The property of superfluidity, first discovered in liquid $^4$He, is closely related to the Bose-Einstein condensation (BEC) of interacting bosons\textsuperscript{1}. However, even at zero temperature, when the whole bosonic quantum liquid would become superfluid, only a fraction of it would remain Bose-condensed at zero momentum\textsuperscript{2}. This is due to quantum depletion phenomenon, whereby particles are excited to larger momenta states due to interparticle interactions and quantum fluctuations. Quantum depletion of weakly interacting atomic BECs in thermal equilibrium is well understood theoretically\textsuperscript{3} but is difficult to measure\textsuperscript{4–7}. Driven-dissipative systems, such as condensates of exciton-polaritons (photons coupled to electron-hole pairs in a semiconductor) are even more challenging, since their nonequilibrium nature is predicted to suppress quantum depletion\textsuperscript{8}. Here, we observe quantum depletion of an optically trapped\textsuperscript{9} high-density exciton-polariton condensate\textsuperscript{10,11} by directly detecting the spectral branch of elementary excitations populated by this process. Analysis of the population of this branch in momentum space shows that quantum depletion of an exciton-polariton condensate can closely follow or strongly deviate from the equilibrium Bogoliubov theory, depending on the fraction of matter (exciton) in an exciton-polariton. Our results reveal the effects of exciton-polariton interactions beyond the mean-field description and call for a deeper understanding of the relationship between equilibrium and nonequilibrium BECs.
The fundamental understanding of interacting cold bosonic gases was developed by N. Bogoliubov, whose theory predicted the consequences of interparticle interactions for the properties of Bose-Einstein Condensates (BECs). According to this theory, an interacting BEC is characterised by a modified phonon-like dispersion of elementary excitations at long wavelengths (or short wavevectors) that explains the superfluid properties of weakly interacting BECs. The crux of the theory is the non-perturbative transformation of Bogoliubov quasiparticles, where a condensate excitation at a given momentum is expressed as a superposition of counter-propagating single-particle states. The quantum fluctuations of the interacting particles in the ground state are responsible for the non-zero occupation of these elementary excitations at zero temperature, leading to the so-called quantum depletion of the condensate population. Quantum depletion was observed in weakly interacting BECs of ultracold atoms and is the main reason for a low condensed fraction of strongly interacting superfluid $^4$He. This effect is predicted to have pronounced experimental signatures, where the occupation of elementary excitation modes exhibits a distribution in momentum space $N(k)$ scaling as $k^{-4}$ for long wavevectors. This behaviour is challenging to observe in weakly interacting atomic BECs, because the momentum distribution is not preserved in the time-of-flight measurements and is influenced by interactions during the expansion of the condensate.

Exciton-polariton condensates, which are part-light part-matter bosonic condensates formed in a semiconductor microcavity, allow direct measurement of their momentum space distribution and excitations through the cavity photoluminescence signal. Each exciton-polariton (or polariton) is a strongly coupled quantum well exciton and a cavity photon. Due to the finite lifetime of the confined photon state, the polariton eventually decays and a photon escapes the microcavity retaining the energy and momentum of the polariton. The finite lifetime results in the inherent driven-dissipative nature of exciton-polariton condensates, where the system needs constant pumping to maintain a population of the condensate, hence the steady state is reached based on a balance between driving and dissipation. In addition, the finite lifetime often prevents full thermalisation of the condensate, which is typically manifested by a macroscopic occupation of several single-particle energy states rather than a single ground state. Furthermore, the constant energy flow in exciton-polariton condensates strongly
influences the elementary excitation spectrum, which can possess a gapped mode or exhibits a flat dispersionless Goldstone mode at the low energy limit, gradually recovering the textbook Bogoliubov dispersion at longer wavevectors. Nonetheless, exciton-polariton condensates preserve superfluid properties, although their features are currently understood as a rigid state under continuous coherent driving.

The striking feature of the Bogoliubov excitation spectrum is the appearance of two branches which are positive (normal branch – NB) and negative (ghost branch – GB) with respect to the condensate energy. While the NB can be occupied by the process of thermal excitation (thermal depletion), the GB is populated solely by the quantum depletion process, thus its appearance in the photoluminescence spectrum can serve as a direct probe of beyond mean-field effects (quantum fluctuations) in an exciton-polariton condensate. Quite notably, the quantum effects of polariton-polariton interactions have been recently demonstrated, but at the single-particle level, through correlation experiments on strongly confined exciton-polaritons. There have been several attempts to measure the full excitation spectrum of exciton-polariton condensates including populating both excitation branches using resonant pump-probe schemes and intense incoherent driving. However, none of these approaches created the condensates in a spontaneous, steady-state configuration. More importantly, the population of the GB was forced by scattering on a defect or by an additional resonant laser beam, hindering the direct observation of many-body quantum effects.

The linear Bogoliubov spectrum of a spontaneously created high-density exciton-polariton condensate has been observed, but only the positive energy NB photoluminescence was visible in the momentum space and its population was naturally dominated by thermal excitations of the condensate, which scaled as \( k^{-2} \) in the low wavevector limit. Recently, the problem of reduced visibility of the GB was tackled theoretically, showing that the nonequilibrium effects can suppress the quantum depletion and its signatures in the excitation spectrum of exciton-polariton condensates photoluminescence.

In this work, we create a steady-state high-density exciton-polariton condensate in an ultrahigh-quality GaAs-based microcavity with a long polariton lifetime and observe directly the
manifestation of quantum depletion in the condensate excitation spectra (see Methods). This is achieved by an optical excitation scheme, where an annular spatial distribution of a nonresonant pump laser\textsuperscript{11,29} creates a similarly shaped distribution of incoherent excitonic reservoir particles that provides both gain and a trapping potential for the exciton-polaritons\textsuperscript{9}. At a sufficiently high pump power, a single-mode condensate in the interaction-dominated Thomas-Fermi regime\textsuperscript{11} forms inside the trap away from the direct influence of the pump-induced reservoir. The spatial separation of the pump and the condensate allows us to filter out the photoluminescence (see Methods) originating from regions with significant overlap with the reservoir and analyse the emission of the condensate and its excitations. In addition, the single-mode condensate ensures that we are dealing with a simple many-body state consisting of the macroscopically occupied ground state of the pump-induced trap. To test both the equilibrium and nonequilibrium features of the exciton-polariton condensate, we study two values of

![Figure 1. High-density single-mode condensation. (a) Pump power dependence of the total mean polariton density inside the trap (filled circles) and the occupation number of the $k_\parallel = 0$ state (empty circles). Ground state condensation threshold $P_{th}$ is indicated with an arrow. (b-d) Energy integrated, real-space images of exciton-polariton luminescence at the three density regimes marked in panel (a) shown together with (e-g) the corresponding real-space spectra taken in the middle of each image. (b, e) Images far below condensation threshold, $n < 0.02 \, \mu m^{-2}$. (c, f) Multimode condensation in the intermediate regime, $n = 18 \, \mu m^{-2}$. (d, g) High-density, interaction dominated single-mode regime, $n = 1615 \, \mu m^{-2}$. Dashed circle in (b-d) represents the shape of the ring excitation. The colour scale is linear. Data is presented for the photonic detuning, $\Delta = -3.7 \, meV$ (see Supplementary Information for the excitonic detuning).
detuning between the cavity photon and the exciton energies $\Delta = E_c - E_x$, positive ($\Delta = +1.8$ meV) and negative ($\Delta = -3.7$ meV). These two values, accessible via the microfabricated cavity wedge (see Methods), reflect either a more matter-like (excitonic) or a light-like (photonic) nature of the polaritons, where the Hopfield coefficients$^{10}$ determining the exciton fraction are $|X|^2 \approx 0.56$ and $|X|^2 \approx 0.39$ at $k_{||} = 0$, respectively. Additionally, the excitonic or photonic nature of exciton-polaritons affects their ability to achieve thermal equilibrium$^{30}$.

In our experiment, we utilise a continuous wave (CW) laser and create a steady state polariton condensate. Nevertheless, the condensation features are very similar to those observed in the pulsed excitation scheme$^{11}$. The typical condensate spectra are presented in Figure 1 together with the dependency of the polariton density and the ground state occupancy on pump power (Fig. 1a). Below the condensation threshold, laser-induced high-energy excitons relax and form exciton-polaritons with large wavevectors and energies, which form a local potential barrier and dominate the photoluminescence under these low-power excitation conditions, Figs. 1b, 1e. With the increase of pumping power, exciton-polaritons increase in density until they condense into a fragmented condensate with the macroscopic occupation of several modes of the trap, see Figs. 1c, 1f. This fragmentation is due to the weak polariton-polariton interaction and inefficient phonon-mediated relaxation processes at intermediate densities$^{31,32}$. Multimode condensation manifests itself in a smooth nonlinear rise in polariton density at pumping powers slightly before single mode condensation sets in, see Fig. 1a. After reaching the threshold at large polariton densities, stimulated scattering and efficient energy relaxation drive the condensation towards a single-mode ground-state condensate with a spatially homogeneous density distribution and well-defined energy, as seen in Figures 1d, 1g. In this interaction-dominated Thomas-Fermi regime, we can reliably measure the spectrum of condensate excitations, and perform a direct comparison with the Bogoliubov theory.

In order to investigate the excitations of the steady state exciton-polariton condensate, we measure the energy-resolved far-field emission of the condensate, which corresponds to the momentum- and energy-resolved distribution of exciton-polaritons. Figure 2a presents the excitation spectrum of a single mode condensate at intermediate densities, where the excitation spectrum is indistinguishable from the single-particle dispersion, i.e. the condensate
interaction energy is too small to modify considerably the Bogoliubov spectrum within the linewidth of the photoluminescence signal. The result of the momentum space integration is presented in Fig. 2b in double logarithmic scale. One can distinguish the condensate profile (the strongest signal located near \(k_\parallel = 0\), where \(k_\parallel\) is the polariton momentum in the plane of the quantum well) from the thermal excitations, which are visible at longer wavevector range and are fitted with a thermal distribution, Fig. 2b (see Methods\(^6\)). The condensate at \(k_\parallel = 0\) has a finite width in momentum space, which is a consequence of the spatial confinement in an optical trap\(^27\).

The momentum spectra differ significantly in the high-density regime around \(n \sim 10^3 \mu\m^{-2}\), where an exceptionally strong signal from the ground state exceeds all other contributions in the spectrum within the dynamical range of the CCD camera, see Fig. 3a. The condensate emission also reveals a characteristic Airy pattern due to diffraction of the condensate photoluminescence on a circular aperture we use as a real space filter (see Methods). To reveal the much weaker signal of the excitation branches, we imposed an edge filter in momentum space.

**Figure 2. Momentum space photoluminescence of a polariton condensate** (a) Momentum-space spectrum of the exciton-polariton condensate at the excitonic detuning \((\Delta = +1.8 \text{ meV})\), where excitations can be detected together with the strong signal from the \(k_\parallel = 0\) condensate for \(n = 70 \mu\m^{-2}\). Solid line is the single-particle (non-interacting) polariton dispersion. The colour scale is logarithmic. (b) Extracted momentum space occupation of the condensate and the thermal excitations in the normal branch in the log-log scale. Dashed-dotted line indicates the profile of thermal excitations fit with the effective temperature \(T_{\text{eff}} \approx 10 \text{ K}\).
space, blocking the strongest contribution to the signal up to about 0.55 \( \mu m^{-1} \), Fig. 3b and 3c. Remarkably, the signal from the two branches becomes clear and distinguishable, despite the strong contribution of the diffracted condensate photoluminescence. The appearance of the GB signal is an evidence of quantum depletion of the exciton-polariton condensate, being a consequence of quantum fluctuations in the steady state.

**Figure 3. Measurement of the renormalized excitation spectrum.** (a) Full photoluminescence of the high-density exciton-polariton condensate at the photonic detuning \( (\Delta = -3.7 \text{ meV}) \) and \( n \approx 1590 \mu m^{-2} \). (b) Excitation spectrum of the polariton condensate in (a) measured with a momentum edge filter covering the signal up to \( k_\parallel \approx 0.55 \mu m^{-1} \). (c) Excitation spectrum measured at the excitonic detuning \( (\Delta = +1.8 \text{ meV}) \) and \( n \approx 2200 \mu m^{-2} \). Color scales are logarithmic and images (b,c) are saturated. Green solid lines indicate extracted spectral positions of the branches. Solid white lines represent single-particle dispersions and dashed lines correspond to the renormalized Bogoliubov dispersions fitted to the data. (d) Extracted condensate energies (chemical potential \( \mu = gn \)) for both detunings displaying a linear dependence on density.
Fitting the renormalised excitation branches (see Methods and Supplementary Information) allows us to extract the chemical potential $\mu$ of the condensate as a function of the condensate density, which follows closely the expected linear dependence $\mu = gn$, where $g$ is the polariton-polariton interaction strength and $n$ is the extracted polariton density, see Fig. 3d. The extracted slopes yield $g = 0.086 \pm 0.003 \, \mu eV \mu m^2$ for the photonic detuning, and $g = 0.116 \pm 0.002 \, \mu eV \mu m^2$ for the excitonic detuning, which agrees very well with the measurement of the interaction strength in the pulsed excitation regime and with the theoretical predictions for the polariton-polariton interaction constant$^{11}$. We note that in the CW regime, the direct measurement of the interaction constant from the blueshift of the condensate energy in the Thomas-Fermi regime is not possible because of the incomplete density depletion of the reservoir, which effectively lifts the zero-point energy of the optically-induced potential (see Supplementary Information).

The essential information on the mechanisms populating the elementary excitation branches, summarised in Fig. 4, is contained in the characteristic momentum occupation distributions $N(k_{\parallel})$. The employed filtering technique allows us to measure the occupation distributions in the long wavevector range, i.e. $k_{\parallel} \xi > 1$, where $\xi = \frac{\hbar}{\sqrt{2mgn}}$ is the healing length and $m$ is the polariton effective mass (see Supplementary Information). In this wavevector range, the NB occupation is characterised by nonequilibrium features at both probed values of the exciton-photon detuning, see Figs. 4b and 4c. At densities $n < 10^3 \, \mu m^{-2}$, $N_{NB}$ is displaying thermal-like distributions at higher momenta for the excitonic detuning. However, at the largest probed densities, thermal excitations are reduced, leading to the population of excited states of the trap for both photonic and excitonic polaritons, Fig. 4b and 4c. This is caused by the interplay of the different populating mechanisms of the NB, as schematically depicted in Fig. 4a. In addition to thermal and quantum depletion of the condensate, the inefficient energy relaxation of polaritons naturally leads to an occupation of high-$k_{\parallel}$ states (see Supplementary Information). These high-energy polaritons originate from the potential barrier region (the reservoir) and are more prevalent for more photonic polaritons where the interactions and thermalisation are much weaker$^{10,30}$. The peak around $k_{\parallel} = 2 \, \mu m^{-1}$ observed for the excitonic detuning in Fig. 4b originates from high-energy states on top of the pump region, which spread all over the area of
the trap, and are similar to a high-energy state observed in a single spot excitation of a high-quality sample \(^{33}\). Additionally, polariton buildup and accumulation at high-energy states may be linked to the polariton-to-reservoir upconversion mechanism, which has been observed at strong coherent pumping fields in multiple independent experiments and is a source of the incoherent reservoir generation within the trap \(^{20,21,34–36}\).

![Figure 4. Depletion mechanisms - analysis of the extracted momentum space distributions](a) Schematics showing the renormalised dispersions of the condensate excitations and possible occupation mechanisms due to quantum depletion, thermal depletion and relaxation of high-energy polaritons. (b,c) Normal branch occupation for high-density polariton condensates at the (b) excitonic \((\Delta = +1.8 \text{ meV})\) and (c) photonic \((\Delta = -3.7 \text{ meV})\) detunings. Dashed line in (b) is a guide to the eye reference of a thermal distribution of excitations at an effective temperature \(T_{\text{eff}} \approx 30 K\). High-\(k_\parallel\) polaritons are more pronounced at higher densities for the photonic detuning. (d,e) Ghost branch occupancies for (d) excitonic and (e) photonic detunings. For more excitonic polaritons, the GB occupation behaves according to the equilibrium theory, following the asymptotic power-law decay at large momenta. At the photonic detuning, the GB occupation shows a deviation from the Bogoliubov theory, indicating the dominating non-equilibrium character of the quantum fluctuations. Plots (b-e) are in log-log scale.
In contrast to the NB, the GB is populated solely by quantum fluctuations of the high-density polariton condensate. Therefore, one expects to observe clear signatures in the momentum space distribution as predicted by the Bogoliubov theory. Indeed, the occupation distribution shows a $k^{-4}$ decay for the excitonic detuning, see Fig. 4d. This is in agreement with the Bogoliubov theory prediction of the asymptotic behaviour at large wavevectors and suggesting the equilibrium-like character of condensate quantum depletion despite the deviations caused by nonequilibrium effects in the NB distributions. Additionally, we observe a quadratic increase of the GB occupation as a function of the condensate density (see Methods and Supplementary Information). The most remarkable behaviour of the GB occupation distributions is observed at the photonic detuning, Fig. 4e. Here, in spite of the rising population density (and pump power), we observe a gradual transition from the $k^{-4}$ distribution to a plateau approaching $k^{-1}$. The deviations from the equilibrium distributions were predicted by nonequilibrium theories\textsuperscript{37}, indicating that at photonic detunings polariton condensate fluctuations are mediated mostly by the reservoir-condensate interactions, and the polariton-polariton interaction is not playing the main role. This is possible considering that both the reservoir and condensate density increase with pump power, as well as polariton-polariton interactions are weaker for more photonic polaritons (with the interaction strength scaling as\textsuperscript{11} $\sim |X|^4$). Additionally, the reservoir and the condensate still overlap at the periphery of the trap. Therefore, in our system, we observe a crossover from the near-equilibrium regime of quantum fluctuations at the excitonic detuning to a fully nonequilibrium regime at the photonic detuning. Our experimental findings, being a first direct probe of quantum fluctuations in a many-body driven-dissipative BEC, are beyond the current theoretical understanding of nonequilibrium condensates\textsuperscript{37,38}. Thus, they call for further development of a theory describing the quantum depletion of BECs in the crossover from thermal equilibrium to far-beyond equilibrium conditions. Furthermore, in the regime where the equilibrium Bogoliubov theory of quantum depletion does apply, our experiment paves the way for the measurement of the Tan's contact\textsuperscript{6,39} for exciton-polariton condensates (see Methods). This, in turn, will allow us to test whether the exciton-polariton condensates exhibit universal thermodynamical properties of a system with contact interactions\textsuperscript{40}.

Methods

Experiment

The sample used in the experiment is a high-quality factor GaAs-based microcavity characterised by a long cavity photon lifetime exceeding 100 ps\textsuperscript{41}. The 3\(\lambda/2\) cavity consists of distributed Bragg reflectors with 32 (top) and 40 (bottom) pairs of alternating Al\(_{0.2}\)Ga\(_{0.8}\)As/AlAs layers and an active region of 12 GaAs/AlAs quantum wells of 7 nm nominal thickness positioned in three groups at the maxima of the confined photon field. The normal mode anticrossing (Rabi splitting) is measured to be about \(\hbar\Omega = 15.9 \pm 0.1\ \text{meV}\textsuperscript{42}\), the exciton resonance energy is \(E_X = 1.6062 \ \text{eV}\), and the cavity photon effective mass is about \(3.4 \times 10^{-5} \ m_0\), where \(m_0\) is the free electron mass\textsuperscript{11,43}. In all experiments the microcavity is kept in a continuous flow helium cryostat, ensuring the sample temperature of 7-8 K.

The nonresonant excitation in the experiment was provided by a single-mode continuous-wave Ti:Sapphire laser tuned to a reflectivity minimum of the microcavity (around 719 nm) for efficient photon absorption in the quantum wells. To minimise the thermal heating of the sample, the laser pump was chopped with an acoustic optical modulator at 10 kHz and 5\% duty cycle. The ring-shaped excitation profile is created by utilising an axicon lens in a confocal configuration between two imaging lenses that produces a hollow beam\textsuperscript{44} when re-imaged onto the sample surface via a microscope objective of NA = 0.5. The same objective collects the photoluminescence from the sample. The imaging setup is composed of four lenses in confocal configuration for measurements of near- and far-field emission image planes\textsuperscript{29}. The image filtering is performed in the intermediate conjugate planes with an optical iris in real-space and a movable razor-blade edge in momentum space. The filtered signal is then imaged onto the monochromator slit and dispersed by a grating, allowing measurement of spatial and
momentum spectra of exciton-polariton photoluminescence. The signal is recorded by a high-efficiency EMCCD camera. The calibrated collection efficiency of the setup and the signal integration is performed in momentum space, and the detailed description of the integration formulas are given elsewhere.

**Analysis of the Bogoliubov excitation branches**

One can diagonalize a simplified Hamiltonian of a Bose-Einstein condensate of weakly interacting bosons using quasiparticle operators at a given wavevector $k^{45}$: $\hat{b}_k = u_k \hat{a}_k + v_{-k} \hat{a}^\dagger_{-k}$, which is a linear combination of creation and annihilation single-particle operators for a boson at given wavevector, $\hat{a}^\dagger_k$, $\hat{a}_{-k}$ and the amplitudes are expressed as:

$$u_k, v_{-k} = \pm \frac{1}{\sqrt{2\epsilon(k)}} \sqrt{\frac{\hbar^2 k^2}{2m}} + gn \pm \epsilon(k),$$

where $\epsilon(k)$ is the Bogoliubov dispersion in equilibrium:

$$\epsilon(k) = \sqrt{\frac{\hbar^2 k^2}{2m} \left( \frac{\hbar^2 k^2}{2m} + 2gn \right)}$$

Occupation of the single-particle excited states is expressed as $\langle \hat{a}^\dagger_k \hat{a}_k \rangle = (|u_k|^2 + |v_{-k}|^2) \langle \hat{b}^\dagger_k \hat{b}_k \rangle + |v_{-k}|^2$. Here, the first term, proportional to $\langle \hat{b}^\dagger_k \hat{b}_k \rangle = 1/[\exp(\epsilon(k)/k_bT) - 1]$, is describing the thermal depletion of the condensate. At zero temperature, $T = 0$, there is no thermal occupation of Bogoliubov quasiparticles $\langle \hat{b}^\dagger_k \hat{b}_k \rangle = 0$, and the nonzero occupation of single-particle states is due to quantum depletion $\langle \hat{a}^\dagger_k \hat{a}_k \rangle = |v_{-k}|^2$. The GB states are populated due to quantum depletion, therefore the GB occupation can be expressed as $N_{GB}(k) = |v_{-k}|^2$.

Taking the asymptotic behaviour of $N_{GB}$, one finds that in the low wavenumber regime $N_{GB}(k) \xrightarrow{k \xi \ll 1} \frac{mg}{2\hbar k} \propto k^{-1}$, which was inaccessible in our experiment, and in the opposite regime $N_{GB}(k) \xrightarrow{k \xi \gg 1} \frac{m^2 g^2 n^2}{\hbar^4 k^4} \propto k^{-4}$. The asymptotic value $\lim_{k \to \infty} N(k)k^4 = C$ is referred to as Tan’s contact, a universal quantity relating contact interactions to the thermodynamics of a many-body system. The contact in the equilibrium theory depends quadratically on peak density $C \propto n^2$, in agreement with the values extracted from the experiment (see Supplementary Fig. 7).

In the case of driven-dissipative systems, the Bogoliubov dispersion is modified and, after adiabatic elimination of the reservoir modes, the dispersion can be expressed in the analytical form:

12
\[ \epsilon_{neq}(k) = -i \frac{\hbar \Gamma}{2} + \sqrt{\epsilon^2(k) - \left(\frac{\hbar \Gamma}{2}\right)^2}, \]

where the nonequilibrium relaxation parameter \( \Gamma \to \gamma_{LP} \) and \( \gamma_{LP} \) represents the polariton decay rate. In our case, the polariton lifetime exceeds 100 ps\(^4\), so \( \hbar \Gamma \approx 3 - 5 \mu eV \), which has a negligible contribution to the fitted dispersion at large wavevectors measured in this work. Therefore, for the purpose of the analysis, we use an approximation of equilibrium dispersion \( \epsilon(k) \). The fitting of the dispersions of elementary excitations is performed using a single fitting parameter, the condensate interaction energy \( \mu = gn \).

**Condensate filtering in real space**

To ensure that the collected photoluminescence (PL) originates from the condensate in the trap only and not from polaritons near the pump region, we use a real space filter as shown in Supplementary Figure 1a. The filter is an iris placed in the intermediate real space (near-field)

Supplementary Figure 1 (a) Energy integrated PL of the high-density condensate showing the edge of the real space filter (dotted circle) and the outline of the excitation profile (dashed circle). (b) Real space spectrum of the high-density condensate filtered in both real space (dotted lines) and momentum space (edge filter, not shown). The signal outside the real space filter is due to diffraction on the filter edges. Image is saturated and the colour scale is logarithmic.
image plane of the optical setup, centred with respect to the condensate position. The diameter is optimized to minimise the diffraction on its edges and to filter out the signal from the barrier region. All dispersion measurements presented in the main text were performed using this filtering technique. Supplementary Figure 1b shows the real-space spectrum when we combine the real space and the momentum space edge filters. Similarly to the momentum-resolved spectra of Figure 3 of the main text, the dominant emission originates from the condensate at \( E \approx 1.600 \) meV. More importantly, one can observe that the NB and GB states are spread all over the trap and do not come from the barrier region. The signal outside the real space filter is due to diffraction.

**Condensation at the excitonic detuning**

Supplementary Figure 2 presents the data taken for the excitonic detuning (\( \Delta = +1.8 \) meV), which shows similar features to the photonic detuning case, see Figure 1 of the main text. In the power dependent density measurements, Suppl. Fig. 2a, one can observe a nonlinear growth of the density before the condensation at \( k_\parallel = 0 \) starts at around 70 mW. Similarly to the photonic detuning case, this is caused by the macroscopic occupation of excited states at lower pump power due to inefficient relaxation to the ground state. Additionally, there are macroscopically occupied high-energy modes located on top of the barrier\(^1\), as can be seen in Suppl. Fig. 2b, 2d.

**Supplementary Figure 2 (a)** Pump power dependence of the total mean polariton density inside the trap (dark circles) and the occupation number of the \( k_\parallel = 0 \) state (light circles). Ground state condensation threshold \( P_{\text{th}} \) is indicated with an arrow. **(b, c)** Energy integrated, real-space images of exciton-polariton photoluminescence at two density regimes marked in panel (a) shown together with **(d, e)** the corresponding real-space spectra taken in the middle of each image. **(b, d)** Intermediate density regime, \( n \approx 7 \) \( \mu \text{m}^{-2} \), where the high density mode is visible together with the ground state. **(c, e)** High-density, single mode condensation, \( n \approx 2200 \) \( \mu \text{m}^{-2} \).
These modes coexist with the single-energy condensate inside the trap and manifest themselves in the peaked occupation at high k-vectors, see Figure 4 of the main text.

Supplementary Figure 3 Density-dependent blueshift of the ground state extracted from the \( k_\parallel = 0 \) spectrum. Solid lines are linear fits to the high-density data.

Density-dependent blueshift of the ground state

Supplementary Figure 3 presents the exciton-polariton energy blueshifts extracted from the density-dependent measurements. Below the condensation threshold, at low densities, there is an anomalously large blueshift due to interactions with the reservoir and the optically induced potential\(^2,3\). At large densities above the condensation threshold, the blueshift is a linear function of polariton density in the trap, indicating that the condensate is in the interaction-dominated Thomas-Fermi regime. We note, however, that under CW excitation there is an inefficient reservoir spatial hole-burning\(^4\), which means that there is a non-negligible contribution of polariton-reservoir interactions to the blueshift within the trap. This is manifested in larger-than-expected slopes and non-zero low-density limit of the linear dependencies of the blueshift on density, \( E = sn + \Delta E \). In the considered cases here, the slopes are: \( s = 0.209 \pm 0.002 \) \( \text{meV} \mu\text{m}^2 \) for the excitonic detuning and \( s = 0.2341 \pm 0.0034 \) \( \text{meV} \mu\text{m}^2 \) for the photonic detuning. These values are about two times larger than those expected to arise due to polariton-polariton interactions\(^5\) and the slope is larger for the photonic detuning (smaller Hopfield coefficient), which contradicts the expected behaviour, based on the expression of the polariton-polariton interaction constant\(^7,8\):

\[ E = sn + \Delta E. \]
\[ g = \frac{|X|^4}{2N_{QW}} g_X, \]

where \(|X|^2\) is the excitonic Hopfield coefficient determining the fraction of an exciton in the exciton-polariton quasiparticle, \(g_X\) is the exciton-exciton interaction constant, and \(N_{QW}\) stands for number of quantum wells in the microcavity.

**Condensate spatial shape at large densities**

The high-density interaction-dominated regime is characterised by a smooth and nearly-homogeneous distribution of the ground state wavefunctions within the area defined by the optical trap. To verify this property, we extracted the real-space density distributions of condensed polaritons, which is reflected in the indensity distribution of the cavity photoluminescence taken along the real-space spectrum at the energy of the condensate, see Suppl. Fig. 2e and Figure 1g in the main text. The measured profiles in the high-density regime are summarised in Supplementary Figure 4. At large densities, \(n > 10^3 \mu m^{-2}\), the shape of the ground state wavefunction remains almost constant with further increase in density. The small modulations on the top of the condensate wavefunction is a result of local sample imperfections, reflecting the actual confining potential of the sample.

Extraction and fitting of the excitation branches

Below we provide details of the fitting procedure of the excitation spectra presented in Figure 3 of the main text. The excitation spectra in momentum space are recorded on the CCD camera, where each pixel column corresponds to a wavevector $k_{\parallel}$. Examples of spectral profile at different finite wavevectors are presented in Suppl. Figs. 5a,b and 5d,e. The signal is dominated by the diffracted light from the condensate, which arises from the real space filtering. On the high-energy side, one can observe the photoluminescence of the normal branch (NB), whose spectral lineshape is irregular and is composed of the occupation of many confined excited states of the optically-induced trap. The lineshape of the NB is fitted with a Voigt function to extract the intensity and energy from the peak area and centre, respectively, see Suppl. Figs 5a, 5d. The low-energy peak is the signal of the ghost branch (GB), which is much weaker as shown in the zoomed-in plots in Suppl. Figs. 5b and 5e. In contrast to the NB, the lineshapes of the GB states are smooth and are fitted to Lorentzian functions for extraction of the energy peak positions and its intensity. The extracted energy dispersion of the GB is then fitted with the

(a, d) Show the full spectra, where NB is fitted with the Voigt function (dashed line). (b, e) Zoomed spectra with examples of fitting to the weak GB signal with Lorentzian lines (dashed lines). (c, f) Examples of fitting to the renormalized Bogoliubov spectrum in the GB.
Bogoliubov spectrum $\epsilon(k)$ (see Methods), and the condensate interaction energy $\mu = gn$ is the only fitting parameter. Examples of the renormalized spectra fits are presented in Suppl. Figs. 5c and 5f. Note that we fit the GB dispersion only due to the clarity of this data, as the GB states are populated only via quantum depletion. This is unlike the NB that has additional contributions from high-energy states coming from top of the barrier, which results in an extracted dispersion that deviates from the Bogoliubov prediction, see Figure 3 in the main text.

**Healing length and the crossover wavevector**

The healing length of the condensate is calculated in the standard way, using the textbook definition $\xi = \frac{\hbar}{\sqrt{2}\sqrt{m\mu}}$, where $m$ is the polariton effective mass and $gn$ is the interaction energy extracted from the fitting of the GB excitation spectra. The calculated crossover wavevector $\xi^{-1}$, where the dispersion changes from linear to quadratic, is summarised in Suppl. Fig. 6 for the two detunings used in the experiment. The results show that our momentum-

space filtering technique allows for probing the long wavevector ($k > \xi^{-1}$) part of the elementary excitations spectrum.

**Density dependence of the contact**

As described in the Methods section of the main paper, the direct measurement of the GB occupation in momentum space allows one to extract the value of the Tan’s contact from the $N_{GB}(k) \propto Ck^{-4}$ dependency at large k-vectors. Assuming the local density approximation (LDA) in the middle of the trap, where the condensate density is a smooth function, the proportionality coefficient should depend quadratically on the peak density $C \propto n^2$. Verification of this relation is presented in Supplementary Figure 7. The peak density has been extracted from real-space spectra in the middle of the trap, to avoid averaging of the density with the periphery of the condensate. We note that the contact $C_\infty$ measured for an atomic BEC, e.g., in Ref. 6, is defined as the limit of density distribution in momentum space rather than the

occupation number. In a two-dimensional quantum gas, it is therefore related to the quantity defined above as $C_\infty = CS/(2\pi)^2$, where S is the area of the condensate in real space. Both $C_\infty$ and $C$ exhibit quadratic dependence on the peak density in the LDA.
