We use two continuous-wave (CW) laser beams of 780 nm and 515 nm to optically drive ⁸⁵Rb atoms in a heated vapor cell to a low-lying Rydberg state 10D_{5/2}. We observe a collimated ultraviolet (UV) beam at 311 nm, corresponding to the transition frequency from the 11P_{3/2} state to the 5S_{1/2} state. This indicates the presence of a coherent four-wave mixing process, built up by two input laser fields as well as a terahertz (THz) radiation of 3.28 THz that is generated by amplified spontaneous emission between the 10D_{5/2} and the 11P_{3/2} states. We characterize the 311 nm UV light generation and its dependence on various physical parameters. This scheme could open up a new possibility for generating narrow-band THz waves as well as deep UV radiation.

Laser-induced coherence among quantum states in an atomic medium leads to greatly enhanced nonlinear susceptibilities compared to that of solid state crystal media [1], and gives rise to fascinating phenomena such as electromagnetically induced transparency (EIT) [2], coherent population trapping (CPT) [3], and lasing without inversion (LWI) [4]. Nonlinear optical processes in such coherently prepared atomic media have been extensively studied for a wide range of applications. In particular, four-wave mixing (FWM) in alkali atomic gases is used to produce entangled states of light [5] and photon pairs [6], to construct quantum memories [7], and to transfer orbital angular momentum between near-infrared and blue light fields [8]. A very active area of research on FWM has been the investigation of frequency up and down conversion by using continuous wave excitation lasers in hot atomic vapors, which enables the efficient generation of new coherent optical fields in the visible and infrared regions [9–20].

In this paper, we investigate the generation of collimated UV light using ⁸⁵Rb in a thermal natural rubidium atomic vapour via a parametric four-wave mixing process involving the low-lying Rydberg states 10D_{5/2} and 11P_{3/2}. The relevant energy levels and the corresponding transitions of the experiment are shown in Fig. 1. The two transitions, 5S_{1/2} → 5P_{3/2} (transition 1) and 5P_{3/2} → 10D_{5/2} (transition 2), are driven by two near-resonant laser fields at 780 nm and 515 nm, respectively. We experimentally observe a collimated and single wave-length laser beam at 311 nm, which corresponds to the 11P_{3/2} → 5S_{1/2} transition (transitions 3 and 4 in Fig. 1). We attribute this generated 311 nm beam to a four-wave mixing process from the two input lasers as well as the 3.28 THz radiation emitted on the 10D_{5/2} → 11P_{3/2} transition (transition 3 in Fig. 1). The generation of this THz radiation via amplified spontaneous emission is facilitated by the long radiative lifetime of the 10D_{5/2} state (∼780 ns) [21].

Note that a similar scheme involving the lower lying states 5D_{5/2} and 6P_{3/2} has been studied in several experiments using rubidium vapors [9–16], where a collimated blue light at 421 nm, corresponding to the transition 6P_{3/2} → 5S_{1/2}, is produced via a four-wave mixing process. A generated 5.2 μm infrared radiation corresponding to the transition 5D_{5/2} → 6P_{3/2}, enabling the FWM process, has been observed in some of the experiments [14]. The difference between our scheme and the works in [9–16] is that, instead of the 5D_{5/2} state, a low-lying Rydberg state is being excited by pump lasers. As a result, two very different frequencies outside the typical optical regime are generated, namely a THz field on transition 3 and a UV field on transition 4. In our current setup, the direct measurement of the generated 3.28 THz field is hindered by the opacity of the fused-silica vapour cell windows at THz frequencies. However, the presence of the THz field is firmly established by the observation of the collimated 311 nm UV light.

Our experimental setup is illustrated in Fig. 2. Two
pump lasers consist of a 780 nm Titanium Sapphire (Ti:Sa) laser driving transition 1 and a 515 nm external cavity diode laser (ECDL) driving transition 2. The frequency of the 780 nm pump laser is determined via an optical beat note measurement with a 780 nm reference laser, which is locked on the 5S_{1/2} F=3 to 5P_{3/2} F=4 transition. Meanwhile, the 515 nm pump laser is stabilized to a 515 nm reference laser via frequency offset locking \[ \delta \] . We lock this 515 nm reference laser to the 515 nm pump laser frequencies by scanning them independently. The wavelength of the generated UV beam is measured with a grating spectrometer, and the only detectable wavelength is at \sim 311 nm, as shown in Fig. 2 (b). This wavelength corresponds to the 11P_{3/2} \rightarrow 5S_{1/2} transition.

The wavelength of the generated UV beam is measured with a grating spectrometer, and the only detectable peak is at \sim 311 nm, as shown in Fig. 2 (b). This wavelength corresponds to the 11P_{3/2} \rightarrow 5S_{1/2} transition. None of the other UV wavelengths listed in Table I corresponding to the transitions nP_{3/2} \rightarrow 5S_{1/2} with n < 11, are visible on this power scale. We make the following simple arguments to explain this observation. The third order nonlinear susceptibility of FWM in atomic media is proportional to the product of the dipole matrix elements of the four corresponding transitions. Since all the possible FWM pathways in Table I share the same two pumping transitions, the generated UV power of a FWM pathway, proportional to the square of the third order nonlinearity, will largely be determined by \[ |d_{DP} \cdot d_{P3}|^2 \] , where \[ d_{DP} \] and \[ d_{P3} \] are the dipole moments of the two cascade transitions. The values given in the last column of Table I indicate that the nonlinearity of the four-wave mixing via transitions 3 and 4 is much larger than that of other FWM pathways, which results in the domination of the 311 nm in the generated light.

The above spatial and spectral measurements confirm that this collimated UV beam is generated by four-wave mixing instead of spontaneous emission. Next we discuss the dependence of the UV generation on the two pump laser frequencies by scanning them independently. In Fig. 4 (a), the generated UV power is plotted as a function of the 780 nm detuning (\delta_{780nm}) and the two-photon
detuning ($\delta_{780\text{nm}} + \delta_{515\text{nm}}$). The optimal UV generation is observed near the two-photon resonance of transitions 1 and 2 with a width of around 250 MHz, which we attribute to Doppler broadening. Along the horizontal axis, an asymmetric peak appears with a sharp edge at around $\delta_{780\text{nm}} = 1.65 \text{ GHz}$ and a long tail of width $\approx 800 \text{ MHz}$ for $\delta_{780\text{nm}} > 1.65 \text{ GHz}$. This feature can be understood as follows. We have experimentally verified that the strong Kerr-lensing near the resonance of transition 1 distorts the 780 nm pump beam, and renders the FWM process ineffective. The beam restores its original shape at a detuning $\delta_{780\text{nm}} \sim 1.6 \text{ GHz}$, where the coherence of FWM survives and produces the 311 nm light that we observe. Note that a similar effect due to Kerr-lensing has been observed before in the generation of 421 nm light via FWM [12].

To check whether the optimal detuning of $\delta_{780\text{nm}} \sim 1.6 \text{ GHz}$ is related to the coherence induced by coupling to both hyperfine levels of the 5S$_{1/2}$ state [10], we repeat the spectroscopic measurements with an additional repumper ECDL locked on the 5S$_{1/2}$ F=2 $\rightarrow$ 5P$_{1/2}$ F=2 transition of the D1 line. This repumper laser will redistribute most of the ground state population into the hyperfine level 5S$_{1/2}$ F=3. Fig. 4(b) shows that this repumper causes no shift in the optimal detuning compared to that in Fig. 4(a), but results in an overall increase of 15% in the UV output. This result suggests that the UV generation observed is mostly due to the population in the 5S$_{1/2}$ F=3 level.

We investigate the dependence of the generated UV light on the input laser powers, while keeping the detuning of both lasers at the values where maximum UV generation is observed. In Fig. 5 all curves show that the generated UV power first increases with increasing 780 nm power. A further increase of the 780 nm power results in a reduction of the UV generation. To better understand this dependence, we simulate the light propagation inside the vapor cell within a simple four-level model and semi-classical Maxwell-Bloch equations [28] where atomic motion is accounted for by transit relaxation [29]. We find that the predicted UV power and its dependence on the pump powers agree qualitatively with the measurements. In particular, our simulations suggest that the reduction of the generated UV light at

TABLE I. Table of frequencies ($\nu$), wavelengths ($\lambda$), and dipole matrix elements ($d_{DF}$ and $d_{PS}$) for the transitions 10D$_{5/2} \rightarrow$ nP$_{3/2}$ and nP$_{3/2} \rightarrow$ 5S$_{1/2}$ [27]. Given in the last column are the values of $|d_{DF} \cdot d_{PS}|^2$. The 10D$_{5/2} \rightarrow$ nF transitions and further cascade transitions from nF states back to the 5S$_{1/2}$ state are not considered here.

FIG. 4. Generated UV power as a function of the 780 nm pump laser detuning ($\delta_{780\text{nm}}$) and the two-photon detuning ($\delta_{780\text{nm}} + \delta_{515\text{nm}}$) without the repump laser (left) and with the repump laser (right). The horizontal dashed line denotes the atomic two-photon resonance $\delta_{780\text{nm}} + \delta_{515\text{nm}} = 0$. The cell temperature is 126°C, while the 515 nm and 780 nm pump lasers have a power of 19 mW and 150 mW, respectively.

![FIG. 5](image-url)

FIG. 5. Generated UV power as a function of the 780 nm pump power for the 515 nm pump powers of 19 mW (black square), 15 mW (red circle), and 10 mW (blue triangle). The data is taken at 123°C. The solid lines are linear fits to the data of lower 780 nm powers, and the slopes of these fits with fitting errors are plotted as a function of the 515 nm power in the inset. The solid line in the inset is a linear fit.
large 780 nm input powers can be explained by a reduction of the $5S \to 5P \to 10D$ excitation efficiency due to the light-induced dressing of the 5P states. In the inset of Fig. 5, the slopes of the linear fits at small 780 nm powers are shown to increase linearly with the 515 nm pump power, and has no sign of saturation within the range of 515 nm power available in our experiment. This indicates that using higher 515 nm power will improve the UV generation.

The density-dependence of the generated UV power is shown in Fig. 6, where both detunings and 780 nm pump power are configured for maximum UV output at a fixed 515 nm pump power of 14 mW. At low densities, the generated UV power increases steadily with atomic density. However, UV generation falls sharply to almost zero for densities larger than $3 \times 10^{13}$ cm$^{-3}$, which persists even with increasing 780 nm power and/or adjusting the laser detunings. This abrupt reduction may be due to ions created by collisions between Rydberg atoms [30, 31], which induce Stark shifts of atomic levels. Further investigation is needed to verify this assumption.

In conclusion, we have demonstrated the generation of deep UV light via FWM involving low lying Rydberg states. Despite multiple decay pathways from the upper Rydberg level 10D$_{5/2}$, the dominant FWM process involves the most strongly dipole-coupled Rydberg level 11P$_{3/2}$. This results in the generation of a nearly monochromatic UV beam, while other FWM pathways give rise to a much weaker nonlinearity and are thus strongly suppressed.

Besides being useful for up conversion to deep UV radiation, this scheme of optically pumping atomic media into low-lying Rydberg states may offer a possibility for building up a continuous wave (CW) THz source with high spectral brightness. This is especially interesting, given that there has been tremendous efforts [32–34] to develop compact, narrow-linewidth, high-power THz sources. Even though it is not possible to extract the THz radiation in our current apparatus, our theoretical simulations allow us to estimate the amount of THz radiation generated on the 10D$_{5/2}$ $\rightarrow$ 11P$_{3/2}$ transition. We find that, under the current experimental conditions, the maximal power of the THz beam co-propagating with the other beams is of the order of 1 - 10 µW before the exit of the vapor cell. Note that in our system the vast majority of THz photons is generated via amplified spontaneous emission and not four-wave mixing due to the large imbalance between the dipole moments of transitions 3 and 4, $d_{DP}/d_{PS} >> 1$ (see Table I). To facilitate extraction of the THz radiation, a new vapour cell with silicon output window is being constructed. To further increase the power of the generated UV or THz fields, a build-up cavity may be used. In summary, we believe that our experimental demonstration lays the ground work for further utilizing this scheme to generate coherent deep UV and THz radiations not easily accessible by other methods.
