Abstract

Given the piecewise approach to modeling intermolecular interactions for force fields, they can be difficult to parameterize since they are fit to data like total energies that only indirectly connect to their separable functional forms. Furthermore, by neglecting certain types of molecular interactions such as charge penetration and charge transfer, most classical force fields must rely on, but do not always demonstrate, how cancellation of errors occurs among the remaining molecular interactions accounted for such as exchange repulsion, electrostatics, and polarization. In this work we present the first generation of the (many-body) MB-UCB force field that explicitly accounts for the decomposed molecular interactions commensurate with a variational energy decomposition analysis, including charge transfer, with force field design choices...
that reduce the computational expense of the MB-UCB potential while remaining accurate. We develop these goals starting with water cluster data up through pentamers, and we demonstrate that high accuracy is maintained when the force field is subsequently validated against conformational energies of larger water cluster data sets and radial distribution functions of the liquid phase.

1 Introduction

The field of molecular modeling has historically relied on a simple representation of the potential energy surface of molecules based on what is known as the pairwise additive approximation. However, pairwise additive forces are limited when there is an asymmetric environment, such as the heterogeneity of an interface, anisotropic electric fields in native and synthetic enzyme active sites, the complex structural organization of functional materials, and the design of new drug molecules for which highly directional molecular interactions must be finely tuned for binding specificity. Undoubtedly, creating a higher accuracy force field for this range of system complexity requires the introduction of new functional forms that describe many-body interactions such as polarization and non-classical effects like charge penetration. Powerful success stories for improved accuracy in prediction are evident from advanced force fields that incorporate such physics, i.e. SIBFA (Sum of Interactions Between Fragments Ab initio computed), the CHARMM Drude model, Atomic Multipole Optimized Energetics for Biomolecular Applications (AMOEBA), Gaussian Electrostatic Model (GEM), Effective Fragment Potential (EFP), and MB-Pol. Even so, the greater complexity of this additional physics also poses greater challenges for rational force field design, as well as algorithmic and software challenges needed to increase computational efficiency in order to be used effectively for sampling in the condensed phase.

The rational design challenge is manifested in the fact that the advanced force fields are often not as transferable as desired, proving surprisingly brittle in blind-prediction chal-
lenges, while other MB potentials such as MB-Pol disregard transferability in favor of explicitly parameterizing each new chemical system to ensure high accuracy with commensurate increases in computational expense. Another way forward to impact the force field design and sampling challenge is to systematically develop computationally tractable force field terms that match the decomposition of first principles quantum mechanical (QM) interaction energies. These piecewise contributions, including permanent and induced electrostatics, Pauli repulsion, dispersion, charge penetration, and in some cases charge transfer, can be revealed by chemically motivated energy decomposition analysis (EDA) methods. There are already successful efforts in this direction such as the effective fragment potential (EFP) method, force fields based upon symmetry-adapted perturbation theory (SAPT), or that are analyzed through variational absolutely-localized-molecular-orbitals (ALMO)-EDA methods. It is well-known that various EDA schemes all agree in the asymptotic region for most intermolecular interactions, but due to inherent non-separability of the QM energies into individual pieces, EDA schemes are non-unique in the so-called overlapping region at or near equilibrium. Our view is that a force field that reproduces (without explicit fitting) the piecewise energy decomposition of any particular EDA scheme in the form of a truncated many-body expansion, and in turn shows that it is transferable to describe a larger or more complex system or phase, is an important way to fully validate any particular EDA approach.

In our previous work, we compared piecewise decomposition of the AMOEBA water force field with ALMO-EDA at the level of $\omega$B97X-V/def2-QZVPPD for various water and water-ions systems. We found that AMOEBA’s individual terms are very well formulated in the asymptotic region for inherently long-ranged interactions when compared to ALMO-EDA. However, there is considerable difference between the energy breakowns from ALMO-EDA and AMOEBA on both sides of the equilibrium geometry for water and ion-water clusters. Not surprisingly, the observed difference with the ALMO-EDA energy components is likely due to the fact that most of the AMOEBA force field parameters are
fitted to total energies from QM (in particular using MP2). This indirect connection to the piecewise energy terms results in an inherent inability to account for the missing CT and CP interactions to ensure cancellation of errors through their neglect. In fact we have shown that AMOEBA attempts to capture the missing CT and CP terms either through the polarization term or through its 14-7 vdW potentials by softening the VdW radii, but does so incoherently across the energy terms that depends on the particular water cluster and water-ion systems considered.\textsuperscript{51,52}

In this work we describe the general and rational design of the first generation MB-UCB force field based on a complete set of decomposable functional forms, including charge transfer, that captures term-by-term the ALMO-EDA decomposition of small water clusters (up through pentamers only). The use of ALMO-EDA is motivated by its greater simplicity of the decomposed terms, avoidance of perturbation theory, the ability to separate charge transfer from polarization, and which can be combined with accurate density functionals.\textsuperscript{56,58} The MB-UCB force field will be the first direct test as to whether variational EDAs can offer advantages over the popular SAPT approach in practice.

In addition, the functional forms of the individual molecular interactions of the MB-UCB force field are designed with one primary goal in mind: the accounting of all molecular interactions that are either fit to or validated against the ALMO-EDA for greater accuracy, while maintaining a strict adherence to model choices and algorithms that keeps the computational cost manageable for condensed phase sampling. We have implemented all of the force terms for the MB-UCB model, and find that the condensed phase simulation well reproduces the experimental radial distribution functions of the liquid, with much improved accuracy compared to previous iAMOEBA\textsuperscript{59} and AMOEBA models.\textsuperscript{55,60} This sets the stage for future reports on molecular dynamics simulation of MB-UCB to validate its liquid water properties across the water phase diagram, and to complete an MB-UCB potential for chain molecules such as proteins that also requires validation using condensed phase simulations.
2 Theory

For the direct comparison with \textit{ab initio} energy components, we used the energy decomposition analysis\textsuperscript{39} based on the ALMO-EDA method\textsuperscript{61,62} to separate the total non-bonded interaction energy into individual contributions

\[ E_{\text{int}} = E_{\text{elec}} + E_{\text{Pauli}} + E_{\text{disp}} + E_{\text{pol}} + E_{\text{CT}} \]  \hspace{1cm} (1)

where \( E_{\text{elec}} \), \( E_{\text{Pauli}} \), \( E_{\text{disp}} \), \( E_{\text{pol}} \), and \( E_{\text{CT}} \) corresponds to the contributions from the permanent electrostatics, Pauli repulsion, dispersion, polarization and charge transfer, respectively.

Derivation of each of the individual energy components of ALMO-EDA are described elsewhere.\textsuperscript{61,62} Several points should be noted. First, the so-called geometric distortion energy is not required for our present purposes. Second, as we have discussed previously,\textsuperscript{51} the most appropriate choice for \( E_{\text{elec}} \) is the quasi-classical expression, which depends only on the geometry of the individual monomer of interest. Third, we use the fragment electric response function approach (at the dipole+quadrupole level) to evaluating the energy lowering due to polarization, ensuring a well-defined basis set limit.\textsuperscript{63}

All the ALMO-EDA calculations are performed at the level of \( \omega B97X-V/\text{def2-QZVPPD} \)\textsuperscript{56} using the Q-Chem software package.\textsuperscript{64} \( \omega B97X-V \) is a hybrid generalized gradient approximation (hybrid GGA) functional which includes the VV10 non-local correlation functional for dispersion correction, and has been well validated against coupled cluster benchmarks,\textsuperscript{56,65} including in previous assessments of AMOEBA\textsuperscript{51} The def2-QZVPPD basis\textsuperscript{57} has been established as very close to the basis set limit for DFT calculations of molecular interaction energies.\textsuperscript{65}

The MB-UCB force field is designed for functional forms that well-reproduce the ALMO-EDA decompositions of the non-bonded terms, while the valence terms of the MB-UCB force field are the same as that used by AMOEBA\textsuperscript{18,66} that in turn is based on the early MM3 force field.\textsuperscript{67} The MB-UCB force field is subsequently validated on hexamer and large water
cluster data sets at equilibrium geometries, and for highly distorted states from water dimers to decamers reported previously by Wang and co-workers\textsuperscript{13,14}. We also have implemented the forces for the MB-UCB model and report the gOO(r), gOH(r), and gHH(r) radial distribution functions. The entire model has been implemented in an in-house version of the Tinker software package\textsuperscript{68} and will be made available upon request.

2.1 Permanent electrostatics

The permanent electrostatics is modeled by considering atom centered multipoles, consisting of monopoles ($q$), dipoles ($\mu$), and with optional treatment of higher order quadrupoles $Q$. The total permanent electrostatics between all the atom pairs is expressed as

$$E_{\text{elec}} = \sum_{i<j} M_i^T T_{ij} M_j$$

(2)

where $M$ is the multipole vector and $T_{ij}$ is the multipole interaction matrix that consists of appropriate derivatives of $\frac{1}{r_{ij}}$ according to the multipole expansion. In this work we consider two multipole models in which the multipole expansion is truncated at the level of dipoles or quadrupoles on each atomic site.

Multipole expansions of the permanent electrostatics describe the anisotropy of the electrostatic interactions at mid-range and recovery of the $1/r$ functional form at long-range, however near equilibrium and in the very short range, when two atomic electron cloud overlaps, the multipole expansion model breaks down due to the quantum mechanical effects of charge penetration. With the exception of the GEM model\textsuperscript{29,30} which uses a density fitting formalism to express the molecular density in a Hermite Gaussian auxiliary basis, earlier incarnations of advanced force fields have used Thole damping\textsuperscript{69} functions to avoid the need to incorporate charge penetration effects.

Charge penetration models in force fields are based on a strategy of separating the atomic charge into a core nuclear charge and smeared electron cloud charge. In fact many advanced
force fields have begun to adopt some variation of the CP models\textsuperscript{12,15-19,29,70–73} proposed by Gordon and co-workers\textsuperscript{15,19} or Piquemal et al.\textsuperscript{18} The main difference between these two CP models are the use of different damping functions to approximate the value of the overlap integral. Here, we have used the Piquemal model to account for the charge penetration effect, but only applying it as a monopole-monopole ($q - q$) correction.\textsuperscript{13} Therefore, the modified charge-charge electrostatic interactions between two atoms $A$ and $B$ with atomic charges $q_A$ and $q_B$ is expressed as

$$E_{q-q}^{\text{elec}} = \frac{Z_A Z_B}{r} + \frac{Z_A(Z_B - q_B)}{r} f_{\text{damp}} + \frac{Z_B(Z_A - q_A)}{r} f_{\text{damp}} + \frac{(Z_A - q_A)(Z_B - q_B)}{r} f_{\text{overlap}} \quad (3)$$

where, $Z$ is the effective core charge (equal to the number of valence electrons), $q$ is the atomic monopole and hence $Z - q$ describes the magnitude of the negatively charged electron cloud. The first term in Eq. 3 is for the core-core interaction, the second and third terms describe the interaction between core and electron clouds of the other atoms and finally the fourth term accounts for the electron-electron interactions between each of the atoms. The two damping functions, $f_{\text{damp}} = (1 - \exp(-\alpha r))$ and $f_{\text{overlap}}^{\text{damp}} = (1 - \exp(-\beta_A r))(1 - \exp(-\beta_B r))$, require two parameters, $\alpha$ and $\beta$, to control the damping of core-electron and electron-electron interactions, respectively. From Eq. 3 and the two damping functions, it is clear that the charge penetration corrections can be made to decrease rapidly, and that the electrostatic energy will correctly reduce to classical Coulombic multipolar interactions in the medium and asymptotic long-range limits.

### 2.2 Polarization energy

Polarization is explicitly incorporated in MB-UCB by induced dipoles at polarizable sites located on the atomic centers.\textsuperscript{55} The induced dipoles ($\mu^{\text{ind}}$) at a polarizable site $i$ with
polarizability $\alpha_i$ is expressed as

$$\mu_{\text{ind}}^i = \alpha_i \left[ \sum_j T_{ij} M_j - \sum_{j \neq i} T^{d-d}_{ij} \mu_{\text{ind}}^j \right]$$

(4)

Where $T$ and $M$ are the multipole-multipole interaction matrix and polytensor permanent multipoles, respectively, and $T^{d-d}$ is the dipole-dipole interaction tensor. The first term of Eq. 4 is for the direct polarization of the induced dipoles by the permanent multipoles with field $E_i$ and the second term is the mutual induction by induced dipoles on all the other sites. Thus Eq. 4 can be rewritten as

$$\mu_{\text{ind}}^i = \alpha_i \left[ E_i - \sum_{j \neq i} T^{d-d}_{ij} \mu_{\text{ind}}^j \right]$$

(5)

$$\Rightarrow \alpha_i^{-1} \mu_{\text{ind}}^i + \sum_{j \neq i} T^{d-d}_{ij} \mu_{\text{ind}}^j = E_i$$

(6)

and can be represented in general matrix form as

$$\begin{pmatrix}
\alpha_1^{-1} & T^{d-d}_{12} & \ldots & T^{d-d}_{1N} \\
T^{d-d}_{12} & \alpha_2^{-1} & \ldots & T^{d-d}_{2N} \\
\vdots & \vdots & \ddots & \vdots \\
T^{d-d}_{1N} & T^{d-d}_{2N} & \ldots & \alpha_N^{-1}
\end{pmatrix}
\begin{pmatrix}
\mu_1 \\
\mu_2 \\
\vdots \\
\mu_N
\end{pmatrix}
= \begin{pmatrix}
E_1 \\
E_2 \\
\vdots \\
E_N
\end{pmatrix}$$

(7)

In Eq. 7, the off-diagonal blocks $T^{d-d}$ are the Thole damped\textsuperscript{69} Cartesian interaction tensors between induced dipoles of two polarizable sites $i$ and $j$, while the diagonal blocks are the inverse of the atomic polarizability. Because in an anisotropic media an applied electric field will induce an anisotropic polarization response, we recently introduced the model for the anisotropic atomic polarizabilities\textsuperscript{53} as a rank two tensor.
\[
\alpha_i^{-1} = \begin{pmatrix}
\alpha_{i,xx} & \alpha_{i,xy} & \alpha_{i,xz} \\
\alpha_{i,yx} & \alpha_{i,yy} & \alpha_{i,yz} \\
\alpha_{i,zx} & \alpha_{i,zy} & \alpha_{i,zz}
\end{pmatrix}^{-1}
\]  
(8)

In this work we use a standard conjugate gradient self-consistent field (CG-SCF) solver\textsuperscript{74} to obtain the induced dipoles and the polarization energy (\(E_{\text{pol}}\)) using Eqs. 7 and 8

\[
E_{\text{pol}} = -\frac{1}{2} \sum_i \mu_{\text{ind}}^i E_i
\]  
(9)

In future work the anisotropic polarization will be combined with our iEL/SCF and SCF-less approaches that reduces the computational expense of this step,\textsuperscript{75,76} while also adding the benefits of a resonance controlled multi-time stepping algorithm,\textsuperscript{77} when used in molecular dynamics.

### 2.3 Charge transfer energy

Recently, Deng et al.\textsuperscript{78} used an empirical many-body function to decompose SAPT induction energy into polarization and charge transfer energies. Here we focus on their CT expression, given by

\[
E_{\text{CT}} = -\frac{1}{2} \sum_i \mu_{\text{ct}}^i E_i
\]  
(10)

\[
\mu_{\text{ct}}^i = \alpha_{i,\text{ct}} \sum_j T_{ij}^{\text{ct}} M_j
\]  
(11)

where \(\alpha_{i,\text{ct}}\) controls the charge transfer energy between two atoms through a response to the permanent electrostatics. To be clear, we note that this CT model has no explicit charge flow. The multipole interaction matrix (\(T^{\text{ct}}\)) elements are damped with an exponential damping function

\[
T_{\zeta}^{\text{ct}} = -\int_3^{\text{ct}} \frac{r_{ij}^{\zeta}}{r_{ij}^3}, \quad \zeta = x, y, z
\]  
(12)
where

\[ f^{ct}_3 = [1 - d \exp(-bu^3)], u = \frac{r_{ij}}{(\alpha_i^{ct} \alpha_j^{ct})^{\frac{1}{6}}} \]  

(13)

in which the two parameters \( b \) and \( d \) are responsible for the exponential decay of the charge transfer energy, which should be more short-ranged that polarization. However, unlike the Deng et al. model,\textsuperscript{78} which only considered the direct charge transfer between the atomic sites, we also consider the mutual CT term

\[ E_{CT-\text{ind}} = -\frac{1}{2} \sum_i \mu_{i}^{ct-\text{ind}} E_i^{ct} \]  

(14)

\[ \mu_i^{ct-\text{ind}} = \alpha_i^{ct} \left[ \sum_j T_{ij}^{ct} M_j - \sum_{j \neq i} r_{ij}^{ct[d-d]} \mu_j^{ct-\text{ind}} \right] \]  

(15)

that recovers a greater amount of the many-body character of charge transfer, albeit with the understanding that no explicit charge flow is operative.

### 2.4 vdW interactions

The remaining energy terms in ALMO-EDA, Pauli repulsion and dispersion, are modeled in MB-UCB as a van der Waals interaction using a buffered 14-7 pairwise-additive function proposed by Halgren\textsuperscript{79}

\[ E_{vdW} = \sum_{i<j} \epsilon_{ij} \left( \frac{1 + \delta}{\sigma_{ij} + \delta} \right)^7 \left( \frac{1 + \gamma}{\sigma_{ij}^{'} + \gamma} - 2 \right) \]  

(16)

\( \epsilon \) defines the energy scale, and \( \sigma = \frac{r}{R_0} \) is the dimensionless distance between two atoms, where \( R_0 \) is the distance corresponding to the minimum energy. Like AMOEBA,\textsuperscript{80} we set the two constants \( \delta \) and \( \gamma \) to 0.12 and 0.07, respectively, while \( \epsilon \) is optimized for the MB-UCB model.
2.5 Parameterization Strategy

In previous studies of the many-body expansion of the AMOEBA polarizable model, we found that liquid water potential energies were fully recovered through four-body terms, while truncation at the level of five-body terms were required to reproduce forces. \(^8\) Hence the MB-UCB model is parameterized on the water monomer, dimer, trimer, tetramer, and pentamer cluster data sets only.

In our previous study of polarization anisotropy, the atomic permanent electrostatics and anisotropic polarizabilities were obtained from the \textit{ab initio} calculations at the level of \(\omega\text{B97X-V/def2-QZVPP}\) using the Williams-Stone-Misquitta (WSM) generalized distributed multipole analysis (GDMA) \(^8\) with the help of CamCASP suite program. \(^8\) We kept the same monopole and dipole parameters as the original AMOEBA03 model, \(^5\) and optimized the atomic quadrupoles to reproduce the \textit{ab initio} electrostatic potential (ESP) (using MP2/aug-cc-pVTZ) on a grid of points outside the van der Waals surface (MB-UCB-MDQ).

However in this work we have made a different design decision by eliminating the permanent quadrupoles, and thus we have again used the WSM approach to reoptimize both the permanent monopole and dipole parameters with anisotropic polarization to reproduce the single water molecule electrostatics (MB-UCB-MD). To improve the electrostatics in the short range further, we have adopted the charge penetration model with parameters taken directly from the literature, \(^13\) but only applied to the monopole electrostatics. We later present results establishing that there is no need to refit their CP parameters for either the MB-UCB-MDQ or MB-UCB-MD permanent electrostatics. We note that we do not fit to ALMO-EDA for the permanent electrostatics or polarization, but use it simply as a validation tool for the geometric scans of small water clusters. But for the charge transfer model, the CT parameters were fitted to reproduce the ALMO-EDA charge transfer energies for the data set consisting of water dimers, trimers, tetramers and pentamers extracted from AMOEBA MD simulations.

Finally for the van der Waals interaction of the MB-UCB model, we fitted the parameters
in Eq. 17 from the remaining energy difference between the ωB97X-V/def2-QZVPPD total binding energy and the previous model energy terms

\[ E_{\text{Pauli}} + E_{\text{disp}} = E_{\text{abinitio}} - E_{\text{elec}} - E_{\text{pol}} - E_{\text{CT}} - E_{\text{valence}} \]  

(17)

that will not only account for the Pauli and dispersion interactions, but will also clean up any disparities between ALMO-EDA and the individual \( E_{\text{elec}} \), \( E_{\text{pol}} \), and \( E_{\text{CT}} \) terms of MB-UCB.

The van der Waals parameters were optimized using data sets containing more than 9604 geometries consisting of water dimers, trimers, tetramers, and pentamers. Then, we performed a validation study of our complete MB-UCB model over larger water cluster data sets and liquid water properties.

3 Results

For consideration of the breakdown of individual intermolecular interactions, we performed a piecewise decomposition of the MB-UCB force field to directly compare with the ALMO-EDA components for the water dimer and trimer along various scanned coordinates. For the water dimer, the oxygen-oxygen distance is used as the scanned coordinate, where as for water trimer one of the water molecules is moved from the centroid of the triangle formed by the three oxygen atoms.\textsuperscript{51,52} Additionally, permanent electrostatics were computed for 50 random configurations extracted from a 50 ps MD simulation at 298 K, with each configuration separated by 1 ps.

From Figures 1a and 1b it is clear that for the permanent electrostatics with inclusion of CP that the MB-UCB model is in excellent agreement with the ALMO-EDA result not only asymptotically but in the compressed region as well. It should be emphasized that we do not fit the permanent electrostatics to ALMO-EDA, and hence this provides clear evidence of compatibility between \( E_{\text{elec}} \) from ALMO-EDA and our CP-corrected electrostatics. An equally important result is that both the MD and MDQ multipole truncations of the MB-
UCB force field each agree very well with the ALMO-EDA result.

Figure 1: Change in (a,b) permanent electrostatics, (c,d) polarization energy, and (e,f) charge transfer energy for the water dimer (H$_2$O)$_2$ (left) and water trimer (H$_2$O)$_3$ (right) along the scanned coordinate for ALMO-EDA and the MB-UCB models. The 0 Å distance in the water trimer corresponds to the equilibrium geometry. We consider truncation of the multipole expansion of the MB-UCB models up to dipoles (MD) and up to quadrupoles (MDQ).

Figure 2a further supports the conclusion that the permanent electrostatics are in good agreement between ALMO-EDA and MB-UCB when examining the water pentamer set derived from a molecular dynamics trajectory. Overall the correlation is excellent, with the MB-UCB model exhibiting slight over-polarization in comparison to ALMO-EDA, but much...
less so than what we originally found for AMOEBA03 as reported in previous work.\textsuperscript{53} Again we find very little sensitivity to the truncation level of the multipole expansion, suggesting that the monopole-dipole electrostatic design choice will be a good one, at least for water.

![Figure 2: Correlation of electrostatic (a), polarization (b) and charge transfer energies (c) obtained from ALMO-EDA and MB-UCB using monopole-dipole (MD) and monopole-dipole-quadrupole (MDQ) for 50 random configurations extracted from a MD simulation.](image)

We have previously shown that the incorporation of atomic anisotropic polarizabilities in the MB-UCB offers significantly better agreement with the ALMO-EDA polarization for the water dimer, trimer and the MD-pentamer results than found using standard AMOEBA03.\textsuperscript{55} Figures 1c, 1d, and 2b reexamines the anisotropic polarization energy of MB-UCB, but this time for the two multipole truncations, in which we find that both agree very well with the ALMO-EDA polarization energy.\textsuperscript{63} Again the anisotropic polarization of the MB-UCB model was developed independently of the ALMO-EDA result, suggesting that using two very different approaches for deriving the fixed electrostatics and the polarization response, that the GDMA and ALMO-EDA decompositions mutually reinforce their basic correctness.

The MB-UCB model differs from most other many-body force fields with the inclusion of a model for the charge transfer interaction. Using a parameterization that is intentionally fit to the ALMO-EDA decomposition for charge transfer, the MB-UCB force field’s computed charge transfer energies are thus compared between the two multipole truncations for both the water dimer and water trimer in Figures 1e, 1f, and 2c. It is evident that the general induction functional form used for the charge transfer energy is able to reasonably recapit-
ulate the \textit{ab initio} charge transfer energy from ALMO-EDA using either level of multipole truncation, but with much less fidelity than found for the electrostatics. It is certainly desirable to reconsider the choice of functional form in future work to better describe charge flow. Even so, the level of qualitative and even quantitative agreement is quite good given the limitations of the functional form.

![Figure 3](image.png)

**Figure 3**: Different components of the charge transfer energy along the scanned coordinate for water dimer (H$_2$O)$_2$ (left) and trimer (H$_2$O)$_3$ (right) using decomposition of SAPT vs ALMO-EDA. Dotted green line is the equilibrium O-O distance in water dimer. Distance 0 Å in the water trimer corresponds to the equilibrium geometry.

It is worth considering the charge transfer energy calculated using the SAPT decomposition proposed by Deng et al.,\textsuperscript{78} which is seen to underestimate the charge transfer energy compared to the ALMO-EDA for the water dimer and trimer (Figure 3). The underestimation of their CT energy compared to MB-UCB and ALMO-EDA can be due to either the neglect of the mutual charge transfer energy in their induction formulation, and/or their empirical separation of the SAPT induction energy into polarization and charge transfer components. We can test one of these two possibilities directly by removing the mutual charge transfer operation in the MB-UCB model, leaving behind only the direct charge transfer energy, showing that indeed the charge transfer energy would be underestimated in the short range as a result (see Figure 3a). Given that the agreement between ALMO-EDA and MB-UCB model using GDMA for the polarization energy is mutually reinforcing, i.e. given that they agree quantitatively although the intermolecular polarization is derived independently of each other, we conclude that the empirical separation of the SAPT induction...
energy has underestimated the charge transfer and overestimated the polarization energy.\textsuperscript{78} This conclusion is consistent with detailed comparison of the energy decomposition schemes themselves on a variety of model systems.\textsuperscript{84}

In Figure 4 we compare the van der Waals energy of the MB-UCB force field using Eq. 16 against the combined energy term $E_{\text{Pauli}} + E_{\text{disp}}$ from ALMO-EDA. For both the water dimer and trimer, the MB-UCB van der Waals energy agrees quite well with the ALMO-EDA throughout the scanned coordinates, with a similar trend observed for the MD extracted water pentamers. What is pleasing about this result is that the MB-UCB model is also fitting any disagreements between the individual $E_{\text{elec}}$, $E_{\text{pol}}$, and $E_{\text{CT}}$ terms of MB-UCB with ALMO-EDA. Thus the excellent agreement in the van der Waals energy is a reflection that there is very effective cancellation of small errors among these terms.

![Figure 4](image-url)

Figure 4: Change in the van der Waals energy along the scanned coordinate for water dimer (H$_2$O)$_2$ (a), trimer (H$_2$O)$_3$ (b) and the correlation of vdW energy between ALMO-EDA and MB-UCB of 50 random configurations extracted from a MD simulation (c). Distance 0 Å in the water trimer corresponds to the equilibrium geometry.

Table 1 provides a validation suite for dimers through 20-mer water cluster conformational energies at stationary point geometries (minima and transition states) evaluated with MP2 or CCSD(T) taken from previously reported literature.\textsuperscript{55,85–90} Overall the MB-UCB-MDQ and MB-UCB-MD models are in good agreement with the reference ab initio data for small water clusters, with larger errors for larger clusters, but all are within the same range of error of AMOEBA,\textsuperscript{55} AMOEBA14\textsuperscript{60} or iAMOEBA\textsuperscript{59} force fields.
Table 1: Comparison of binding energies between MB-UCB and \textit{ab initio} references for different water clusters of various sizes.

What is more relevant for the condensed phase is to consider distorted water cluster geometries taken from a liquid water simulation reported by Wang and co-workers.\(^{59,60}\) Using the 21,604 geometries for water clusters from dimers to decamers, we have developed a complete benchmarking suite using $\omega$B97X-V/def2-QZVPPD\(^{56}\) which in turn has been well-validated against a wide range of binding energies using the CCSD(T) gold standard.\(^{65}\) When compared against the data set of the previously reported benchmarks based on RI-
MP2/heavy-aug-cc-pVTZ, Figure 5a indicates that the previous RI-MP2 results systematically overbind with respect to the DFT reference. The MB-UCB-MDQ (Figure 5b) and MB-UCB-MD (Figure 5c) models also have a slight tendency to underbind, although it is also evident that both perform equally well against the DFT benchmark.

Figure 5: Correlation of water cluster binding energies from dimer to decamers for various energy models. (a) comparison of water dimers to decamers for 21,604 configurations between RI-MP2/heavy-aug-cc-pVTZ and ωB97X-V/def2-QZVPPD. Comparison from water hexamers to decamers for 12,002 configurations between ωB97X-V/def2-QZVPPD and (b) MB-UCB-MDQ and (c) MB-UCB-MD. Density of points represented by blue (low) to yellow (high) in the heatmap.

Figure 6 reports the gOO(r), gOH(r) and gHH(r) radial distribution functions for MB-UCB-MD water generated from the NVT ensemble under ambient conditions. It is evident that the MB-UCB-MD model is in excellent agreement with the family of allowed gOO(r) functions based on the experimental studies of Skinner and co-workers, and the gOH(r) and gHH(r) functions are also in notably good agreement with the neutron scattering studies of Soper. The MB-UCB-MD model, which is formulated on just small water cluster data from monomer to pentamers, offers significant improvement in liquid structure over previously reported iAMOEBA and AMOEBA models that tend to be over-structured in spite of being fit to condensed phase data. More work is required to completely characterize the MB-UCB model for water, but the fact that no condensed phase data was used to create the MB-UCB-MD model is a promising result.
4 Discussion and Conclusion

The performance of all force fields rely on accurate representations of the individual energy components such as permanent electrostatics, many-body polarization, the van der Walls potential, and non-classical effects such as charge penetration and charge transfer to yield the total intermolecular energy. However many force fields are parameterized with respect to either total energy and forces of high quality QM data and/or fits to experimental properties, and thus they are only indirectly connected to the individual energy components. In order to minimize errors among the individual energy terms of the decomposed QM energy, we have developed the MB-UCB force field based on the same breakdowns of ALMO-EDA.
when analyzed on small water cluster data. By incorporating charge penetration\textsuperscript{18} to better describe the short range electrostatics, accompanied with atomic anisotropic polarizabilities to improve the polarization energy,\textsuperscript{53} as well as introducing a simple model for the charge transfer energy,\textsuperscript{78} we have found excellent agreement with the ALMO-EDA breakdown with respect to these energy components. Furthermore we have shown that we can eliminate the need for the algebra-intensive quadrupoles of the permanent electrostatics for water. As a result, we have shown that MB-UCB quantitatively describes the binding energies of both small and large water clusters compared to the \textit{ab initio} binding energies.

The limited existence of good functional forms to model charge transfer in force fields has been mainly due the fact that there has been no chemically motivated way of separating out the charge transfer energy in an electronic structure calculation. Therefore, most of the advanced force fields lack an explicit model for the charge transfer energy term. However with the development of ALMO-EDA, which rigorously decouples polarization from charge transfer effects, it can provide guidance for incorporating charge transfer into an advanced force field. For the MB-UCB model we have further developed a highly empirical model for treating CT as an induction effect\textsuperscript{78} by augmenting it with a mutual induction term that introduces a greater many-body response. Although lacking the quantum mechanical effect of charge flow, the explicit representation of both CT and polarization is a step beyond the standard SAPT assumption of combining them into one induction term. In particular, because the exponential damping for CT is made more short-ranged than it is for polarization, we are able to correctly describe the different spatial range dependencies of these two terms that captures an important aspect of their quantum mechanical differences.

In summary, this study introduces the first generation MB-UCB model, setting the stage for soon to be reported work on how well it describes the condensed phase properties of bulk water and salt solutions. Because we have developed new algorithms to evaluate the many-body interaction energies and forces that reduces\textsuperscript{75} or eliminates\textsuperscript{76} the self-consistent field steps, the overall computational cost of the MB-UCB model is just that of the evaluation
of the pairwise permanent electrostatics. Because the MB-UCB model only needs to utilize
permanent atomic monopoles and dipoles for water, it should be computationally competitive
with standard force fields but with greater accuracy afforded by its many-body character.
The next stage of the MB-UCB force field development is for biologically relevant molecules
starting with protein chemistry using amino acid building blocks, and ultimately extending
the model to nucleic acids and drug molecules, and other non-biochemical systems as well.
