size $O_p(\gamma_n^{-1} n^{1/3})$.

(ii) If $\gamma_n \to -\infty$ then the largest strongly connected component of $\vec{G}(n, p)$ has size $O_p(\lvert \gamma_n^{-1} \rvert n^{1/3})$.

However, in contrast to $G(n, p)$, Luczak and Seierstad also show that within the critical window, the complex strongly connected components (that is, those which do not just consist of a single directed cycle) occupy only $O_p(n^{1/3})$ vertices in total. This shows that the critical components are very much “thinner” objects than in the setting of $G(n, p)$, where the complex components occupy $O_p(n^{2/3})$ vertices.

In a very recent preprint [5], Coulson shows that, on rescaling by $n^{-1/3}$, the size of the largest strongly connected component of $\vec{G}(n, p)$ in the critical window is tight, with explicit upper and lower tail bounds.

Figure 1: A directed graph on [17]. Its strongly connected components have vertex sets $\{3, 6, 9, 10, 14, 16\}, \{1, 2, 5, 17\}, \{7, 11\}, \{4\}, \{8\}, \{12\}, \{13\}$ and $\{15\}$.

In this paper, we investigate the behaviour within the critical window in more detail, and in particular we prove a scaling limit for the strongly connected components. We do this by relating a particular subgraph of $\vec{G}(n, p)$ to a spanning forest of $G(n, p)$, and the convergence of that spanning forest (thought of as a collection of discrete metric spaces, one per component) to a collection of random $\mathbb{R}$-trees. Similar tools have already been used to study the components of $G(n, p)$ in the same critical window, leading to the main theorem of [2].
Theorem 1.2 (Addario-Berry, Broutin and Goldschmidt [2]). Let \( p = p(n) = \frac{1}{n} + \lambda n^{-4/3} \) for fixed \( \lambda \in \mathbb{R} \). Let \((A_1(n), A_2(n), \ldots)\) be the connected components of \( G(n, p) \), each considered as a metric space by endowing the vertex-set with the graph distance. Then
\[
\left( \frac{A_i(n)}{n^{1/3}}, i \in \mathbb{N} \right) \overset{(d)}{\rightarrow} (\mathcal{A}_i, i \in \mathbb{N}),
\]
where \( \mathcal{A} = (\mathcal{A}_i, i \in \mathbb{N}) \) is a random sequence of compact metric spaces, and the convergence is in distribution for the \( \ell^4 \) metric for sequences of compact metric spaces based on the Gromov–Hausdorff distance.

We will immediately give a description of the scaling limit \( \mathcal{A} \). Define \( W^\lambda(t) = W(t) + \lambda t - t^2/2 \) for \( t \geq 0 \), where \( W \) is a standard Brownian motion, and let \((\sigma_i, i \in \mathbb{N})\) be the collection of excursion lengths above the running infimum of \( W^\lambda \), ranked in decreasing order. For \( \sigma > 0 \), let \( \tilde{e}^{(\sigma)} \) be a Brownian excursion with length \( \sigma \) biased by the exponential of its area, so that if \( e^{(\sigma)} \) is a Brownian excursion of length \( \sigma \) then for any non-negative measurable test function \( g \), we have
\[
\mathbb{E}\left[ g\left( \tilde{e}^{(\sigma)} \right) \right] = \frac{\mathbb{E}\left[ \exp\left( \int_0^\sigma e^{(\sigma)}(u) du \right) g(e^{(\sigma)}) \right]}{\mathbb{E}\left[ \exp\left( \int_0^\sigma e^{(\sigma)}(u) du \right) \right]}.
\]
Let \( \mathcal{T}_\sigma \) be the \( \mathbb{R} \)-tree encoded by \( 2\tilde{e}^{(\sigma)} \). We make some additional point-identifications in this tree. Let \((t_1, \ldots, t_K)\) be the points of a Poisson random measure on \([0, \sigma]\) with intensity \( \tilde{e}^{(\sigma)}(t) dt \). The point \( t_j \in [0, \sigma] \) corresponds to a point \( x_j \) in \( \mathcal{T}_\sigma \) at distance \( 2\tilde{e}^{(\sigma)}(t_j) \) from the root. For all \( 1 \leq j \leq K \), we identify \( x_j \) with a uniformly chosen point on its path to the root. Write \( \mathcal{G}_\sigma \) for the resulting metric space. Finally, conditionally on \((\sigma_i, i \in \mathbb{N})\), the metric spaces \( \mathcal{A}_1, \mathcal{A}_2, \ldots \) are independent and, for each \( i \in \mathbb{N} \), \( \mathcal{A}_i \) has the law of \( \mathcal{G}_\sigma \).

While metric spaces provide the natural setting in which to consider scaling limits of undirected graphs, this is no longer the case in the directed setting: we need some extra structure to encode the orientations. Let us make some useful definitions.

By a directed multigraph, we mean a triple \((V, E, r)\) where
- \( V \) and \( E \) are finite sets.
- \( r = (r_1, r_2) \) is a function from \( E \) to \( V \times V \), with \( r_1(e) \) and \( r_2(e) \) for \( e \in E \) being respectively the tail and head of \( e \).

We will refer to the case where \( V = \{v\} \), \( E = \{e\} \) and \( r_1(e) = r_2(e) = v \) as a loop. \( X = (V, E, r, \ell) \) is a directed multigraph with edge lengths if \( (V, E, r) \) is a directed multigraph and \( \ell \) is a function from \( E \) to \( (0, \infty) \) which assigns each edge a length. A special role will be played by the degenerate case of a loop whose single edge is assigned length 0, which we call \( \mathcal{L} \). The length \( \text{len}(X) \) of \( X \) is given by \( \sum_{e \in E} \ell(e) \).

We now define a distance between directed multigraphs with edge lengths \( X = (V, E, r, \ell) \) and \( X' = (V', E', r', \ell') \) in such a way that they are close if there is a graph isomorphism from \( X \) to \( X' \) which changes the lengths very little. Specifically, let \( \text{Isom}(X, X') \) be the set of graph isomorphisms from \( X \) to \( X' \), that is pairs of bijections \( f \) from \( V \) to \( V' \) and \( g \) from \( E \) to \( E' \) such that, for all \( e \in E \), \( r'(g(e)) = (f(r_1(e)), f(r_2(e))) \). Then set
\[
d_{\mathcal{G}}(X, X') = \inf_{(f, g) \in \text{Isom}(X, X')} \sup_{e \in E} |\ell(e) - \ell'(g(e))|.
\]
Note that if $X$ and $X'$ do not have the same graph structure, then $\text{Isom}(X, X')$ is empty and $d_{\mathcal{G}}(X, X')$ is set to infinity. Let $\mathcal{G}$ be the set of (isometry classes of) directed multigraphs with edge lengths. Then $(\mathcal{G}, d_{\mathcal{G}})$ is a Polish space.

Let $C_i(n)$ for $i \geq 1$ be the strongly connected components of $\mathcal{G}_i(n, p)$, listed in decreasing order of size, breaking ties by increasing order of the lowest labelled vertex. We view these strongly connected components as directed multigraphs with edge lengths, by assigning to each edge a length of 1, and then removing all vertices with degree 2 and merging their corresponding edges into paths of length greater than 1. In the case of a strongly connected component which consists of a single directed cycle with $k \geq 2$ vertices, we think of it as a loop of length $k$. Similarly, we think of isolated vertices as loops of length 0. Finally, since there are at most $n$ components, we complete the list with an infinite repeat of $\mathcal{L}$, the loop of length 0.

We can now state our main theorem.

**Theorem 1.3.** Suppose $p = p(n) = \frac{1}{n^4} + \lambda n^{-4/3} + o(n^{-4/3})$. There exists a sequence $\mathcal{C} = (C_i, i \in \mathbb{N})$ of random strongly connected directed multigraphs with edge lengths such that, for each $i \geq 1$, $C_i$ is either 3-regular or a loop, and such that

$$\left( \frac{C_i(n)}{n^{1/3}}, i \in \mathbb{N} \right) \overset{(d)}{\longrightarrow} (C_i, i \in \mathbb{N})$$

with respect to the distance $d$ defined by

$$d(A, B) = \sum_{i=1}^{\infty} d_{\mathcal{G}}(A_i, B_i),$$

for $A, B \in \mathcal{G}^{\mathbb{N}}$.

In particular, the limit object $\mathcal{C}$ has finite total length. We will show later that $\mathcal{C}$ has only finitely many complex components (i.e. components which are not loops). So Theorem 1.3 implies the convergence in distribution of the number of complex components of $\mathcal{G}_i(n, p)$, their rescaled numbers of vertices, and their excesses (where the excess of a component is given by its number of edges minus its number of vertices). This, in particular, significantly strengthens Theorems 13 and 14 of [16]. Finally, we also show that, if we ignore the edge lengths, then any fixed finite sequence of 3-regular strongly connected directed multigraphs occurs with positive probability.

We defer a proper description of $\mathcal{C}$, which is rather involved, to Section 4 below. As is the case for $(A_i, i \in \mathbb{N})$, the $(C_i, i \in \mathbb{N})$ are derived from the $\mathbb{R}$-trees encoded by the excursions of $W^\lambda$. However, the strongly connected components $(C_i, i \in \mathbb{N})$ are much simpler objects than $(A_i, i \in \mathbb{N})$ which, for example, have a rich fractal structure coming from their relationship to the Brownian continuum random tree. A closer analogy is obtained by instead looking at the scaling limit of a special subgraph of $G(n, p)$: its core. The core of a graph is defined to be the maximal subgraph of minimum degree 2, and consists of the the vertices and edges which lie in cycles, as well as those in paths joining cycles. (It can be obtained by successively deleting leaves and their incident edges from the graph until no leaves remain.) It is possible to define an analogous notion of a core for the scaling limit $A$ of the critical random undirected graph. This comprises the cycle structure created by the point-identifications we make in the $\mathbb{R}$-trees encoded by the excursions of $W^\lambda$. Indeed, for each $i \geq 1$, $\text{core}(A_i)$ is an undirected multigraph with edge-lengths which is empty if there are no
point-identifications, is a loop if there is a single point-identification, and is otherwise 3-regular. The directed multigraphs with edge lengths \((C_i, i \in \mathbb{N})\) are similarly obtained by making (a different collection of) point-identifications in the \(\mathbb{R}\)-trees encoded by the excursions of \(W^\lambda\). In this context, a single \(\mathbb{R}\)-tree may give rise to one or more strongly connected components, or indeed none. The fact that we obtain an \(\ell^1\) convergence in Theorem 1.3, comes from the property that for very small \(\sigma\), an \(\mathbb{R}\)-tree with the same distribution as \(T_\sigma\) is very unlikely to produce any strongly connected components at all.

The rest of this paper is structured as follows. In Section 2, we introduce some standard terminology and then describe the depth-first exploration which we use in order to understand the directed graph \(\vec{G}(n,p)\). A key role is played by a particular class of edges known as back edges, and we discuss back edges in both the discrete and continuum settings in Section 3. In Section 4, we prove some useful properties of the scaling limit \(C\). Section 5 contains the proof of Theorem 1.3. In Section 6, we prove the further properties of the scaling limit mentioned immediately after the main theorem.

2 Some graph theory

2.1 Basic terminology

We recall here some elementary graph theoretic terminology which we will use throughout the paper.

**Directed graphs and strongly connected components.** Let \(\vec{G}\) be a directed graph. For a directed edge \((x, y)\) of \(\vec{G}\), we say that \(x\) is the tail of the edge and \(y\) is its head. For two vertices \(x\) and \(y\), we also say that \(x\) is a parent of \(y\) (and \(y\) is a child of \(x\)) if there is an edge from \(x\) to \(y\), and that \(x\) is an ancestor of \(y\) (and \(y\) is a descendant of \(x\)) if there is a directed path from \(x\) to \(y\).

A directed graph \(\vec{G}\) is strongly connected if for every pair \(\{u, v\}\) of distinct vertices of \(\vec{G}\) there exists a directed path from \(u\) to \(v\) and a directed path from \(v\) to \(u\). For a general directed graph \(\vec{G}\), its strongly connected components are the maximal strongly connected subgraphs. The strongly connected components partition the vertex set but note that, unlike for undirected graphs, edges of \(\vec{G}\) may lead from one strongly connected component to another.

**Trees and plane trees.** A discrete tree is a connected undirected graph \(T\) with no cycles. For two vertices \(x\) and \(y\) in \(T\), we write \([x, y]\) for the unique path between \(x\) and \(y\). Our trees will often be rooted at a specified vertex \(\rho\). This allows us to think of \(T\) as a directed graph, by orienting all of its edges away from \(\rho\).

A planar ordering, also known as topological sort, of a rooted tree \(T\) is any total order \(>\) on its vertex set such that every directed edge \((u, v)\) of \(T\) is “increasing”, in the sense that \(v > u\). A rooted plane tree is then a rooted tree endowed with a planar ordering.

**Directed multigraphs.** Recall the definition of a directed multigraph from the introduction. Directed multigraphs have the same notion of ancestor and descendant as directed graphs, and have strongly connected components in the same way. Note that the loop is strongly connected. The excess of a strongly connected directed multigraph \((V, E, r)\) is defined to be \(|V| - |E|\). If the excess is strictly positive then we say that the multigraph is complex.
2.2 The exploration process

The strongly connected components of any directed graph can be found in time which is linear in the sum of the sizes of the vertex and edge sets, by using various algorithms. Several linear-time algorithms, including Tarjan’s algorithm [19] and the so-called path-based algorithms (see [7] for an example), rely on a depth-first search, that is a procedure which consists in exploring the graph in such a way that, after we visit a vertex, we visit all of its as-yet unseen descendants before backtracking. Broadly speaking, as we traverse the graph, some information is kept in the form of a stack, which allows us to determine the strongly connected components.

For our study of \( \vec{G}(n,p) \), we use a variant of these ideas to give a simple algorithm which does not directly yield the strongly connected components, but instead uses the fact that the vertex set is \([n]\) to give a specific plane spanning forest which will be a key part of the structure of the strongly connected components. We use the now-standard ordered depth-first search exposed, for example, in [2], but with the modification that we only allow ourselves to follow edges in the direction of their orientation. Let us give a precise definition of the construction and, along the way, remind the reader of the depth-first exploration for undirected graphs. Let \( \vec{G} \) (resp. \( G \)) be any directed graph (resp. undirected graph) on \([n]\). Inductively on \( i \in \{0, \ldots, n\} \), we define an ordered list \( O_i \) of open vertices (the stack) which have been seen but not yet explored, and a set \( A_i \) of explored vertices:

- **i = 0:** let \( O_0 = (1) \) and \( A_0 = \emptyset \).
- **Induction step:** given \( O_i \) and \( A_i \), let \( v_i \) be the first vertex of \( O_i \) and let \( A_{i+1} = A_i \cup \{v_i\} \). Let \( N_i \) be the set of out-neighbours (resp. neighbours) of \( v_i \) which are not in \( O_i \cup A_i \). Construct \( O_{i+1} \) by removing \( v_i \) from \( O_i \), and adding in the elements of \( N_i \) in increasing order (such that the smallest element of \( N_i \) is now at the start of \( O_{i+1} \)). If, however, this leads to \( O_{i+1} = \emptyset \), then add to it the smallest element of \( \{1, \ldots, n\} \setminus A_{i+1} \).

This procedure builds a directed spanning forest \( F_{\vec{G}} \) of \( \vec{G} \), by saying that two vertices \( x \) and \( y \) are linked by an edge from \( x \) to \( y \) if there exists \( i \) for which \( x = v_i \) and \( y \in N_i \). We call \( F_{\vec{G}} \) the forward depth-first forest of \( \vec{G} \).

We also obtain a total order of \([n]\), given by \((v_0, \ldots, v_{n-1})\), and which is a planar ordering of \( F_{\vec{G}} \), in the sense that it is a topological sort of each of each its trees and it also functions as a total order on the set formed by the trees. From this, the edges of \( \vec{G} \) are partitioned into two categories: the forward edges, which are increasing for this order, and the back edges, which are decreasing. The forward edges can themselves also be separated into two groups: those which are edges of \( F_{\vec{G}} \), and those which are not, which we call surplus edges. (In the case of the undirected graph \( G \), we still get a forest \( F_G \), but all edges of \( G \) are either part of the forest or are surplus edges.)

The combination of forward edges and back edges is what creates the strongly directed components of \( \vec{G} \). Notice in particular that, since there are no forward edges going between different trees of \( F_{\vec{G}} \), each strongly connected component lies within a single such tree. Moreover, since strongly connected components are made of cycles, any strongly connected component with at least two vertices must contain at least one forward and one back edge. As a consequence of the forthcoming Proposition 3.1, if such a component does not contain a surplus edge, then it must contain an ancestral back edge – that is one which goes from a vertex to one of its ancestors. We deduce from this a useful bound: the number of strongly connected components of \( \vec{G} \) is smaller than the sum of its numbers of surplus edges and ancestral back edges.
Figure 2: The planar embedding of exploration forest of the graph in Figure 1. Surplus edges and back edges are then dotted, and respectively straight and curved. (The strongly connected components have vertex sets \( \{3, 6, 9, 10, 14, 16\}, \{1, 2, 5, 17\}, \{7, 11\}, \{4\}, \{8\}, \{12\}, \{13\} \) and \( \{15\} \).

Note that the surplus edges of \( G \) are taken from the set of edges permitted by \( F_{\tilde{G}} \), which are the pairs \((u, v)\) such that there exists \( i \) such that \( u \) and \( v \) are both in \( O_i \). In this case, \( v \) is a sibling of an ancestor of \( u \) which occurs later in the planar ordering. In fact, given \( F_{\tilde{G}} \), we can add or remove any permitted edge to \( \tilde{G} \), and this will not change \( F_{\tilde{G}} \). The same holds true for back edges. Thus, conditionally on \( F_{\tilde{G}(n,p)} \), the permitted surplus edges and back edges of \( \tilde{G}(n,p) \) appear independently with probability \( p \). This leads to the following proposition, which allows us to relate \( \tilde{G}(n,p) \) to \( G(n,p) \) by their explorations.

**Proposition 2.1.** For any directed graph \( \tilde{G} \) on \([n]\) we call \( \tilde{G}_{\text{fwd}} \) the undirected graph whose edges are the forward edges of \( \tilde{G} \). We then have the following:

(i) \( F_{\tilde{G}(n,p)}^{(d)} = F_{G(n,p)} \)

(ii) \( (\tilde{G}(n,p))_{\text{fwd}}^{(d)} = G(n,p) \)

(iii) One can couple \( G(n,p) \) and \( \tilde{G}(n,p) \) in the following way: first sample \( G(n,p) \), which creates in particular a depth-first ordering on \([1, \ldots, n] \). Then let \( \tilde{G}_{\text{fwd}}(n,p) = G(n,p) \), and add to it each of the possible back edges \((v_i, v_j)\) for \( j < i \) independently with probability \( p \).

\(^{1}\)Note also that \( F_{\tilde{G}} \) determines the exploration process fully, so defining the permitted edges using the \( O_i \) is unambiguous.
Proof. The proof of (i) is straightforward by induction: notice that, in the explorations of both $\tilde{G}(n,p)$ and $G(n,p)$, for all $i$, given $O_i$ and $A_i$, the neighbourhood $N_i$ contains each element of $\{1, \ldots, n\} \setminus (O_i \cup A_i)$ independently with probability $p$. Thus, each step of the forward exploration of $\tilde{G}(n,p)$ has the same distribution as the corresponding step of the depth-first exploration of $G(n,p)$, and in particular the forests they build have the same distribution.

Part (ii) is obtained by observing that, both for $\tilde{G}(n,p)$ and $G(n,p)$, given the exploration forest, each permitted surplus edge is present independently with probability $p$. Similarly, (iii) follows from the fact that, given $\tilde{G}_{\text{fwd}}(n,p)$, each back edge is present independently with probability $p$. \hfill \Box

This proposition motivates the study of a process which adds back edges to trees. The next section will formalise this, especially for the continuum trees which arise in the scaling limit of $G(n, 1/n + \lambda n^{-4/3})$.

3 Back edges on discrete and continuum trees

3.1 The discrete case

Let $T = (V(T), E(T))$ be a finite rooted plane tree, with root $\rho$. Recall that for two vertices $x$ and $y$ of $T$, $[x, y]$ is the path between $x$ and $y$. We think of $T$ as a directed graph, by orienting all the edges away from $\rho$.

Consider a set $B$ of additional edges between elements of $V(T)$ which go backwards for the planar order. Such an edge is called ancestral if it leads from a vertex $v$ to an ancestor of $v$. We sort some of the elements of $B$ into generations and colour the tree as follows.

- Generation 1: let $((x_i^1, y_i^1), i \in \{1, \ldots, N(1)\})$ be the edges of $B$ which are ancestral, sorted in increasing planar order, and declare $S_1 = \bigcup_{i=1}^{N(1)} [\rho, x_i^1]$ to be the subset of colour 1.

- For $n \in \mathbb{N}$, let the edges of generation $n + 1$ be the elements $((x_i^{n+1}, y_i^{n+1}), i \in \{1, \ldots, N(n + 1)\})$ of $B$ such that $y_i^{n+1} \in S_n$, again listed in increasing planar order. Then declare $S_{n+1} = \bigcup_{i=1}^{N(n+1)} [\rho, x_i^{n+1}] \setminus S_n$ to be the subset of colour $n + 1$.

Let $l_n$ be the number of vertices in $S_n$.

Proposition 3.1. Let $X$ be the directed graph obtained by taking $T$ (with edges directed away from $\rho$) and adding all the edges of $B$. Let $X^*$ be the subgraph of $X$ where we remove any element of $B$ that is not of the type $(x_i^n, y_i^n)$ for some $n \in \mathbb{N}$ and $1 \leq i \leq N(n)$. Then $X$ and $X^*$ have the same strongly connected components.

Proof. By definition, if an element $(x, y)$ of $B$ belongs to a strongly connected component of $X$, then it is possible to reach an ancestor of $x$ starting from $y$ and following edges of $X$. One of these edges is then necessarily an ancestral back edge, and then by induction, all the back edges on this path are in $X^*$. \hfill \Box

This seemingly innocuous lemma is, in fact, a key tool for us. Indeed, if $T$ is taken to be a large tree of $F_G(n,p)$ (meaning it has size of order $n^{2/3}$), and $B$ is the set of back edges of $\tilde{G}(n,p)$ which join elements of $T$, then $B$ has size of order $n^{1/3}$. However, as we will see later, the number of back edges in $X^*$ remains of order 1. This means that the reduction from $X$ to $X^*$, while not changing the strongly connected components, allows us to ignore the majority of the back edges at no cost.
3.2 The continuum case

3.2.1 \(\mathbb{R}\)-trees and notation

We recall here some basic terminology about \(\mathbb{R}\)-trees; more information concerning their use in probability may be found in the survey paper [14]. An \(\mathbb{R}\)-tree is any metric space \((T, d)\) such that

- For all \(x, y \in T\), there exists a unique distance-preserving map \(\phi_{x,y}\) from \([0, d(x, y)]\) into \(T\) such that \(\phi_{x,y}(0) = x\) and \(\phi_{x,y}(d(x, y)) = y\). We write \([x, y]\) for the image of \(\phi_{x,y}\).

- For all continuous and one-to-one functions \(c : [0, 1] \to T\), we have \(c([0, 1]) = \|c(0), c(1)\|\).

Our \(\mathbb{R}\)-trees will be typically be rooted, which means we distinguish a point of \(T\) called the root, usually denoted \(\rho\). For \(x, y \in T\), we say that \(x\) is an ancestor of \(y\), or that \(y\) is a descendant of \(x\), if \(x \in [\rho, y]\), and we call the the point \(x \land y\) such that \([\rho, x] \cap [\rho, y] = [\rho, x \land y]\) the most recent common ancestor of \(x\) and \(y\). The degree of a point \(x \in T\) is the number of connected components of \(T \setminus \{x\}\). If \(x\) has degree 1 we call it a leaf.

The \(\mathbb{R}\)-trees we encounter will be all be encoded by functions. A function \(f : [0, \sigma] \to \mathbb{R}_+\) is called an excursion function if it is continuous and \(f(x) = 0\) if and only if \(x = 0\) or \(\sigma\). Let \(\hat{f} : [0, \sigma]^2 \to \mathbb{R}_+\) be defined by \(\hat{f}(x, y) = \min_{s \in [x, y]} f(s)\). Then \(\hat{f}\) encodes a pseudo-distance \(d_f\) on \([0, \sigma]\), defined by \(d_f(x, y) = f(x) + f(y) - 2\hat{f}(x, y)\), and an \(\mathbb{R}\)-tree \(T_f\), defined by \(T_f = [0, \sigma]/\{d_f = 0\}\).

The natural projection from \([0, \sigma]\) to \(T_f\) will be called \(p_f\), and we let the root of \(T_f\) be \(p_f(0) = p_f(\sigma)\). \(T_f\) also inherits a natural total order from \([0, 1]\) which we call the planar order. Finally, for \(x, y \in [0, \sigma]^2\), we let \(x \land y = \inf\{t \in [x, y] : f(t) = \hat{f}(x, y)\}\).

From now on, we assume moreover that:

- \(f\) is \(\alpha\)-Hölder for some \(\alpha \leq 1\) (with Hölder constant \(C > 0\)),

- \(p_f(x)\) is a leaf for almost all \(x \in [0, \sigma]\).

In the sequel, it will often be the case that the functions \(f\) we consider have unique local minima. If this holds then the resulting \(\mathbb{R}\)-tree \(T_f\) is binary (meaning its points all have degree at most 3).

We will later on need the following extension of the Hölder property.

Lemma 3.2. For \(x \in [0, \sigma]\) and \(y, y'\) in \([x, \sigma]\), we have

\[|\hat{f}(x, y) - \hat{f}(x, y')| \leq C|y - y'|^\alpha.\]

Proof. Assume \(y \leq y'\). Notice that, if \(x \land y' \leq y\) then \(\hat{f}(x, y) = \hat{f}(x, y')\), thus we can assume \(x \land y' \in (y, y')\), hence \(\hat{f}(x, y') \leq \hat{f}(x, y)\). Moreover, \(\hat{f}(x, y') \geq f(y) - C|y' - y'|^\alpha \geq \hat{f}(x, y) - C|y' - y'|^\alpha\), and thus \(|\hat{f}(x, y) - \hat{f}(x, y')| \leq C|y' - y'|^\alpha\). \(\square\)
3.2.2 Constructing the identifications

We now describe a random process which will give us a finite number of vertex identifications which go backward for this planar ordering: pairs of points of the form \((x, y)\) with \(x > y\) for the planar ordering and an “arrow with zero length” pointing from \(x\) to \(y\). Specifically, we will define inductively for all \(n \in \mathbb{N}\):

- times \(0 \leq s_1^n < s_2^n < \ldots < s_{N(n)}^n \leq \sigma\), with projections \(x_i^n = p_f(s_i^n)\);
- a subset \(S_n\) of \(T_f\) defined inductively by \(S_1 = \bigcup_{i=1}^{N(1)} [\rho, x_1^1]\) and \(S_{n+1} = \bigcup_{i=1}^{N(n+1)} [\rho, x_1^i] \setminus S_n\);
- points \(y_1^n, \ldots, y_{N(n)}^n\) in \(S_n\), which are the heads of arrows originating at the \((x_i^n, i \leq N(n))\).

We start with the base case \(n = 1\), which is a little different from the others. Let \(s_1^1 < s_2^1 < \ldots < s_{N(1)}^1\) be the points of a Poisson random measure on \([0, \sigma]\) with intensity \(f(x)dx\), and \(x_1^i = p_f(s_1^i)\) for \(i \leq N(1)\). For each \(i \leq N(1)\), let then \(y_i^1\) be a uniform random point on the segment \([\rho, x_1^i]\), all sampled independently from one another. Finally, let \(S_1 = \bigcup_{i=1}^{N(1)} [\rho, x_1^i]\).

Let us now move from \(n \in \mathbb{N}\) to \(n + 1\). If \(N(n) = 0\) then the process stops. If not, we define for \(t \in [s_1^n, \sigma]\) an evolving subset \(S_n(t)\) of \(S_n\) and its length \(\ell_n(t)\), by induction on \(k\) for which \(t \leq s_k^n\) (where, for convenience, we set \(s_{N(n)+1}^n = \sigma\)). \(S_n(t)\) will be the set of possible heads for an eventual back edge arising at \(t\). For \(k = 1\) we let \(S_n(s_1^n) = \{x_1^1\}\) and, assuming we are given \(S_n(t)\) up to \(t = s_k^n\), for \(t \in (s_k^n, s_{k+1}^n]\) we let \(S_n(t) = S_n(s_k^n) \cup (S_n \cap [x_k^n, x_k^n \wedge p_f(t)])\). Now let \(s_1^{n+1} < \ldots < s_{N(n+1)}^{n+1}\) be the arrival times of a Poisson point process on \([s_1^n, \sigma]\) of intensity \(\ell_n(t)dt\), and let \(y_i^{n+1}\) be uniform on the finite length space \(S_n(s_i^{n+1})\), independently of the everything else.

![Diagram](image.png)

Figure 3: The first two generations of identifications on a tree. Lengths of the segments are represented by \(a, \ldots, t\) for the next figures.

Observe that we necessarily have \(s_1^1 \leq s_2^1 \leq \ldots \leq \sigma\) (so that, in particular, the first back edge in the planar ordering is always ancestral). It is, however, in principle possible for the sequence \((s_1^n)_{n \geq 1}\) to accumulate, with the consequence that there are infinitely many back edges. That this is not the case, but that rather \(N(n) = 0\) for some finite \(n\), is a consequence of the following lemma.
Lemma 3.3. For all $n \in \mathbb{N}$ and $t \in [s^n_1, \sigma]$, we have $\ell_n(t) \leq C(t - s^n_1)^{\alpha}$.

Proof. Fix $n \in \mathbb{N}$. We prove this by induction on $k$ such that $t \leq s^n_k$. The result is clear for $k = 1$ since $\ell_n(s^n_1) = 0$ and, assuming that it is true for all $t \in [s^n_1, s^n_k]$ for some $1 < k < n$, then for $t \in [s^n_k, s^n_{k+1}]$, we get that $\ell_n(t) - \ell_n(s^n_k)$ is smaller than or equal to the length of $[x^n_k, x^n_k \wedge p_f(t)]$, which is $f(s^n_k) - \hat{f}(s^n_k, t)$. By the induction hypothesis and Lemma 3.2, we then have $\ell_n(t) \leq C(s^n_k - s^n_1)^{\alpha} + C(t - s^n_k)^{\alpha}$. Since $\alpha \leq 1$, the $\alpha$-th power is subadditive and so $\ell_n(t) \leq C(t - s^n_1)^{\alpha}$. \square

In order to see that the process terminates, we argue as follows. By Lemma 3.3, we have for all $n \in \mathbb{N}$,

$$
\mathbb{P}[N(n + 1) > 0 | N(n) > 0] \leq \mathbb{P}[X \leq 1 - s^n_1 | N(n) > 0] \leq \mathbb{P}[X \leq 1] < 1
$$

where $X$ is the first arrival time of a Poisson point process with rate $Ct^{\alpha}dt$. Hence, $\mathbb{P}[N(n) > 0] \leq (\mathbb{P}[X \leq 1])^n$ and so almost surely there exists an $n$ such that $N(n) = 0$.

Remark 3.4. It is also possible to build the pairs $(s^n_i, y^n_i)$ without the generational structure, i.e. realising them as $((s_i, y_i), 1 \leq i \leq N)$, with (say) increasing first co-ordinate. This is done by setting $s_0 = 0$ and then, inductively for $i \geq 0$, taking $s_{i+1}$ to be the first arrival time of a Poisson process on $[s_i, \sigma]$ with local rate at time $t$ given by

$$
\sum_{k=1}^{i} \left(f(s_k) - \hat{f}(s_{k-1}, s_k)\right) + f(t) - \hat{f}(t, s_i),
$$

and finishing the construction if we reach time $\sigma$. Write $x_i = p_f(s_i)$ for $1 \leq i \leq N$. Then note that the above expression is the length of the subtree of $T_f$ spanned by the leaves $x_j$ for $j \leq i$ and $p_f(t)$; we let $y_i$ be uniform on this subtree for all $i$.

Using this point of view, it follows straightforwardly that

$$
\mathbb{P}[N = n, s_i \in dt_i \forall i \leq n] = 
\prod_{k=1}^{n} \left( \sum_{i=1}^{k} f(t_i) - \hat{f}(t_{i-1}, t_i) \right)
\times \exp \left( - \int_{0}^{\sigma} \left( f(t) - \hat{f}(t, I(t)) + \sum_{i=1}^{I(t)} \left(f(t_i) - \hat{f}(t_{i-1}, t_i)\right) \right) dt \right) dt_1 \ldots dt_n,
$$

where $t_0 = 0$ and, for $t \in [0, \sigma]$, $I(t) = \max\{i : t_i < t\}$.

3.2.3 The resulting strongly connected components

Let $T_f^{col} = \bigcup_{n=0}^{\infty} S_n$ be the subtree formed by all coloured points, and quotient it by the equivalence relation $\sim$ which identifies $x^n_i$ and $y^n_i$ for $n \in \mathbb{N}$ and $i \in \{1, \ldots, N(n)\}$, to obtain a rooted metric space

$$
\mathcal{M}_f = T_f^{col} / \sim.
$$

Since $T_f^{col}$ has only finitely many leaves, we may also view $\mathcal{M}_f$ as a finite rooted directed multigraph $\hat{M}_f$ whose edges are endowed with lengths: the vertices of $\hat{M}_f$ are the images of the $(y^n_i)$ and of the branchpoints of $T_f$, and the directions are inherited from $T_f^{col}$ (which we always think of as having
edges directed away from the root). We observe that, with the exception of the root (which is a leaf almost surely), the vertices of $M_f$ all have degree at least 3. Now remove all edges which do not lie in a strongly connected component of $M_f$ and delete any isolated vertices thus created. This yields a collection of strongly connected components of minimum degree 2. If there remain vertices of degree precisely two, we apply the following merging operation. Pick an arbitrary vertex of degree 2 and merge its two incident edges as long as they are different edges, summing their lengths. This yields a collection $C_f$ of strongly connected directed multigraphs with edge-lengths, as illustrated in Figure 4.

![Diagram](image1)

![Diagram](image2)

Figure 4: A representation of $M_f$ if all the identifications were given in Figure 3, and the resulting strongly connected components.

4 The scaling limit

4.1 Excursions of Brownian motion with parabolic drift

Let $(W(t), t \geq 0)$ be a standard Brownian motion. For $\lambda \in \mathbb{R}$ and $t \geq 0$, let $W^\lambda(t) = W(t) + \lambda t - t^2/2$ and let $\overline{W}^\lambda(t) = \inf_{0 \leq s \leq t} W^\lambda(s)$. Let $B^\lambda(t) = W^\lambda(t) - \overline{W}^\lambda(t)$, and let $\Gamma^\lambda$ be the set of excursions of $B^\lambda$.

**Proposition 4.1.** For $\alpha \in \{2, 3\}$, we have $\mathbb{E} \left[ \sum_{\gamma \in \Gamma^\lambda} |\gamma|^\alpha \right] < \infty$ a.s.
The \( \alpha = 2 \) case is Lemma 25 of Aldous [3], which we extend here to \( \alpha = 3 \). Our method also works for all \( \alpha > 3/2 \) but we omit the details for the sake of brevity. We first need a standard result on moments of hitting times of Brownian motion with constant drift.

**Lemma 4.2.** For \( \mu > 0 \) and \( b > 0 \), let \( T(b, \mu) = \inf\{t \geq 0 : W(t) - \mu t = -b\} \). Then we have

\[
\mathbb{E}[T(b, \mu)] = \frac{b}{\mu} \quad \text{and} \quad \mathbb{E}[(T(b, \mu))^2] = \frac{b(1 + b\mu)}{\mu^3}
\]

*Proof.* The Laplace transform of \( T(b, \mu) \) is given by

\[
\mathbb{E}[e^{-\theta T(b, \mu)}] = \exp\left( b\mu - b\sqrt{\mu^2 + 2\theta} \right), \quad \theta > 0
\]

(see, for example, in Exercise 5.10 in Chapter 3 of [11]) and the first two moments of \( T(b, \mu) \) follow from differentiating twice. \( \Box \)

*Proof of Proposition 4.1.* Let \( \gamma \) be an excursion of \( B^\lambda \), and \( l \) and \( r \) its endpoints. We have

\[
|\gamma|^3 = 3 \int_l^r (r-t)^2 \, dt.
\]

If we write, for \( t \geq 0 \), \( H_t = \min\{s > 0 : B^\lambda(t+s) = 0\} \), we then have

\[
\sum_{\gamma \in \gamma^\lambda} |\gamma|^3 = 3 \int_0^\infty H_t^2 \, dt
\]

and so we only need to prove that \( \int_0^\infty \mathbb{E}[H_t^2] \, dt < \infty \). To do this we split the integral into \( \int_0^\tau \mathbb{E}[H_t^2] \, dt \) and \( \int_\tau^\infty \mathbb{E}[H_t^2] \, dt \) where \( \tau = \max(0, 2\lambda + 1) \).

For \( t > \max(0, \lambda) \) and \( s \geq 0 \), we have \( \lambda s - (t+s)^2/2 + s^2/2 \leq (\lambda - t)s \). Thus, conditionally on \( B^\lambda(t) \), we get that \( H_t \) is stochastically dominated by \( T(B^\lambda(t), t-\lambda) \), which leads to

\[
\mathbb{E}[H_t \mid B^\lambda(t)] \leq \frac{B^\lambda(t)}{(t-\lambda)^2} \quad \text{and} \quad \mathbb{E}[(H_t)^2 \mid B^\lambda(t)] \leq \frac{B^\lambda(t)(1 + (t-\lambda)B^\lambda(t))}{(t-\lambda)^3}.
\]

In particular, we have

\[
\int_\tau^\infty \mathbb{E}[H_t^2] \, dt \leq \int_\tau^\infty \frac{\mathbb{E}[B^\lambda(t)] + (t-\lambda)\mathbb{E}[(B^\lambda(t))^2]}{(\lambda - t)^3} \, dt.
\]

However, it is also established in the proof of Lemma 25 of [3] that, for \( t > 2\lambda \), the random variable \( B^\lambda(t) \) is stochastically dominated by an exponential variable with parameter \( t - 2\lambda \), implying that \( \mathbb{E}[B^\lambda(t)] \leq 1/(t-2\lambda) \) and \( \mathbb{E}[(B^\lambda(t))^2] \leq (1 - 2\lambda + t)/(t-2\lambda)^2 \). In consequence, \( \int_\tau^\infty \mathbb{E}[H_t^2] \, dt < \infty \).

To bound \( \int_0^\tau \mathbb{E}[H_t^2] \, dt \), notice that we have \( H_t \leq \tau - t + H_\tau \leq \tau + H_\tau \) for \( t \leq \tau \). Hence,

\[
\mathbb{E}[H_t^2] \leq \tau^2 + 2\tau \mathbb{E}[H_\tau] + \mathbb{E}[H_t^2] < \infty
\]

\[
\leq \tau^2 + 2\tau \frac{\mathbb{E}[B^\lambda(\tau)]}{\tau - \lambda} + \mathbb{E}[B^\lambda(\tau)] + \frac{\mathbb{E}[(B^\lambda(\tau))^2]}{(\tau - \lambda)^2},
\]

and this uniform upper bound is finite since \( B^\lambda(\tau) \) is stochastically dominated by an exponential variable which has moments of all orders. It follows that we do indeed have \( \int_0^\tau \mathbb{E}[H_t^2] \, dt < \infty \).  \( \Box \)
4.2 Bounds for a single tree

Let \( \sigma > 0 \). We let \( f = 2\tilde{e}(\sigma) \) be a tilted Brownian excursion with length \( \sigma \), whose distribution is determined by

\[
\mathbb{E}[g(\tilde{e}(\sigma))] = \frac{\mathbb{E}\left[g(\sqrt{\sigma}e(\cdot/\sigma)) \exp\left(\frac{\sigma^{3/2}}{1^{1/2}} e(x) dx\right)\right]}{\mathbb{E}\left[\exp\left(\frac{\sigma^{3/2}}{1^{1/2}} e(x) dx\right)\right]},
\]

for any non-negative measurable function \( g \), where \( e \) is a standard Brownian excursion. We perform the construction detailed in Section 3.2, defining the \( \mathcal{R} \)-tree \( T_\sigma \) (we now replace the subscript \( f \) by \( \sigma \) since henceforth all of our coding functions will be of this type), performing \( N_\sigma(n) \) identifications at the \( n \)-th generation for \( n \in \mathbb{N} \) and thus building the directed multigraph with edge lengths \( \mathcal{M}_\sigma \). The following proposition will enable us to control the number of strongly connected components of \( \mathcal{M}_\sigma \).

**Proposition 4.3.** Let \( c = \mathbb{E}[\int_0^1 e(t) dt] = F'(0) \) where \( F(z) = \mathbb{E}[e^2 \int_0^1 e(t) dt] \) is the moment generating function of the Airy distribution, which is an entire function [10]. We have the following asymptotics: as \( \sigma \to 0 \),

(i) \( \mathbb{P}[N_\sigma(1) = 0] = 1 - 2c\sigma^{3/2} + O(\sigma^3) \)

(ii) \( \mathbb{P}[N_\sigma(1) = 1, N_\sigma(2) = 0] = 2c\sigma^{3/2} + O(\sigma^3) \)

(iii) \( \mathbb{P}[N_\sigma(1) \geq 2 \text{ or } N_\sigma(2) \geq 1] = O(\sigma^3) \).

Moreover,

(iv) \( \sup_{\sigma > 0} \sigma^{-3}\mathbb{E}[N_\sigma(1)1_{\{N_\sigma(1) \geq 2\}}] < \infty \).

**Proof.** Instead of working with \( \tilde{e}(\sigma) \), we express the probabilities in terms of a standard Brownian excursion \( e \) and its area \( A = \int_0^1 e(t) dt \). For (i), recalling that \( N_\sigma(1) \) follows, conditionally on \( e(\sigma) \), a Poisson distribution with parameter \( \int_0^\sigma 2\tilde{e}(\sigma)(x) dx \), we have

\[
\mathbb{P}[N_\sigma(1) = 0] = \frac{\mathbb{E}\left[\int_0^{\sigma} 2^{2} e(t) dt, e^{\sigma^3/2} \int_0^1 e(t) dt\right]}{\mathbb{E}\left[\int_0^{\sigma} e^{\sigma^3/2} \int_0^1 e(t) dt\right]} = \frac{F(-\sigma^3/2)}{F(\sigma^3/2)} = 1 - 2c\sigma^{3/2} + O(\sigma^3).
\]

We begin (ii) and (iii) by computing

\[
\mathbb{P}[N_\sigma(1) = 1] = \frac{\mathbb{E}\left[2\sigma^{3/2} A e^{-\sigma^3/2} A\right]}{\mathbb{E}\left[e^{\sigma^3/2} A\right]} = \frac{2\sigma^{3/2} F'(-\sigma^3/2)}{F(\sigma^3/2)} = \frac{2\sigma^{3/2}(c + O(\sigma^3/2))}{1 + O(\sigma^3/2)} = 2c\sigma^{3/2} + O(\sigma^3).
\]

Next, we write

\[
\mathbb{P}[N_\sigma(1) = 1, N_\sigma(2) = 0] = \frac{\mathbb{E}\left[\int_0^{\sigma} A \sigma^3/2 \int_0^1 2e(x) \exp\left(-\sigma^3/2 \int_x^1 2(e(x) - \tilde{e}(x, y) dy\right) dx\right]}{\mathbb{E}[e^{\sigma^3/2} A]}.
\]
Using $|1 - e^{-u}| \leq u$ for $u \geq 0$, we obtain

$$
\mathbb{P}[N_1 = 1] - \mathbb{P}[N_1 = 1, N_2 = 0] \leq 4\sigma^3 \mathbb{E} \left[ e^{-2\sigma^3/2} \int_0^1 \mathbb{E}(x) dx \int_x^1 (\mathbb{E}(x) - \mathbb{E}(x,y)) dy \right]
\leq 4\sigma^3 \mathbb{E} \left[ \int_0^1 (\mathbb{E}(x))^2 dx \right].
$$

Now note that $\int_0^1 (\mathbb{E}(x))^2 dx$ has finite expectation because it is smaller than $(\sup \mathbb{E})^2$, which is indeed integrable (sup $\mathbb{E}$ has sub-Gaussian tails, see [13]). So the above quantity is $O(\sigma^3)$. This finishes the proof of both (ii) and (iii).

Finally, since $N_1$ is integer-valued, we have

$$
\mathbb{E}[N_1 1_{\{N_2 \geq 2\}}] = \mathbb{E}[N_1] - \mathbb{P}[N_1 = 1]
= \mathbb{E}[2\sigma^3/2. e^{\sigma^3/2} A] - \mathbb{P}[N_1 = 1]
= 2\sigma^{3/2} \left( F'(\sigma^3/2) - F'(-\sigma^3/2) \right)
/ F(\sigma^3/2).
$$

This proves that $\mathbb{E}[N_1 1_{\{N_2 \geq 2\}}] = O(\sigma^3)$ as $\sigma \to 0$, but we also want the bound as $\sigma$ tends to infinity. To this end, we write

$$
\mathbb{E}[N_1 1_{\{N_2 \geq 2\}}] \leq 2\sigma^{3/2} F'(\sigma^3/2) / F(\sigma^3/2)
$$

and simply aim to prove that $F'(x) = O(x F(x))$ as $x \to \infty$. Quoting [10, Section 7], we have

$$
F(x) = \sum_{n=0}^{\infty} a_n x^n,
$$

where

$$
a_n \sim \frac{3\sqrt{2}}{(n-1)!} \left( \frac{n}{12e} \right)^{n/2}.
$$

The desired domination will follow from the fact that $\frac{(n+1)a_{n+1}}{a_n}$ (the ratio of the coefficients of $x^n$ in $F'(x)$ and $xF(x)$) is uniformly bounded for $n \geq 1$, which is true, since the sequence in fact converges:

$$
\frac{(n+1)a_{n+1}}{a_n} \sim \frac{n+1}{n(n-1) 12e} \left( \frac{n}{12e} \right)^{n/2} \sim \frac{1}{12e} \left( \frac{n}{12e} \right)^{n/2} \to \frac{1}{12}.
$$

This completes the proof. \qed

### 4.3 Two properties of the scaling limit

Let $(\sigma_1, \sigma_2, \ldots)$ be the lengths of the excursions of $B^\lambda$, listed in decreasing order. For each $i \geq 1$, let $D_i$ be an independent copy of $M_{2\sigma_i}$ and let $D = \bigcup_{i=1}^{\infty} D_i$. We think of $D$ as a countable directed multigraph with edge lengths.
**Theorem 4.4.** The number of complex connected components of $D$ has finite expectation.

*Proof.* We abuse notation slightly and call $N_{\sigma_i}(n)$ the number of $n$-th generation identifications in $D_i$ for $n \in \mathbb{N}$. For all $i \geq 1$, let $K_i$ be the number of complex components in $D_i$. Each complex component contains at least one ancestral back edge and so $K_i \leq N_{\sigma_i}(1)$. Furthermore, if there is exactly one ancestral back edge, at least one back edge must be present in the second generation in order to obtain a complex component, so that $P[K_i = 1] \leq P[N_{\sigma_i}(1) = 1, N_{\sigma_i}(2) \geq 1] + P[N_{\sigma_i}(1) \geq 2]$. Hence, by (ii) and (iv) from Proposition 4.3,

$$
E[K_i | \sigma_i] = P[K_i = 1 | \sigma_i] + E[K_i \geq 2 | \sigma_i] \\
\leq P[N_{\sigma_i}(1) = 1, N_{\sigma_i}(2) \geq 1 | \sigma_i] + P[N_{\sigma_i}(2) \geq 2 | \sigma_i] + E[N_{\sigma_i}(1) \{N_{\sigma_i}(1) \geq 2\} | \sigma_i] \\
\leq C \sigma_i^3
$$

for some $C > 0$. Thus,

$$
E \left[ \sum_{i=1}^{\infty} K_i \right] \leq C E \left[ \sum_{i=1}^{\infty} \sigma_i^3 \right] < \infty.
$$

The following property of $D$ is not surprising, but requires proof.

**Proposition 4.5.** The strongly connected components of $D$ all have different lengths a.s.

This follows straightforwardly from the following lemma, in which we work on a single tree.

**Lemma 4.6.** Let $\sigma > 0$. Then

(i) for all $x > 0$,

$$
P[M_{\sigma} \text{ has a strongly connected component of length } x] = 0
$$

(ii) $P[M_{\sigma} \text{ has two strongly connected components with equal lengths}] = 0$.

*Proof.* Let $e^{(2\sigma)}$ be the excursion function encoding the tree $T_\sigma$ from which $M_{\sigma}$ is obtained, let the selected leaves be $(x_i, i \in \{1, \ldots, N\})$, and let $C^{(\sigma)}_1, \ldots, C^{(\sigma)}_K$ be the strongly connected components of $M_{\sigma}$, ordered by the order of appearance of their first elements in the planar ordering of $T_\sigma$. For each $k \in \mathbb{N}$, on the event where $k \leq K$, let $E_k = \{i \in \{1, \ldots, N\} : x_i \in C^{(\sigma)}_k \}$ be the set of indices of the leaves implicated in the construction of the $k$th strongly connected component, let $u_k = x_{\min E_k} \land x_{\max E_k}$ be the MRCA of those leaves, let $\rho_k = \sup \{x \in \|\rho, u_k\| : \exists j \neq k, x \in C^{(\sigma)}_j \}$ be the root of the subtree giving rise to the $k$th strongly connected component, and let $T_k = \bigcup_{i \in E_k} \|\rho_k, x_i\|$ be that subtree. Finally, let $n_k = \# \{i \in E_k, z_i \in \|\rho_k, u_k\| \}$, be the number of heads along the line-segment separating $\rho_k$ from $u_k$. Notice then that the length of $C^{(\sigma)}_k$ is exactly that of $T_k$, minus the initial part between $\rho_k$ and the first $y_i$ to be encountered. However, since the $y_i$ are chosen uniformly from the length measure, this means that $\|\rho_k, u_k\|$ is split according to a Dirichlet variable with $n_k + 1$ components. Specifically, we have

$$
\text{len}(T_k) - \text{len}(C^{(\sigma)}_k) = (f(u_k) - f(\rho_k)) \Delta_1^k
$$
Figure 5: For point (i), focusing on the second component, $\mathcal{T}_2$ contains the leaves $s_3, s_4, s_5$, and the length of its initial segment $f(u_2) - f(\rho_2)$ is split by a Dirichlet$(1, 1, 1)$ into $(a, b, c)$. For (ii), conditioning on $\rho_2$ being in $\mathcal{T}_1$, then this split is still $(1, 1, 1)$.

where, conditionally on $n_k$, $Z^k_1$ is the first component of a vector $\Delta^k = (\Delta^k_1, \ldots, \Delta^k_{n_k+1})$ which has Dirichlet$(1, \ldots, 1)$ distribution. Since Dirichlet distributions have a density, we obtain

$$\mathbb{P}[\text{len} (C_k^{(\sigma)}) = x \mid k \leq K, \text{len} (\mathcal{T}_k), f(u_k), n_k] = 0,$$

and integrating and taking the union over all $k$ gives us (i).

To prove (ii), consider two integers $k$ and $l$. If $k \leq K$ and $l \leq K$, let

$$A_k = \{ \rho_k \notin C_l^{(\sigma)} \}$$

and

$$A_l = \{ \rho_l \notin C_k^{(\sigma)} \}.$$

Observe that $\mathbb{P}[A_k \cup A_l] = 1$, since $C_k^{(\sigma)}$ and $C_l^{(\sigma)}$ do not intersect. Now, on the event $A_l$, $\mathcal{T}_k$ and $\mathcal{T}_l$ intersect either at point $\rho_k$ or not at all, and we can still write

$$\text{len}(\mathcal{T}_k) - \text{len}(C_k^{(\sigma)}) = (f(u_k) - f(\rho_k))\Delta^l_1$$

where, conditionally on $\mathcal{T}_l$, $n_k$ and the event $A_l$, $\Delta^l_1$ is the first component of a Dirichlet$(1, \ldots, 1)$ vector. This means that the length of $C_k^{(\sigma)}$ has a (conditional) density, and integrating, we get

$$\mathbb{P}[\text{len} (C_k^{(\sigma)}) = \text{len} (C_l^{(\sigma)}) \mid A_l, k, l \leq K] = 0.$$

Symmetrising then yields that

$$\mathbb{P}[\text{len} (C_k^{(\sigma)}) = \text{len} (C_l^{(\sigma)}) \mid k, l \leq K] = 0,$$

and taking a countable union yields (ii).
Proof of Proposition 4.5. We label the strongly connected components of $D$ in such a way that, for $i \in \mathbb{N}$, those which belong to $D_i$ are called $C_{i,1}, \ldots, C_{i,K_i}$. Consider $C_{i,k}$ and $C_{j,l}$ for $i,j,k,l \in \mathbb{N}$. We can assume $i \neq j$ as the case where $i = j$ has already been treated. Conditionally on the excursion lengths $(\sigma_i, i \in \mathbb{N})$, $C_{i,k}$ and $C_{j,l}$ are independent and we have $\mathbb{P}[\text{len}(C_{i,k}) = x] = 0$ for all $x > 0$. Thus we have $\mathbb{P}[\text{len}(C_{i,k}) = \text{len}(C_{j,l}) | \text{len}(C_{i,l})] = 0$, and integrating to remove the conditioning yields $\mathbb{P}[\text{len}(C_{i,k}) = \text{len}(C_{j,l})] = 0$, ending the proof.

5 Convergence of the strongly connected components

For $n \in \mathbb{N}$, let $p = p(n)$ such that $p = 1/n + \lambda n^{-4/3} + o(n^{-4/3})$ as $n \to \infty$. Recall that $(C_i(n), i \in \mathbb{N})$ are the strongly connected components of $\vec{G}(n, p)$, listed in decreasing order of size (with ties broken by using the increasing order of smallest vertex-label), where we treat isolated vertices as copies of the loop of zero length, and additionally append infinitely many copies of the loop of zero length. Let $(C_i, i \in \mathbb{N})$ be the strongly connected components of $D$, listed in decreasing order of length. If there are only finitely many such components, we append an infinite sequence of copies of the loop of zero length.

We restate the main theorem.

Theorem 1.3.

$$
\left( \frac{C_i(n)}{n^{1/3}}, i \in \mathbb{N} \right) \overset{(d)}{\to} (C_i, i \in \mathbb{N})
$$

with respect to the distance $d$ defined by

$$
d(A, B) = \sum_{i=1}^{\infty} d_{\vec{G}}(A_i, B_i),
$$

for $A, B \in \vec{G}^{\mathbb{N}}$.

The aim of this section is to prove this theorem. We begin by discussing some topological issues related to $d_{\vec{G}}$. We then prove a series of preliminary results, before finally turning to the proof of Theorem 1.3.

5.1 $d_{\vec{G}}$ and the Gromov–Hausdorff distance

Recall from the introduction the definition of directed multigraphs with edge lengths, and for two such objects $X = (V, E, r, \ell)$ and $X' = (V', E', r', \ell')$, their distance is defined by.

$$
d_{\vec{G}}(X, X') = \inf_{(f, g) \in \text{Hom}(X, X')} \sup_{e \in E} |\ell(e) - \ell'(g(e))|
$$

Elements of $\vec{G}$ can also be viewed as metric spaces, by thinking of each edge as a line segment and forgetting the orientation of the edges. This means that we can also compare them by using the Gromov–Hausdorff distance $d_{\text{GH}}$ (see Chapter 7 of [4] for an introduction to the Gromov–Hausdorff distance and its use). The resulting topology is however weaker, as the following lemma shows.

Lemma 5.1. For $X \in \vec{G}$ and $X' \in \vec{G}$, we have

$$
d_{\text{GH}}(X, X') \leq \frac{1}{2} |E| d_{\vec{G}}(X, X')
$$

18
Conversely, any point \( y_i \) of a sequence of points in \([y]\) satisfies \( k \) of a line segment implies convergence of its length. Let us then focus on the induction step: the Gromov–Hausdorff topology. Take a common embedding of the \( \rho \) and let us fix \( \rho \) and \( \rho_n \) (resp. \( \rho \)) and \( k \) selected distinct leaves \((x_{i,n}, 1 \leq i \leq k)\) (resp. \((x_{i}, i \leq k))\). Then let

\[
\mathcal{T}_n = \bigcup_{i=1}^{k} [\rho_n, x_{i,n}]
\]

be the subtree spanned by the \( k \) selected leaves and the root (and define \( \mathcal{T} \) similarly). View it as an element of \( \mathcal{G} \) by taking as verticiax the root, the leaves, and all the branch points, orienting each edge away from \( \rho_n \) (resp. \( \rho \)) and giving each edge the length of its corresponding metric path.

Suppose that \((\mathcal{T}_n, \rho_n, x_{1,n}, \ldots, x_{k,n})\) converges to \((\mathcal{T}, \rho, x_1, \ldots, x_k)\) for the \((k+1)\)-pointed Gromov–Hausdorff topology, and that \( \mathcal{T} \) is binary. Then \( \mathcal{T}_n \) converges to \( \mathcal{T} \) for \( d_{\mathcal{G}} \). Specifically, the map which sends \( \rho_n \) to \( \rho \) and \( x_{i,n} \) to \( x_i \) for each \( 1 \leq i \leq k \) extends uniquely to a graph isomorphism, under which the length of each edge in \( \mathcal{T}_n \) converges to that of the corresponding edge in \( \mathcal{T} \).

**Proof.** First we prove that the reduced tree \((\mathcal{T}_n, \rho_n, x_{1,n}, \ldots, x_{k,n})\) converges for the \((k+1)\)-pointed Gromov–Hausdorff topology. Take a common embedding of the \( \mathcal{T}_n \) and \( \mathcal{T} \) in a certain compact space \((Z, d)\) such that \( \mathcal{T}_n \to \mathcal{T} \) in the Hausdorff sense, \( \rho_n \to \rho \) and \( x_{i,n} \to x_i \) for all \( i \) and let us show that we also have the Hausdorff convergence of \( \mathcal{T}_n \) to \( \mathcal{T} \). To do this, first notice that, for each \( i \in \{1, \ldots, k\} \), the segment \([\rho_n, x_{i,n}]\) converges to \([\rho, x_i]\). Now noting that any point \( y \in [\rho_n, x_{i,n}] \) satisfies \( d(y, \rho_n) + d(y, x_{i,n}) = d(\rho_n, x_{i,n}) \), we obtain by passing to the limit any point \( y \) of a sequence of points in \([\rho_n, x_{i,n}]\) satisfies \( d(y, \rho) + d(y, x_i) = d(\rho, x_i) \) and thus lies in \([\rho, x_i]\). Conversely, any point \( y \) of \([\rho, x_i]\) with \( d(\rho, y) = t \) is the limit of \( y_n \in [\rho_n, x_{i,n}] \) with \( d(\rho_n, y_n) = t \) (if \( t = d(\rho, x_i) \), then \( y_n = x_{i,n} \) instead). We also have that, for each \( i, j \in \{1, \ldots, n\} \), the MRCA \( x_{i,n} \wedge x_{j,n} \) converges to \( x_i \wedge x_j \) in the embedding above, since any limit point \( y \) must be in \([\rho, x_i]\) and passing the relation

\[
2d(x_{i,n} \wedge x_{j,n}, x_{i,n}) = d(x_{i,n}, x_{j,n}) + d(\rho, x_{i,n}) - d(\rho, x_{j,n})
\]

to the limit yields \( d(y, x_i) = d(x_i \wedge x_j, x_i) \).

The \( d_{\mathcal{G}} \) convergence, with the specific isomorphism mentioned in the statement, can then be proved by induction. The base case \( k = 1 \) is immediate, as the Gromov–Hausdorff convergence of a line segment implies convergence of its length. Let us then focus on the induction step: assume the proposition at rank \( k \in \mathbb{N} \), and let \((\mathcal{T}_n, n \in \mathbb{N})\) be rooted trees with \( k + 1 \) leaves
(\(x_{i,n}\), 1 \(\leq\) \(i\) \(\leq\) \(k+1\)) converging for the \((k+2)\)-pointed Gromov–Hausdorff topology to \(\mathcal{T}\) with root \(\rho\) and leaves \((x_i, 1 \leq i \leq k+1)\).

Consider for all \(n \in \mathbb{N}\) the subtree \(\mathcal{T}^k_n\) of \(\mathcal{T}\) spanned by the root and the first \(k\) leaves \(x_{i,n}\) with \(i \leq k\). Then \((\mathcal{T}^k_n, \rho_n, x_{1,n}, \ldots, x_{k,n})\) converges to \((\mathcal{T}^k, \rho, x_1, \ldots, x_k)\) for the \((k+1)\)-pointed Gromov–Hausdorff topology. By the induction hypothesis, this is also convergence for \(d_{\mathcal{G}}\) and, in particular, the graph structure of \(\mathcal{T}^k_n\) is the same as that of \(\mathcal{T}^k\) for \(n\) large enough.

The graph structure of \(\mathcal{T}^{k+1}_n\), the tree spanned by the root and the \(k+1\) leaves, is then determined by that of \(\mathcal{T}^k_n\) together with the knowledge of which edge of \(\mathcal{T}^k_n\) contains the projection \(p_{n,k}(x_{k+1,n})\) of \(x_{k+1,n}\). However, \(p_{k,n}(x_{k+1,n})\) converges to \(p_k(x_{k+1})\) under the Gromov–Hausdorff convergence, since it is the maximum (in the line segment \([\rho_n, x_{k+1}])\) of \(x_{i,n} \land x_{k+1,n}\) for \(i \leq k\) and each of those terms also converge. Thus, for \(n\) large enough, \(p_{k,n}(x_{k+1,n})\) lies in the line segment of \(\mathcal{T}^k_n\) corresponding to the one in of \(\mathcal{T}^k\) containing \(p_k(x_{k+1})\), and the map sending \(x_{i,n}\) to \(x_i\) for \(i \leq k+1\) does indeed extend to a graph isomorphism.

Once we know the graph structure of \(\mathcal{T}^{k+1}_n\), each edge is either of the form \((x_{i,n} \land x_{j,n}, x_{j,n} \land x_{k,n})\) where \(x_{i,n} \land x_{j,n}\) is an ancestor of \(x_{j,n} \land x_{k,n}\), or \((\rho, x_{i,n} \land x_{j,n})\), and their lengths converge because, as noticed earlier, the branch points \(x_{i,n} \land x_{j,n}\) can be added to the pointed Gromov–Hausdorff convergence.

\[\square\]

**Proposition 5.3.** If the connected components of a directed multigraph \(X\) all have different total lengths, and \((X_n, n \in \mathbb{N})\) is a sequence which converges to \(X\) for \(d_{\mathcal{G}}\), then the strongly connected components of \(X_n\), listed in decreasing order of length and seen as elements of \(\mathcal{G}\), converge to those of \(X\).

**Proof.** Writing \(X = (V, E, \ell)\), let \((C_1, \ldots, C_k)\) be the strongly connected components of \(X\), ordered by decreasing length. For \(n \in \mathbb{N}\) large enough, we have \(X_n = (V, E, \ell_n)\), where \(\ell_n(C_i) \to \ell(C_i)\) as \(n \to \infty\) for all \(i\). In particular, for \(n\) large enough, \(\ell_n(C_i)\) is a strictly decreasing sequence and so \((C_1, \ldots, C_k)\) is the length-decreasing sequence of strongly connected components of \(X_n\), which completes the proof. \[\square\]

### 5.2 The components originating from a single tree

The first part of the proof will consist in proving the convergence of the components originating from a single tree. For \(m \in \mathbb{N}\), we take a plane tree \(T_m\) which has the distribution of a tree component of \(\mathcal{F}_{\mathcal{G}(m, p)}\) conditioned to have size \(m\). We are interested in \(m \sim \sigma n^{2/3}\) so that, in particular, we have \(mp^{2/3} \to \sigma\) as \(m \to \infty\). From [2], up to an unimportant relabelling of the vertices, \(T_m\) has the same distribution as a uniform random labelled tree on \([m]\), biased by \((1-p)^{-a(T_m)}\), where \(a(T_m)\) is the number of permitted edges in \(T_m\). We give this tree a planar embedding by rooting at the vertex labelled 1 and then simply using the increasing order on the labels of the children of any vertex. Let \(H^m : \{0, \ldots, m-1\} \to \mathbb{Z}_+\) be the height function of \(T_m\), such that \(H^m(k)\) is the height of the \(k\)-th vertex in the planar order, starting with \(H^m(0) = 0\). We define \(\|T_m\| = \max_{0 \leq k \leq m-1} H^m(k)\), the height of the tree \(T_m\). Theorem 15 of [2] states that

\[
((m/\sigma)^{-1/2}H^m([m/\sigma]t)), 0 \leq t \leq \sigma \xrightarrow{d} (2e^{(\sigma)}(t), 0 \leq t \leq \sigma)
\]

uniformly as \(m \to \infty\).

As in Proposition 2.1, we include each of the \(\binom{m}{2}\) possible back edges and \(a(T_m)\) possible surplus edges independently with probability \(p\), and let \(X_m\) be the resulting directed graph. The aim of this
section is to show that the rescaled strongly connected components of \(X_m\) converge in distribution to those of \(M_\sigma\). In order to do this, we will use the generational structure of back edges outlined in Section 3.1. Specifically, let \((x^n_{i,m}, y^n_{i,m}), n \in \mathbb{N}, i \leq N_m(n)\) be the back edges obtained with this procedure, and call \(X^*_m\) the subgraph of \(X_m\) obtained by removing any back edges which do not form part of the generational structure, and any surplus edges. We will first show that the strongly connected components of \(X^*_m\) converge to those of \(M_\sigma\), and then that \(X_m\) and \(X^*_m\) have the same strongly connected components with high probability. (In particular, we show that the surplus edges with high probability do not play any role in creating the strongly connected components.)

### 5.2.1 Convergence of the marked points

Our next step is to improve the convergence of the tree \(T_m\) to include the marked points \((x^n_{i,m})\) and \((y^n_{i,m})\).

**Proposition 5.4.** There exists a realisation of \(T_m, T_f, N_m(n), N(n), x^0_{i,m}, y^0_{i,m}, x^n_i, y^n_i\) for all \(m \in \mathbb{N}, n \in \mathbb{N},\) and \(i \leq N_m(n)\) and \(j \leq N(n)\) on a single probability space such that \(N_m(n) \rightarrow N(n)\) a.s. for all \(n \in \mathbb{N}\) as \(m\) tends to infinity, and

\[
\left(\frac{\sigma}{m}\right)^{1/2} T_m, \rho, \left((x^n_{i,m}, y^n_{i,m}), n \in \mathbb{N}, i \leq N_m(n)\right) \xrightarrow{m \rightarrow \infty} (T_f, ((x^n_i, y^n_i), n \in \mathbb{N}, i \leq N(n)))
\]

a.s. for the \((1 + 2 \sum_{n=1}^\infty N(n))\)-pointed Gromov–Hausdorff topology.

Note that the above convergence makes sense since, for \(m\) large enough, \(N_m(n) = N(n)\) for all \(n\).

**Proof.** By Skorokhod’s representation theorem, we may assume that the convergence of \((\frac{\sigma}{m})^{1/2} H^n\) occurs almost surely. As a consequence, there exists a specific metric space \((Z, d_Z)\) and embeddings of \(T_f\) and each \((\frac{\sigma}{m})^{1/2} T_m\) into \(Z\), such that \(T_m\) converges almost surely in the Hausdorff sense to \(T_f\).

Let \(p_m : [0, m] \rightarrow Z\) be the projection of \(\{0, \ldots, m - 1\}\) onto \((\frac{\sigma}{m})^{1/2} T_m\) in order of the depth-first exploration process, linearly interpolated (with \(p_m(m) = p_m(0)\)). The construction of \(Z\) can be done in such a way that \(p_m(\frac{\sigma}{m} \cdot)\) converges pointwise to \(p_f\) on \(Z\), and this convergence is in fact uniform. Indeed, \(d_Z(p_m(\frac{\sigma}{m} x), p_m(\frac{\sigma}{m} y))\) converges uniformly to \(f(x) + f(y) - 2\hat{f}(x, y)\), and so the family \(p_m(\frac{\sigma}{m} \cdot)\) of functions is equicontinuous. So by the Arzelà–Ascoli theorem it converges uniformly.

Building on this, we will find a probability space on which, additionally, \(N_m(n) \rightarrow N(n), x^n_{i,m} \rightarrow x^n_i\) and \(y^n_{i,m} \rightarrow y^n_i\), a.s. for all \(i \leq N(n)\). This is done by induction on \(n \in \mathbb{N}\).

We start with \(n = 1\), and first focus on the \((x_{i,m}(1), i \leq N_m(1))\). Let \((k_{1,m}(1), \ldots, k_{N_m(1),m}(1))\) in \(\{1, \ldots, m\}\) be the positions of \(x^1_{1,m}, \ldots, x^1_{N_m(1),m}\) in the planar ordering of \(T_m\). Since the number of back edges originating at the \(k\)-th point has distribution \(\text{Bin}(H^n(k), p)\), and \(pH^n(|x_m|) \sim (\frac{\sigma}{\sigma})^{-1} f(x)\), standard results on Poisson random measures imply that \(N_m(1)\) converges in distribution to \(N(1)\) and the \((\frac{\sigma}{\sigma})^{-1} k^1_i, i \leq N_m(1)\) converge in distribution to the arrival times of a Poisson point process with intensity \(f(x)dx\), i.e. the \((s^1_i, i \leq N(1))\). (See the proof of Lemma 19 of [2] for a more detailed version of an essentially identical argument.) Since the projections converge uniformly, we can apply them to obtain that \(x^1_{1,m} \rightarrow x^1_i\) for all \(i \leq N(1)\) as well.

Still for \(n = 1\), we may now assume that the convergence of the \((x^1_{i,m}, i \leq N_m(1))\) occurs almost surely, and focus next on \((y^1_{i,m}, i \leq N_m(1))\). For each \(i\), \(y^1_{i,m}\) belongs to the ancestral line of \(x^1_{i,m}\), and
its height is uniform on \( \{0, \ldots, d(\rho, x_{i,m})-1\} \). Since the relation \( d(\rho, y_{i,m}) + d(y_{i,m}, x_{i,m}) = d(\rho, x_{i,m}) \) passes to the limit, any subsequential limit in distribution of \( (y_{i,m}) \) must be an ancestor of \( x_{i,m} \), and its height must be uniform in \([0, f(s_i^1)]\). Thus \( y_{i,m} \) converges in distribution to a uniform ancestor of \( x_{i,m} \), which is none other than \( y_{i,m}^1 \).

By Skorokhod’s theorem, we may now moreover assume that all these convergences occur almost surely.

The induction step uses the same ideas. In \( T_m \), let \( S_n(m) \) be the subset of colour \( n \), and for \( k \geq k_1^m \), define \( S_n(k, m) \) analogously to \( S_n(t) \): it is the part of \( S_n(m) \) encountered when going around the tree from \( p_m(k_1^m) \) to \( p_m(k) \). We also let \( t_n(k, m) \) be the number of vertices in \( S_n(k, m) \). With the induction hypothesis, Proposition 5.2 and the Skorokhod representation theorem, we have that the tree of the \( n \) first generations \( \bigcup_{n=1}^{\infty} S_n(m) \) converges a.s. to \( \bigcup_{n=1}^{\infty} S_n \) for \( d_\varphi \).

Moreover, since the \((\frac{m}{\sigma})^{-1}k_i^m \) converge to the \( s_i^n \), \( S_n([\frac{m}{\sigma}t], m) \) and \( S_n(t) \) take a uniformly close amount of length of each edge, and thus \((\frac{m}{\sigma})^{1/2}t_n([\frac{m}{\sigma}t]) \) converges uniformly to \( t_n(t) \). Since the \( x_{i,m}^{n+1} = p_m(k_i^{m+1}) \) are obtained by giving to each \( k \) a \( \text{Bin}(l_n(k), p) \) number of marks, we obtain that the \((\frac{m}{\sigma})^{-1}k_i^{n+1}, i \leq N_n(n+1) \) converge to the \((s_i^n+1, i \leq N(n+1)) \). The argument for the heads of the directed edges generalises similarly.

The proof of Proposition 5.4 also implies the following corollary.

**Corollary 5.5.** Let \( T_m^{\text{col}} = \bigcup_{n=1}^{\infty} S_n \) and \( T_f^{\text{col}} = \bigcup_{n=1}^{\infty} S(n) \) be the coloured subtrees of \( T_m \) and \( T_f \) respectively. Then

\[
\left( \frac{\sigma}{m} \right)^{1/2} \left( T_m^{\text{col}} \setminus \{\rho\}, (x_{i,m}^n, y_{i,m}^n, n \in \mathbb{N}, i \leq N_m(n)) \right) \xrightarrow{m \to \infty} \left( T_f^{\text{col}} \setminus \{\rho\}, (x_i^n, y_i^n, n \in \mathbb{N}, i \leq N(n)) \right),
\]

a.s. for the \((1 + 2\sum_{n=1}^{N(N))}\)-pointed Gromov–Hausdorff topology. The corresponding lengths also converge a.s.:

\[
\left( \frac{\sigma}{m} \right)^{1/2} \text{len}(T_m^{\text{col}}) \xrightarrow{m \to \infty} \text{len}(T_f^{\text{col}}).
\]

### 5.2.2 Convergence of the coloured graph

Henceforth, the generation-based structure of the back edges will no longer matter, and so we will simplify the notation and just call the marked points \((x_{i,m}, y_{i,m}), i \leq N_m \) and \((x_i, y_i), i \leq N \).

Let \( X_m^* = T_m^{\text{col}} \setminus \text{all back edges} \) for \( i \leq N_m \), and recall that \( \mathcal{M}_f = T_f^{\text{col}} / \sim \), where \( \sim \) is the equivalence relation which identifies \( x_i \) with \( y_i \) for \( i \leq N \). We view them as elements of \( \mathcal{G} \), in a way which will fit the metric on \( \mathcal{G} \). Specifically, we take the vertex set of \( X_m^* \) to consist of \( \rho \), the heads \( y_{i,m} \) of the back edges for \( i \leq N_m \), and the branch points \( x_i \) for \( i \leq N_m \). We take the vertices of \( \mathcal{M}_f \) to be \( \rho \), \( y_i \) for \( i \leq N \) (note that post-identification we have \( x_i = y_i \)), and the branch points \( x_i \) for \( i \leq N \).

Because the Brownian continuum random tree is almost surely binary and the law of \( T_f \) is absolutely continuous with respect to that of the Brownian continuum random tree, \( T_f^{\text{col}} \) is also binary almost surely. It follows that \( \mathcal{M}_f \) has \( 2N \) vertices and, as we will see, the same must also be true for \( X_m^* \) for sufficiently large \( m \).

**Proposition 5.6.** \((\frac{\sigma}{m})^{1/2} X_m^* \xrightarrow{(d)} \mathcal{M}_f \) in \( \mathcal{G} \).

**Proof.** We keep the setting of Proposition 5.4 and work almost surely. By Corollary 5.5, \((\frac{\sigma}{m})^{1/2} T_m^{\text{col}}, \rho, x_{1,m}, \ldots, x_{N_m,m} \) converges for the \((N+1)\)-pointed GH topology to \((T_f^{\text{col}}, \rho, x_1, \ldots, x_N)\).
Proposition 5.2 then makes this a convergence in $\bar{G}$ (taking the root, $(x_{i,m})$ and branch points as vertices). In particular they have the same underlying graph structure for $m$ large enough.

For $m$ large enough, no $x_{i,m}$ is an ancestor of a $x_{j,m}$ or $y_{j,m}$, so the graph structure of $X^*_m$ can be obtained from that of $T^\text{col}_m$ by removing the $x_{i,m}$ and instead connecting the edge ending in $x_{i,m}$ back into $y_{i,m}$. Since $y_{i,m}$ converges to $y_i$ in the Gromov–Hausdorff convergence, it will in particular always be on the same edge of $T^\text{col}_m$ for $m$ large. Thus the discrete structure is constant for $m$ large, equal to that of $\mathcal{M}_f$.

Once we know the discrete structure, the lengths of all the edges then also converge since they can be expressed in terms of the distances between the root, the $(x_{i,m})$ and the $(y_{i,m})$.

Adding in Propositions 5.3 and 4.5, the connected components of $(\sigma^1/2 X^*_m)$, ordered by decreasing sizes, also converge to those of $\mathcal{M}_\sigma$, ordered by decreasing length for $d_{\bar{G}}$.

### 5.2.3 Surplus edges do not contribute

As mentioned before, we now want to prove that the surplus edges contribute to the strongly connected components of $X_m$ with vanishingly small probability. Specifically, we aim to prove the following proposition.

**Proposition 5.7.**

$$\mathbb{P}[X_m \text{ and } X^*_m \text{ have different strongly connected components}] \to 0$$

Let $R(m)$ be the number of surplus edges in $X_m$. For $1 \leq i \leq R(m)$, let $\alpha_{i,m}$ and $\beta_{i,m}$ be the tail and head respectively of the $i$-th surplus edge in increasing planar order of their tails. Let $W_i(m)$ be the number of vertices descending from $\beta_{i,m}$ in $T_m$. Proposition 5.7 will follow if we can establish that the family $\left(\sum_{i=1}^{R(m)} W_i(m), m \in \mathbb{N}\right)$ is tight, namely if

$$\lim_{K \to \infty} \limsup_{m \to \infty} \mathbb{P}\left[\sum_{i=1}^{R(m)} W_i(m) > K\right] = 0. \tag{2}$$

Indeed, for a strongly connected component of $X_m$ to feature a surplus edge, we need at least one back edge to originate from a descendant of some $\beta_{i,m}$ (since any surplus edge in a strongly connected component is part of a cycle and must thus lead to a back edge). Conditionally on $\sum_{i=1}^{R(m)} W_i(m) \leq K$, the probability of this event is smaller than the probability that a Bin($mK, p$) variable is non-zero. Assuming (2) and fixing $\epsilon > 0$, we may find a $K$ sufficiently large that

$$\limsup_{m \to \infty} \mathbb{P}\left[\sum_{i=1}^{R(m)} W_i(m) > K\right] \leq \epsilon/3,$$

and $m$ large enough such that $\mathbb{P}\left[\sum_{i=1}^{R(m)} W_i(m) \geq K\right] \leq \epsilon/2$ and $1 - (1 - p)^{mK} \leq \epsilon/2$ (recall that $p \sim \sigma^{3/2}m^{-3/2}$). Then
\[P[X_m \text{ and } X_m^* \text{ have different strongly connected components}] \leq P\left[\sum_{i=1}^{R(m)} W_i(m) \geq K\right] + 1 - (1 - p)^{mK} \leq \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon.\]

As we have already mentioned, it is shown in [2] that \(T_m\) is a biased version of the uniform labelled tree \(T_m\) on \([m]\) (with a canonical planar embedding): for non-negative measurable test functions \(f\),
\[
E[f(T_m)] = \frac{1}{E[(1 - p)^{-a(T_m)}]} E[(1 - p)^{-a(T_m)} f(T_m)].
\]

We recall that \(a(T)\) denotes the number of surplus edges permitted by the planar structure of a tree \(T\), called its area in [2]. We know from Theorem 12 and Lemma 14 of [2] that
\[
(1 - p)^{-a(T_m)} \xrightarrow{d} e \int_0^\sigma e^{(\sigma)(t)} dt,
\]
and that the sequence on the left-hand side is bounded in \(L^2\). We will prove (2) by first showing the analogous statement for \(T_m\). We need the following lemma, which makes use of Kesten’s tree, that is the tree \(\hat{T}\) consisting of a copy of \(\mathbb{Z}_+\) (the spine), at each point of which we graft an independent Galton–Watson tree with Poisson(1) offspring distribution. We root the resulting infinite tree at 0. (This is the local weak limit of \(T_m\) [8].)

**Lemma 5.8.** (i) Let \(Y(m)\) be the number of vertices of \(T_m\) which lie outside the largest subtree descending from a child of the root. Then
\[
Y(m) \xrightarrow{d} Y,
\]
where \(Y\) is the number of vertices of \(\hat{T}\) which have no ancestors on the spine apart from the root.

(ii) Write \((v_i, i \in \{1, \ldots, m\})\) for the vertices of \(T_m\) in planar order. For \(v \in T_m\), let \(Z_v(m)\) be the number of vertices in the subtree rooted at \(v\). Let \(Y_v(m)\) be the number of such vertices which lie outside the largest of the subtrees rooted at a child of \(v\). Then the \((Y_{v_i}(n), n \in \mathbb{N}, i \leq n)\) are tight:
\[
\lim_{M \to \infty} \limsup_{n \in \mathbb{N}} \sup_{i \in \{1, \ldots, n\}} P[Y_i(n) > M] = 0.
\]

**Proof.** It is well-known that \(T_m\) is a Galton-Watson tree with Poisson(1) offspring distribution, conditioned to have \(m\) vertices and assigned a uniformly random labelling from \([m]\). Knowing this, a proof of (i) can be found within the proof of Proposition 5.2 of [18], so we will just give an informal argument. Let \(T_1(n), \ldots, T_D(n)\) be the subtrees of \(T_n\) rooted at its first generation, with \(D\) being the degree of the root, listed in decreasing order of size. For any non-increasing finite sequence \(\lambda\) of positive integers, one can show that \(P[(\#T_2(n), \ldots, \#T_D(n)) = \lambda]\) converges to \(P[(\#\hat{T}_2, \ldots, \#\hat{T}_D) = \lambda]\), where the \(\hat{T}_i\) are defined similarly, and are well-known to be finite since
they are off the spine of $\hat{T}$. Thus, this limit is a probability distribution. Hence, the sequence $(\#T_2(n), \ldots \#T_D(n))$ converges in distribution, and so does its sum.

Part (ii) follows from the fact that, for all $i$ and $n$, the conditional distribution of $Y_{v_i}(n)$ given $Z_{v_i}(n)$ is the same as that of $Y(Z_{v_i}(n))$. (This is part of the Markov branching property of conditioned Galton-Watson trees, see [9].) Hence, the distributions of all the $Y_{v_i}(n)$ are mixtures of the distributions of the $(Y(k), k \in \mathbb{N})$, which form a tight sequence, and thus are also tight. \qed

Now add to the tree $T_m$ each of the $a(T_m)$ permitted surplus edges independently with probability $p$. Conditionally on $a(T_m)$ this yields a Bin$(a(T_m), p)$ number of surplus edges, for which we write $R(m)$. Write the tails and heads of these surplus edges as $a_{i,m}$ and $b_{i,m}$ respectively, listed in increasing planar order of $a_{i,m}$, for $i \leq R(m)$. We also write $b_{i,m}^-$ for the parent of $b_{i,m}$ in $T_m$. Let $W_i(m)$ be the number of descendants of $b_{i,m}^-$. The following lemma is a version of (2) for $T_m$.

**Lemma 5.9.**

$$
\lim_{K \to \infty} \limsup_{m \to \infty} P \left( \sum_{i=1}^{R(m)} W_i(m) > K \right) = 0.
$$

**Proof.** Fix $\varepsilon > 0$. In Lemma 19 of [2], it is proved that $R(m)$ converges in distribution as $m \to \infty$. An identical argument shows that $R(m)$ converges in distribution as $m \to \infty$ and, in particular, is tight. Therefore, there exists $I > 0$ such that $P(R(m) > I) < \frac{\varepsilon}{2}$ for all $m$. Moreover,

$$
P \left[ \sum_{i=1}^{R(m)} W_i(m) > K \right] \leq P \left[ R(m) > I \right] + P \left[ R(m) \leq I, \sum_{i=1}^{R(m)} W_i(m) > K \right]
$$

$$
\leq \frac{\varepsilon}{2} + P \left[ \sum_{i=1}^{R(m) \wedge I} W_i(m) > K \right].
$$

We then split the event where $\sum_{i=1}^{R(m) \wedge I} W_i(m) > K$ in two: either, for all $i \leq R(m) \wedge I$, the vertex $a_{i,m}$ lies in the largest of the subtrees rooted at the children of $b_{i,m}^-$, in which case we also have $\sum_{i=1}^{R(m) \wedge I} Y_{b_{i,m}^-}(m) > K$, or there exists $i$ for which $a_{i,m}$ is *not* in this largest subtree, which then implies, in particular, that $Y_{b_{i,m}^-}(m) \geq d(a_{i,m}, b_{i,m})$. This leads to

$$
P \left[ \sum_{i=1}^{R(m)} W_i(m) > K \right]
$$

$$
\leq \frac{\varepsilon}{2} + P \left[ \sum_{i=1}^{R(m) \wedge I} Y_{b_{i,m}^-}(m) > K \right] + P \left[ \exists i \leq R(m) \wedge I : Y_{b_{i,m}^-}(m) \geq d(a_{i,m}, b_{i,m}) \right].
$$

By Lemma 5.8, the $(Y_{b_{i,m}^-}(m), i \leq R(m))$ are tight as $m$ tends to infinity, and thus so is the sum of at most $I$ of them:

$$
P \left[ \sum_{i=1}^{R(m) \wedge I} Y_{b_{i,m}^-}(m) > K \right] \leq \frac{\varepsilon}{4}.
$$
for all $m$, for $K$ large enough. For the final term, we may again adapt the argument from Lemma 19 of [2] to see that for each $i$, $m^{-1/2}d(a_{i,m},b_{i,m})$ converges in distribution, where $d$ denotes the graph distance in $T_m$. In particular there exists $\eta > 0$ such that $\Pr[d(a_{i,m},b_{i,m}) \leq m^{1/2}\eta] \leq \frac{\varepsilon}{8I}$. We then have

$$\Pr[i \leq R(m), Y_{b_{i,m}}(m) \geq d(a_{i,m},b_{i,m})] \leq \frac{\varepsilon}{8I} + \Pr[i \leq R(m), Y_{b_{i,m}}(m) \geq m^{1/2}\eta],$$

and by Lemma 5.8 again, $\Pr[i \leq R(m), Y_{b_{i,m}}(m) \geq m^{1/2}\eta] < \varepsilon/8I$ for all $m$ sufficiently large, so that for such $m$,

$$\Pr\left[\exists i \leq R(m) \land I : Y_{b_{i,m}}(m) \geq d(a_{i,m},b_{i,m})\right] \leq \frac{\varepsilon}{4}.$$

Combining all the terms yields

$$\limsup_{m \to \infty} \Pr\left[\sum_{i=1}^{R(m)} W_i(m) > K\right] \leq \varepsilon.$$

\noindent \textbf{Proof of Proposition 5.7.} It remains to show that (2) holds. We use the change of measure to pass from $T_m$ to $T_n$. Call $A(m,K)$ the event where $\sum_{i=1}^{R(m)} W_i(m) > K$ and $A(m,K)$ the event where $\sum_{i=1}^{R(m)} W_i(m) > K$. Then we have

$$\Pr[A(m,K)] = \frac{\mathbb{E}[(1-p)^{-a(T_m)} 1_{A(m,K)}]}{\mathbb{E}[(1-p)^{-a(T_m)}]} \leq \sqrt{\frac{\mathbb{E}[(1-p)^{-2a(T_m)}]}{\mathbb{E}[(1-p)^{-a(T_m)}]}} \sqrt{\Pr[A(m,K)]}.$$

We know that $\mathbb{E}[(1-p)^{-2a(T_m)}]$ is bounded and that $\mathbb{E}[(1-p)^{-a(T_m)}]$ converges to a positive limit. So by Lemma 5.9, we obtain

$$\lim_{K \to \infty} \limsup_{m \to \infty} \Pr[A(m,K)] = 0,$$

as required.

\section*{5.3 Proof of Theorem 1.3}

We first prove that the convergence in Theorem 1.3 occurs in the weaker product topology, namely that for any $k \in \mathbb{N}$,

$$n^{-1/3}(C_1(n),C_2(n),\ldots,C_k(n)) \overset{(d)}{\to} (C_1,C_2,\ldots,C_k)$$

with respect to $d^k_G$. We will later improve this to a convergence with respect to $d$.

\subsection*{5.3.1 Convergence in the product topology}

Let $(T_1^n, T_2^n, \ldots)$ be the forward exploration trees of $G(n,p)$. We list them in decreasing order of their sizes $(Z_1^n, Z_2^n, \ldots)$, and write $(\|T_1^n\|, \|T_2^n\|, \ldots)$ for their heights. We also let $(X_1^n, X_2^n, \ldots)$ be the subgraphs of $G(n,p)$ induced by the vertex-sets of these trees (which include both surplus and back edges). By [3], we have the following convergence for the $\ell^2$ topology on sequences:

$$n^{-2/3}(Z_1^n, i \in \mathbb{N}) \overset{(d)}{\to} (\sigma_i, i \in \mathbb{N}).$$

(4)
Again, using Skorokhod’s theorem, we may work on a probability space for which this convergence occurs almost surely. Moreover, conditionally on \((Z^n_1, Z^n_2, \ldots)\), the \((X^n_i, i \in \mathbb{N})\) are independent, each having the distribution of \(X^n_{Z^n_i}\) as in Section 5.2. Since \(Z^n_i p^{2/3} \to \sigma_i\), we have that the rescaled strongly connected components of \(X^n_i\) converge in distribution to those of \(M_{\sigma_i}\), and this holds jointly for any finite set of indices \(i\). Taking into account Proposition 5.3, the following proposition will give the convergence in Theorem 1.3 for the product topology.

**Proposition 5.10.** For all \(k \in \mathbb{N}\), we have

\[
\lim_{N \to \infty} P[C_1, \ldots, C_k \text{ are contained in } D_1, \ldots, D_N] = 1
\]

and, for all \(n \in \mathbb{N}\),

\[
\lim_{N \to \infty} \liminf_{n \to \infty} P[C_1(n), \ldots, C_k(n) \text{ are contained in } X^n_1, \ldots, X^n_N] = 1.
\]

Proposition 5.10 informally states that, with high probability, large strongly connected components of \(\vec{G}(n, p)\) and \(D\) will only be found in large trees of the forward depth-first forest, making the ordering of both trees and strongly connected components by their lengths compatible. Its proof relies on two lemmas.

**Lemma 5.11.** As \(\sigma \to 0\), we have

\[
P[M_\sigma \text{ has a complex component}] = O(\sigma^3).
\]

For all \(\varepsilon > 0\), we have as \(\sigma \to 0\)

\[
P[\|T_\sigma\| \geq \varepsilon] = O(\sigma^3).
\]

Consequently, for all \(\varepsilon > 0\),

\[
P[M_\sigma \text{ has a component with length greater than } \varepsilon] = O(\sigma^3).
\]

**Lemma 5.12.** There exists \(C > 0\) such that, for all \(n\) large enough and \(1 \leq m \leq n^{2/3}\),

\[
P[X_m \text{ has a complex component}] \leq C \frac{m^3}{n^2}
\]

and

\[
P[X_m \text{ has a component which contains a surplus edge}] \leq C \frac{m^3}{n^2}.
\]

Moreover, for all \(\varepsilon > 0\), there exists \(C > 0\) such that, for \(n\) large enough, and \(1 \leq m \leq n^{2/3}\),

\[
P[\|T_m\| \geq n^{1/3} \varepsilon] \leq C \frac{m^2}{n^{4/3}}.
\]

Consequently, for all \(\varepsilon > 0\), there exists \(C > 0\) such that, for \(n\) large enough,

\[
P[X_m \text{ has a component with length greater than } n^{1/3} \varepsilon] \leq C \frac{m^2}{n^{4/3}}.
\]

Note that for both of these lemmas, the final statement is a consequence of the previous ones by noticing that any component consisting of a single ancestral cycle has length smaller than the height of the tree.
Proof of Lemma 5.11. By Proposition 4.3,
\[ P[M_{\sigma} \text{ has a complex component } \varepsilon] \leq P[N_{\sigma}(1) > 1 \text{ or } N_{\sigma}(2) > 0] = O(\sigma^3). \]

Recalling that \( \|T_{\sigma}\| \) has the same distribution as \( \sup 2e^{(\sigma)} \) and that \( e \) has exponential moments [13], we have
\[
P[\|T_{\sigma}\| > \varepsilon] = P[\sigma^{3/2} \sup \tilde{e} > \varepsilon] \leq \frac{E[e^{\int_{0}^{1} e(t) dt} \sup \tilde{e}^{4}]}{E[e^{\int_{0}^{1} e(t) dt}]} e^{-\varepsilon^{3/2}} \leq E[e^{\varepsilon \sup \tilde{e}}] e^{-\varepsilon^{3/2}} = O(\sigma^3).
\]

This proves (5) and (6); (7) then follows.

For Lemma 5.12, we require some preliminary bounds on the height and area of \( T_{m} \).

Lemma 5.13. There exists a constant \( M > 0 \) such that, for all \( n \) large enough such that \( 1/(2n) < p < 2/n \) and all \( 1 \leq m \leq n^{2/3} \),
\[
E[\|T_{m}\|^4] \leq M m^2 \tag{12}
\]
and
\[
E[(a(T_{m}))^2] \leq M m^3. \tag{13}
\]

Proof. Lemma 25 from [2] gives \( E[\|T_{m}\|^4] \leq M \cdot \max(m^6 n^{-4}, 1) \cdot m^2 \) for all \( n \) large enough and \( m \leq n \), and restricting ourselves to \( m \leq n^{2/3} \) yields (12).

For (13), we follow the beginning of the proof of Lemma 25 from [2]. Let \( q = \max(m^{-3/2}, p) \). Then (3) and Markov’s inequality together yield
\[
P[a(T_{m}) > x m^{3/2}] \leq \frac{E[(1 - q)^{-a(T_{m})}]}{(1 - q)^{-x m^{3/2}}}
\leq \frac{E[((1 - p)(1 - q))^{-a(T_{m})}]}{(1 - q)^{-x m^{3/2}}}
\leq \frac{E[(1 - q)^{-2a(T_{m})}]}{(1 - q)^{-x m^{3/2}}}.
\]

From Lemma 14 in [2], we obtain that \( E[(1 - q)^{-2a(T_{m})}] \leq K \exp 4\kappa \delta^2 \) where \( \delta = \max(2m^{3/2}/n, 1) \).
Since \( q m^{3/2} \geq \delta/4 \), we get
\[
P[a(T_{m}) > x m^{3/2}] \leq K e^{4\kappa \delta^2 - x \delta/4},
\]
and for \( 1 \leq m \leq n^{3/2} \), we have \( 1 \leq \delta \leq 2 \), so that
\[
P[a(T_{m}) > x m^{3/2}] \leq K e^{64 \kappa - x/4}.
\]

It follows that
\[
E \left[ \frac{(a(T_{m}))^2}{m^3} \right] \leq K e^{64 \kappa} \int_{0}^{\infty} e^{-\sqrt{r}/4} dr = 32 K e^{64 \kappa},
\]
which completes the proof.
Proof of Lemma 5.12. We take $n$ large enough for (12) and (13) to hold, and $m \leq n^{2/3}$. Notice first that (10) follows from (12) and Markov’s inequality:

$$
\Pr[\|T_m\| \geq n^{1/3} \varepsilon] \leq \frac{\mathbb{E}[\|T_m\|^4]}{\varepsilon^4 n^{4/3}} \leq \frac{M m^2}{\varepsilon^4 n^{4/3}}.
$$

We now want to show that the probability that $X_m$ contains a strongly connected component which is complex or features surplus edges is also bounded by $m^3 n^{-2}$. Such a component can only arise if one of the following four events occurs:

- $A_m = \{X_m \text{ has at least two ancestral back edges.}\}$
- $B_m = \{X_m \text{ has one ancestral back edge, and at least one other back edge which points} \}
\text{inside the created cycle.}\}
- $C_m = \{X_m \text{ has at least two surplus edges.}\}$
- $D_m = \{X_m \text{ has one surplus edge } (a,b) \text{ and at least one back edge pointing to} \}
\text{an ancestor of } a.\}$

We will give a bound on each of these events separately.

Conditionally on the tree $T_m$, the number of ancestral back edges in $X_m$ has distribution $\text{Bin}(S_m, p)$, where is $S_m$ the sum of the heights of all vertices in $T_m$. By using the well-known domination of $\text{Bin}(k, p)$ by $\text{Poi}(-k \log(1-p))$ and $\Pr[\text{Poi}(\mu) \geq 2] \leq \mu^2$, we have

$$
\Pr[A_m \mid T_m] \leq (-S_m \log(1 - p))^2 \leq M (S_m p)^2
$$

From now on, the constant $M$ can vary from line to line, but never depends on $n$ or $m$.

Since $S_m \leq m \|T_m\|$, by using (12) again, for $n$ large enough we end up with

$$
\Pr[A_m] \leq M \frac{m^2}{n^2} \mathbb{E}[\|T_m\|^2] 
\leq M \frac{m^3}{n^2}.
$$

Given that there is exactly one ancestral back edge in $X_m$, the number of back edges which point back into the cycle created is stochastically dominated by $\text{Bin}(m \|T_m\|, p)$. Hence we have

$$
\Pr[B_m \mid T_m] \leq p S_m (1 - p)^{S_m - 1} (1 - (1 - p)^m \|T_m\|)
\leq M p S_m (m \|T_m\| \log(1 - p))
= Mn^{-2}(m \|T_m\|)^2.
$$

This is the same bound as above, thus leading to

$$
\Pr[B_m] \leq M \frac{m^3}{n^2}
$$

Since the number of surplus edges has distribution $\text{Bin}(a(T_m), p)$, we get $\Pr[C_m \mid T_m] \leq M p^2 a(T_m)^2$ and

$$
\Pr[C_m] \leq M n^{-2} \mathbb{E}[a(T_m)^2].
$$

A similar argument as for $B_m$ also yields

$$
\Pr[D_m] \leq Mn^{-2}m \mathbb{E}[\|T_m\| a(T_m) \mid m] \leq Mn^{-2} \sqrt{\mathbb{E}[\|T_m\|^2] \mathbb{E}[a(T_m)^2]},
$$

and an application of (13) concludes the proof. $\Box$

29
We can now prove the proposition.

\textit{Proof of Proposition 5.10.} Fix \(k \in \mathbb{N}\) and \(\eta > 0\), and let \(\varepsilon > 0\) be small enough that

\[ P[\text{len}(C_k) > \varepsilon] > 1 - \eta. \]

By Lemmas 5.11 and 5.12, there exists \(C > 0\) such that

\[ P[\exists i > N : D_i \text{ contains a component with length greater than } \varepsilon] \leq P[\sigma_{N+1} > 1] + C E \left\{ \sum_{i > N} \sigma_i^3 \right\} \]

and

\[ P[\exists i > N : X_i^n \text{ contains a component with length greater than } n^{1/3} \varepsilon] \leq P[Z_{N+1}^n > n^{2/3}] + C E \left\{ \sum_{i > N} \frac{(Z_i^n)^2}{n^{1/3}} \right\}. \]

By Proposition 4.1 and (4), there exists \(N\) sufficiently large that both of those are smaller than \(\eta\). Then

\[ P[C_1, \ldots, C_k \text{ are in } D_1, \ldots, D_N, \text{ len}(C_k) > \varepsilon] > 1 - 2\eta. \]

From the fact that \((n^{-1/3} X_1^n, \ldots, n^{-1/3} X_N^n) \xrightarrow{(d)} (D_1, \ldots, D_N)\), we deduce that, for \(n\) greater than some \(n_0 \in \mathbb{N}\),

\[ P[C_1(n), \ldots, C_k(n) \text{ are in } X_1^n, \ldots, X_N^n, \text{ len}(C_k(n)) > \varepsilon n^{1/3}] \geq 1 - 3\eta \]

and hence

\[ P[C_1(n), \ldots, C_k(n) \text{ are in } X_1^n, \ldots, X_N^n] \geq 1 - 4\eta. \]

\(\square\)

\textbf{5.3.2 Controlling the tail}

The proof of Theorem 1.3 will be completed if we can show that, for all \(\varepsilon > 0\),

\[ \lim_{k \to \infty} \lim_{n \to \infty} \mathbb{P} \left[ \sum_{i=k+1}^{\infty} d_g(C_i, \mathfrak{L}) > \varepsilon \right] = 0 \]

and

\[ \lim_{k \to \infty} \limsup_{n \to \infty} \mathbb{P} \left[ \sum_{i=k+1}^{\infty} d_g(C_i(n), \mathfrak{L}) > n^{1/3} \varepsilon \right] = 0. \]

\(\mathcal{D}\) may, in principle, contain finitely or infinitely many strongly connected components; recall that if there are only finitely many, the sequence \(\mathcal{C}\) is completed by infinitely many copies of \(\mathfrak{L}\). In this case, let \(i_{\text{max}}\) be the largest integer such that \(C_{i_{\text{max}}} \neq \mathfrak{L}\), and let \(N_{\text{max}}\) be the smallest integer such that \(C_1, \ldots, C_{i_{\text{max}}}\) are contained in \(D_1, \ldots, D_{N_{\text{max}}}\). If, on the other hand, \(\mathcal{D}\) does contain infinitely many strongly connected components, recall that \(\text{len}(C_i) \to 0\) as \(i \to \infty\), and let \(i_{\text{max}} = N_{\text{max}} = \infty\).

We let \(i_{\text{max}}(n)\) and \(N_{\text{max}}(n)\) be the equivalent integers for \(\vec{G}(n, p)\), noting that they are of course finite.
Note that
\[
\lim_{k \to \infty} \mathbb{P}\left[ \sum_{i=k+1}^{\infty} d_{\mathcal{G}}(C_i, \mathcal{L}) > \varepsilon, \ i_{\max} < \infty \right] = 0.
\]
Let \( q = \mathbb{P}[i_{\max} < \infty] \). Let \( \eta > 0 \), and \( N_0 \) and \( i_0 \) be such that \( \mathbb{P}[i_{\max} \leq i_0, N_{\max} \leq N_0] \geq q - \eta \). Since \( n^{-1/3}(X_1^n, \ldots, X_N^n) \xrightarrow{(d)} (D_1, \ldots, D_{N_0}) \) and \( n^{-1/3}(C_1(n), \ldots, C_{i_0}(n)) \xrightarrow{(d)} (C_1, \ldots, C_{i_0}) \), we get that, for \( n \) large enough, \( \mathbb{P}[i_{\max}(n) \leq i_0, N_{\max}(n) \leq N_0] \geq q - 2\eta \). On this event, all the \( C_i(n) \) for \( i > i_0 \) are copies of \( \mathcal{L} \), so we have
\[
\lim_{k \to \infty} \lim_{n \to \infty} \mathbb{P}\left[ \sum_{i=k+1}^{\infty} d_{\mathcal{G}}(C_i(n), \mathcal{L}) > n^{1/3} \varepsilon, \ i_{\max} \leq i_0 \right] \leq 2\eta.
\]
For \( k \in \mathbb{N} \), let \( N(k) \) be the largest integer such that
\[
\mathbb{P}[i_{\max} = \infty, \text{ all components in } D_1, \ldots, D_{N(k)} \text{ have lengths exceeding len}(C_k)] > 1 - q - \eta.
\]
Then by Proposition 5.10 and the convergence of \( n^{-1/3}C_k(n) \) to \( C_k \), it also holds that, for \( n \) large enough, all the components of \( X_1^n, \ldots, X_{N(k)}^n \) have lengths exceeding that of \( C_k(n) \) with probability at least \( 1 - q - 2\eta \). Thus we have
\[
\mathbb{P}\left[ \sum_{i=k+1}^{\infty} d_{\mathcal{G}}(C_i, \mathcal{L}) > \varepsilon, i_{\max} = \infty \right] \leq \eta + \mathbb{P}\left[ \left( \sum_{i=N(k) + 1}^{\infty} \sum_{j : C_j \subset D_i} d_{\mathcal{G}}(C_j, \mathcal{L}) \right) \right] > \varepsilon
\]
and similarly
\[
\mathbb{P}\left[ \sum_{i=k+1}^{\infty} d_{\mathcal{G}}(C_i(n), \mathcal{L}) > n^{1/3} \varepsilon, i_{\max}(n) > i_0 \right]
\]
\[
\leq 2\eta + \mathbb{P}\left[ \left( \sum_{i=N(k) + 1}^{\infty} \sum_{j : C_j(n) \subset X_i^n} d_{\mathcal{G}}(C_j(n), \mathcal{L}) \right) > n^{1/3} \varepsilon \right].
\]
Note that \( N(k) \to \infty \) as \( k \to \infty \): indeed, it is non-decreasing, and so if it converged to a finite limit \( N \), then the probability of \( i_{\max} \) to be infinite and \( D_1, \ldots, D_N \) to contain a smallest component of \( C \) would be at least \( 1 - q - \eta \), a contradiction since there is no smallest component in the infinite case. It is therefore enough to prove that
\[
\lim_{N \to \infty} \mathbb{P}\left[ \sum_{i=N+1}^{\infty} \sum_{j : C_j \subset D_i} d_{\mathcal{G}}(C_j, \mathcal{L}) > \varepsilon \right] = 0
\]
and
\[
\lim_{N \to \infty} \lim_{n \to \infty} \mathbb{P}\left[ \sum_{i=N+1}^{\infty} \sum_{j : C_j(n) \subset X_i^n} d_{\mathcal{G}}(C_j(n), \mathcal{L}) > n^{1/3} \varepsilon \right] = 0.
\]
However, by (5), (8) and (9), for \( N \) large enough, all the components contained in \( (D_i, i \geq N + 1) \) are single ancestral cycles with probability at least \( 1 - \eta \), and for \( n \) large enough, this also holds for
those contained in \((X^n, i \geq N + 1)\). Noting that such components have length at most the height of the underlying tree, and that their number is at most the number of ancestral back edges, we are reduced to proving the following statements:

\[
\lim_{K \to \infty} P\left[ \sum_{i=K+1}^{\infty} N_i(1)\|T_{\sigma_i}\| > \varepsilon \right] = 0 \tag{14}
\]

and

\[
\lim_{K \to \infty} \limsup_{n \to \infty} P\left[ \sum_{i=K+1}^{\infty} A^n_i(1)\|T^n_i\| > n^{1/3} \varepsilon \right] = 0, \tag{15}
\]

where \(A^n_i\) is the number of surplus edges in \(X^n_i\). These may be obtained using the following lemma.

**Lemma 5.14.** (i) There exists \(C > 0\) such that, for \(\sigma < 1\),

\[
\mathbb{E}[N_\sigma(1)\|T_\sigma\|] \leq C\sigma^2.
\]

(ii) There exists \(C > 0\) such that, for \(n\) large enough, and \(1 \leq m \leq n^{2/3}\),

\[
\mathbb{E}[A_m\|T_m\|] \leq C\frac{m^2}{n},
\]

where \(A_m\) is the number of ancestral back edges in \(X_m\).

**Proof.** Part (i) is straightforward: assuming \(\|T_\sigma\|\) and \(N_\sigma(1)\) are built from a tilted excursion \(\tilde{e}^{(\sigma)}\), we have

\[
\mathbb{E}[N_\sigma(1)\|T_\sigma\|] = \mathbb{E}[e^{\int_0^\sigma 2\tilde{e}^{(\sigma)}(t)dt} \sup 2\tilde{e}^{(\sigma)}] = 2\sigma^2 \mathbb{E}[e^{\int_0^\sigma 2\tilde{e}(t)dt} \sup \tilde{e}]
\]

the latter expectation being finite (see the proof of Lemma 5.11). For part (ii), recall that, conditionally on \(T_m\) the distribution of \(A_m\) is stochastically dominated by \(\text{Bin}(m\|T_m\|, p)\). Thus we have

\[
\mathbb{E}[A_m\|T_m\|] \leq p\mathbb{E}[m\|T_m\|^2]
\]

and applying Lemma 5.13 concludes the proof. 

We leave the straightforward adaptation of the arguments used for Proposition 5.10 to prove (14) and (15) to the reader, finishing the proof of Theorem 1.3.

### 6 Further properties of the scaling limit

We write \(C\) for the list of strongly connected components of \(\mathcal{D}\), and \(C_\sigma\) for that of \(\mathcal{M}_\sigma\), in decreasing order of length. Let also \(C_{\text{compl}}\) be the list of complex components of \(C\), i.e. those that are not cycles, also in decreasing order of length. We have not yet been able to find the exact distribution of \(C\) and \(C_\sigma\) for \(\sigma > 0\); this will be the subject of future research. However, we show here that \(C_\sigma\) and \(C_{\text{compl}}\) have a positive probability of being equal to any appropriate fixed family of directed multigraphs.

For sequences \((G_1, \ldots, G_k)\) and \((H_1, \ldots, H_j)\) of directed multigraphs, we write \((G_1, \ldots, G_k) \equiv (H_1, \ldots, H_j)\) if \(j = k\) and \(G_i\) is isomorphic to \(H_i\) for each \(i \leq j\). We extend this notation naturally to the case where one or both of the sequences has edge lengths by simply ignoring the edge lengths.
Proposition 6.1. Let $G_1, \ldots, G_k$ be a finite sequence consisting of 3-regular strongly connected directed multigraphs or loops. We have
\[
P[\mathcal{C}_\sigma \equiv (G_1, \ldots, G_k) > 0].
\]
Assuming that $G_1, \ldots, G_k$ are all complex, we also have
\[
P[\mathcal{C}_\text{compl} \equiv (G_1, \ldots, G_k) > 0].
\]
Let $(e_i, 1 \leq i \leq K)$ be an arbitrary ordering of the edges of $(G_1, \ldots, G_k)$. Then, conditionally on $\mathcal{C}_\sigma \equiv (G_1, \ldots, G_k)$ (resp. $\mathcal{C}_\text{compl} \equiv (G_1, \ldots, G_k)$), $\mathcal{C}_\sigma$ (resp. $\mathcal{C}_\text{compl}$) gives lengths $(\ell(e_i), 1 \leq i \leq K)$ to these edges, and their joint distribution has full support in
\[
\left\{ x = (x_1, \ldots, x_K) \in \mathbb{R}_+^K : \forall 1 \leq i \leq k-1, \sum_{j \neq j \in E(G_i)} x_j \geq \sum_{j \neq j \in E(G_{i+1})} x_j \right\}.
\]

Constructing 3-regular directed multigraphs from trees and back edges. First, we want to show that any of the graphs in which we are interested can be constructed by a procedure which adds back edges to a plane tree. We set this up in a discrete framework. Let $t$ be a discrete plane tree whose vertices have outdegrees in $\{0, 1, 2\}$. We think of this as a directed graph, with edges pointing away from the root. We assume that $t$ has as many leaves as internal vertices of outdegree one, which we call $x_1, \ldots, x_n$ and $y_1, \ldots, y_n$ respectively, in the planar order. We assume, moreover, that for each $i \geq 1$, the internal vertex $y_i$ is visited before the leaf $x_i$ in the depth-first exploration. By identifying $x_i$ and $y_i$ for all $i$, we obtain a directed graph, whose strongly connected components we then extract. Each strongly connected component will have exactly one vertex of degree 2, which we erase, merging its two incident edges. The result is a set of 3-regular strongly connected directed multigraphs. The next lemma asserts that any appropriate collection of such multigraphs can be obtained by this procedure.

Lemma 6.2. For any $(G_1, \ldots, G_k)$, there exist a discrete plane tree $t$ and pairings $(x_i, y_i)$ such that the above construction results in $(G_1, \ldots, G_k)$.

Proof. Notice first that we can focus on the case where $k = 1$. Once this case is treated, the general case can be solved by taking a tree $t$ which contains distinct subtrees corresponding to each $G_i$.

So let $G$ be a fixed strongly connected 3-regular directed multigraph. Noticing that it cannot have vertices with outdegree 0 or 3 and that the sum of the outdegrees of all the vertices is equal to that of all the indegrees, we deduce that there exists $n \in \mathbb{N}$ such that $G$ has $n$ vertices with indegree 1 and outdegree 2, and $n$ vertices with indegree 2 and outdegree 1. Let $a_1, \ldots, a_n$ be the former and $b_1, \ldots, b_n$ the latter, for any ordering such that the edge $(b_1, a_1)$ is exists.

We will give a method to construct the necessary plane tree as well as the backward links between leaves and edges. At each step $t$ will contain a certain number of vertices of $G$, as well as some “open” edges, which have their tails at points in $t$ but are missing their heads.

Start with $t$ initially containing three vertices: a root with outdegree 1, its child (which we arbitrarily call $\rho_0$) which has outdegree 1 as well, and its next neighbour $a_1$, from which originate two open edges. At each step of the algorithm, let $z$ be the leftmost of the deepest vertices of $t$ which have open edges, choose any edge of $G$ starting at $z$ which is not yet featured in $t$, call $u$ the head of that edge, and do the following:
Figure 6: Obtaining a 3-regular connected directed multigraph from a tree with backward identifications. The tree was built using the method presented in the proof of Lemma 6.2.

- If $u$ is not already in $t$, add it at the end of the leftmost open edge, and add one or two open edges at $u$ corresponding to its outdegree in $G$. The edge $(z, u)$ is then a tree edge in $t$.

- If $u$ is already in $t$ but $u \neq a_1$, add a leaf at the end of the leftmost open edge, label that leaf $x_j$ for the smallest available $j$ and let also $u = y_j$. The edge $(z, u)$ is then featured in $t$ as the tree edge $(z, x_j)$, identifying $x_j$ with $u$.

- If $u = a_1$, put a leaf at the end of the leftmost open edge, label that leaf $x_j$ for the smallest available $j$, and let $y_j = \rho_0$. The edge $(z, u)$ is then featured in $t$ as the merging of the tree edges $(z, x_j)$ and $(\rho_0, a_1)$, identifying $x_j$ with $\rho_0$.

Note that this algorithm terminates, and that identifying the pairs $(x_i, y_i)$ in $t$ and removing the root (which is not in its strongly connected component) and $\rho_0$ (which has degree 2 in the strongly connected component) gives us $G$.

Moreover, by construction, the successive vertices appearing as $z$ follow the planar ordering of $t$. This means that at any step, any other vertex of $t$ can be found earlier than $z$ in the contour process, and thus in every pair $(x_i, y_i)$, $y_i$ is seen earlier than $x_i$ in the exploration process, and the identifications indeed go backwards. This remark then ends the proof.

**The coloured tree has full support.** If $T$ is a discrete plane tree and $\mathcal{T}$ is a discrete plane tree with edge lengths (equivalently an $\mathbb{R}$-tree with finitely many leaves which are ordered), we write $\mathcal{T} \equiv T$ if the discrete plane structure underlying $\mathcal{T}$ is $T$. If $\mathcal{T} \equiv T$ then the lengths of the edges of $\mathcal{T}$, in planar order, form a vector in $\mathbb{R}_+^k$ where $k$ is the number of edges of $T$.

Let $T$ be a fixed binary rooted discrete plane tree with $n \in \mathbb{N}$ leaves. For an excursion function $f : [0, \sigma] \to \mathbb{R}_+$, we let $D_T(f)$ be the set of increasing sequences $t = (t_1, \ldots, t_n) \in [0, \sigma]^n$ such that
the \( \mathcal{T}_f(t_1, \ldots, t_n) \equiv T \). This is an open subset of \([0, \sigma]^n\) which can be written explicitly as

\[
D_T(f) = \{ t \in [0, \sigma]^n : t_1 < t_2 \ldots < t_n \text{ and } \forall k \in \{3, \ldots, n\}, \quad \hat{f}(t_{i(k)}, t_{k-1}) < \hat{f}(t_{k-1}, t_k) < \hat{f}(t_{j(k)}, t_{k-1}) \}.
\]

Here the indices \( i(k) \) and \( j(k) \) are defined as follows. Let \( L_1, \ldots, L_n \) be the leaves of \( T \) in planar order (we add \( L_0 = \rho \) for the sake of convenience). For \( k \in \{3, \ldots, n\} \), we then take \( i(k) < j(k) \) to be any two integers in \( \{0, 1, 2, \ldots, k-1\} \) such that, on the path \([\rho, L_{k-1}]\), the two points \( L_{i(k)} \land L_{k-1} \) and \( L_{j(k)} \land L_{k-1} \) are respectively maximal and minimal such that \( L_{i(k)} \land L_{k-1} \leq L_{k-1} \land L_{k} \leq L_{j(k)} \land L_{k-1} \) for the genealogical/planar order.

![Figure 7: For this tree, \( i(3) = 1, j(3) = 2, i(4) = 0, \) and \( j(4) = 1 \). Given an excursion function \( f \), a sequence \( t_1 < t_2 < t_3 < t_4 \) will then be in \( D_T(f) \) iff \( \hat{f}(t_1, t_2) < \hat{f}(t_2, t_3) < f(t_2) \) and \( 0 < \hat{f}(t_3, t_4) < \hat{f}(t_1, t_4) \).

**Lemma 6.3.** We have

\[
\mathbb{P}[\mathcal{T}_f^\text{col} = T] = \int_{t \in D_T(f)} dt \prod_{k=1}^{n} \left( \sum_{i=1}^{k} f(t_i) - \hat{f}(t_{i-1}, t_i) \right) \exp \left( -\int_{0}^{\sigma} \left( f(t) - \hat{f}(t_{I(t)}, t) + \sum_{i=1}^{I(t)} f(t_i) - \hat{f}(t_{i-1}, t_i) \right) dt \right),
\]

where \( t_0 = 0 \) and, for \( t \in [0, \sigma] \), \( I(t) = \max\{i : t_i < t\} \).

Moreover, if we take \( f = 2\hat{e}(\sigma) \) for \( \sigma > 0 \), then

\[
\mathbb{P}[\mathcal{T}_{2\hat{e}(\sigma)}^\text{col} = T] > 0,
\]

and conditionally on \( \mathcal{T}_{2\hat{e}(\sigma)}^\text{col} \equiv T \), the joint distribution of the edge lengths of \( \mathcal{T}_{2\hat{e}(\sigma)}^\text{col} \) has full support in \( \mathbb{R}^{2n-1}_+ \).

**Proof.** The first statement comes from Remark 3.4. For the second statement, we use a comparison with the scaling limit of the undirected random graph. Specifically, Lemma 10 of [1] gives the joint
distribution of the tree shape and the edge lengths in the subtree of $T\tilde{=}^{(σ)}$ spanned by the root and a random collection of leaves which are sampled according to a Poisson point process with intensity $\tilde{e}^{(σ)}(\cdot)$. (This is different from our $2\tilde{e}^{(σ)}(\cdot)$ for ancestral back edges, because, as seen in [2], these identifications come from surplus edges of the undirected graph, the number of which originate at any given vertex being roughly half of the height of said vertex.) In particular, the probability that we obtain the tree shape $T$ and that the lengths of the edges (in planar order) lie in an open set $A \subset (\mathbb{R}_+)^{2n-1}$ is positive, that is

$$E \left[ \int_{t \in D_T(2\tilde{e}^{(σ)})} dt \mathbf{1}_{\{(2\tilde{e}^{(σ)}(t)) \in A'\}} \prod_{k=1}^{n} \tilde{e}^{(σ)}(t_k) \exp \left( - \int_0^\sigma \tilde{e}^{(σ)}(t) dt \right) \right] > 0,$$

where $A' \in \mathbb{R}_+^n$ is the open set such that the heights the leaves of $T$ are in $A'$ if its edge lengths are in $A$. This implies that $E[G] > 0$ where

$$G = \int_{t \in D_T(2\tilde{e}^{(σ)})} dt \mathbf{1}_{\{(2\tilde{e}^{(σ)}(t)) \in A'\}} \prod_{k=1}^{n} \left( \sum_{i=1}^{k} 2\tilde{e}^{(σ)}(t_i) \right),$$

(since $G$ is larger than the variable integrated above) and we then have

$$P[T^{\text{col}}_{2\tilde{e}^{(σ)}} \equiv T, \text{lengths in } A] \geq E \left[ G \exp (- \sigma(n + 1) \sup e^{(σ)}) \right],$$

and this is positive since $\sup e^{(σ)}$ is a.s. finite. \hfill \Box

**Proof of Proposition 6.1.** We first show the result for $C_σ$. Let $t$ and $((x_i, y_i), i \in \{1, \ldots, n\})$ be the discrete tree and pairing of leaves and outdegree-1 vertices given by Lemma 6.2. Moreover, let $T$ be obtained from $t$ by erasing the vertices of degree 2, and merging their adjacent edges. Let

- $(e_1, \ldots, e_K)$ be the edges of $(G_1, \ldots, G_K)$, in any order.
- $(e_1, \ldots, e_K, e_{K+1}, \ldots, e_N)$ those of $t$, in any order completing the previous one.
- $(f_1, \ldots, f_M)$ those of $T$, in planar order.$^2$

By construction, each edge of $(G_1, \ldots, G_K)$, is an edge of $t$, justifying the notation for the edges of $t$. Moreover, each edge of $T$ is obtained by merging edges of $t$, so there exists a partition of $\{1, \ldots, N\}$ with blocks $(S(i), 1 \leq i \leq M)$ such that for each $i \in \{1, \ldots, M\}$, $f_i$ is obtained by merging $e_j$ for $j \in S(i)$. For $i \in \{1, \ldots, n\}$, let $e_T(y_i)$ be the edge of $T$ containing $y_i$. Given this information, we call a collection of positive lengths $\ell(e_i)$, and $\ell(f_i)$ such that $\ell(f_i) = \sum_{j \in S(i)} \ell(e_j)$ an admissible length assignment.

Recall that, from the construction given in Section 3.2.2, conditionally on $T^{\text{col}}_σ$ with leaves $L_1, \ldots, L_p$, the marked internal points $z_1, \ldots, z_p$ are independent and, for each $j$, $z_j$ is uniform on $\cup_{k=1}^{p} [\rho, L_k]$. If $T^{\text{col}}_σ \equiv T$ then this gives rise to a length assignment $\ell$ on $T$, and we have

$$P \left[ z_j \in e_T(y_j), \forall j \in \{1, \ldots, n\} \mid T^{\text{col}}_σ, T^{\text{col}}_σ \equiv T \right] \geq \prod_{j=1}^{n} \frac{\ell(g(y_j))}{\text{len}(T^{\text{col}}_σ)}.$$

Note that in fact we have $M = 2n - 1, N = 3n - 1$ and $K = 3(n - k) + k'$, where $k'$ is the number of unicycles amongst $(G_1, \ldots, G_K)$; however, this fact is not useful here.
Moreover, conditionally on the event \( \{ z_j \in e_T(y_j), \forall j \in \{1, \ldots, n\}, T^\text{col}_0, T^\text{col}_2 \equiv T \} \), for any edge \( f_i \) of \( T \), the probability that \( z_j \), for \( j \) such that \( y_j \in f_i \) are in the right order on \( f_i \) is \( \frac{1}{|S(i)|!} \). If this occurs, then it gives rise to a length assignment \( \ell \) on \( t \) as well, making the whole thing admissible. We then have \( (\ell(e_j), j \in S(i)) = (D_1(i)\ell(f_1), \ldots, D_{|S(i)|}(i)\ell(f_{|S(i)|})) \) where \( D(i) = (D_1(i), \ldots, D_{|S(i)|}(i)) \in \Delta_{|S(i)|} \) has the Dirichlet\((1, \ldots, 1)\) distribution on the \((|S(i)|-1)\)-dimensional simplex \( \Delta_{|S(i)|} \). These events occur independently for different \( i \in \{1, \ldots, M\} \).

Let \( A \) be an open set in \( \mathbb{R}_+^K \). Take open sets \( B \subset \mathbb{R}_+^M \) and \( C_i \in \Delta_{|S(i)|} \) for \( i \in \{1, \ldots, M\} \) such that, for any admissible length assignment, if \( (\ell(f_i), i \in \{1, \ldots, M\}) \in B \) and, for all \( i \), \( (\ell(e_i), j \in S(i)) \in C_i \), then we have \( \ell(e_i), i \in \{1, \ldots, K\} \) \( \in A \). Then

\[
\mathbb{P}\left[ C_\sigma \equiv (G_1, \ldots, G_k), (\ell(e_i), i \in \{1, \ldots, K\}) \in A \right] 
\geq \mathbb{E} \left[ \mathbf{1}_{\{T^\text{col}_0 \equiv T, (\ell(f_i), i \in \{1, \ldots, M\}) \in B\}} \prod_{j=1}^n \frac{\ell(f(y_j))}{\text{len}(T^\text{col})} \prod_{i=1}^M \frac{1}{|S(i)|!} \mathbf{1}_{\{D(i) \in C_i\}} \right].
\]

By Lemma 6.3, the event \( \{T^\text{col}_0 \equiv T, (\ell(f_i), i \in \{1, \ldots, M\}) \in B\} \) occurs with positive probability and, since Dirichlet distributions charge the full simplex, we do indeed have that

\[
\mathbb{P}\left[ C_\sigma \equiv (G_1, \ldots, G_k), (\ell(e_i), i \in \{1, \ldots, K\}) \in A \right] > 0.
\]

We finally turn to the result for \( C^\text{compl} \). Recall that \( (\sigma_i, i \geq 1) \) are the ranked excursion lengths of a Brownian motion with parabolic drift and \( C_i, i \geq 1 \) are independent copies of \( C_{\sigma_i} \). Notice that

\[
\mathbb{P}[C^\text{compl} \equiv (G_1, \ldots, G_k), \text{lengths in } A] 
\geq \mathbb{P}[C \equiv (G_1, \ldots, G_k), \text{lengths in } A, C_i \text{ has no complex components } \forall i \geq 2].
\]

From Propositions 4.1 and 4.3, we deduce that \( (C_i, i \geq 2) \) has no complex components with positive probability. An application of the first part of the proposition then completes the proof. \( \square \)
