June 5, 2019

We introduce fluctuating hydrodynamics approaches on surfaces for capturing the drift-diffusion dynamics of particles and microstructures immersed within curved fluid interfaces of spherical shape. We take into account the interfacial hydrodynamic coupling, traction coupling with the surrounding bulk fluid, and thermal fluctuations. For fluid-structure interactions, we introduce Immersed Boundary Methods (IBM) and related Stochastic Eulerian-Lagrangian Methods (SELM) for curved surfaces. We use these approaches to investigate the statistics of surface fluctuating hydrodynamics and microstructures. For velocity autocorrelations, we find characteristic power-law scalings $\tau^{-1}$, $\tau^{-2}$, and plateaus can emerge depending on the physical regime associated with the geometry, surface viscosity, and bulk viscosity. This differs from the characteristic $\tau^{-3/2}$ scaling for bulk three dimensional fluids. We develop a theory explaining these observed power-laws that can be interpreted using time-scales associated with dissipation within the fluid interface and coupling to the bulk fluid. We then use our introduced methods to investigate in a few example systems how the drift-diffusive dynamics of microstructures compare with and without hydrodynamic coupling within the curved interface.

1. Introduction

Many soft matter systems involve inclusion particles or other microstructures with hydrodynamic interactions mediated through curved fluid interfaces [20,26,38]. This includes the motions of proteins within lipid bilayer membranes [2,4,38,61], surfactants and contaminants in bubble interfaces [22,69], transport in soap films [40,41], and recent systems with nanoparticles or colloids embedded in fluid interfaces [12,14,16,46,52,74,75]. Related hydrodynamic and curvature mediated phenomena also play an important role in biology and physiology, including transport of surfactants in lung alveoli [37,49] or in cell mechanics [51,53,59]. We develop general approaches to model and simulate the collective drift-diffusion dynamics of particles and other microstructures embedded within curved two-dimensional fluid interfaces. At small length and time scales, thermal fluctuations also play an important role.

We develop methods for curved surfaces building on our prior works on stochastic immersed boundary methods and fluctuating hydrodynamics methods [8,9,67]. We also draw on our recent work on developing approaches for deterministic incompressible hydrodynamic flows on curved surfaces [32,33]. Here, we address how to introduce the spontaneous thermal fluctuations and handle the associated drift-diffusive dynamics of microstructures both in the inertial regime and the quasi-steady regime for the hydrodynamics. We develop theory and computational methods that capture for the fluctuations the correlations arising from the hydrodynamic coupling within the curved fluid interface and from the traction stresses with the flows of the surrounding bulk fluids.

There has been a lot of work on approaches for investigating hydrodynamic coupling and diffusion based on the classical Saffman-Delbruck (SD) hydrodynamics [64, 65] which were derived for flat viscous sheets [13, 19, 47, 55, 56, 70]. However, in many problems arising in practice the geometry plays an important role as a consequence of significant curvature on the SD length-scale or from the surface topology. These effects can significantly change the hydrodynamic responses relative to the flat case [32, 39, 62, 67]. This has motivated recent work going beyond the classical Saffman-Delbrück theory for flat viscous sheets by formulating hydrodynamic descriptions that take into account the consequences of geometry and additional mechanics arising for curved fluid interfaces [5, 32, 36, 62, 66, 67].

We introduce general fluctuating hydrodynamics methods for the drift-diffusion of particles and microstructures immersed within curved fluid interfaces. To demonstrate ideas, we focus particularly on the case of interfaces of spherical shape. Extending the Saffman-Delbrück theory [64, 65] derived for flat viscous sheets, we formulate hydrodynamic equations for curved fluid interfaces coupled to the surrounding bulk fluid. We introduce thermal fluctuations accounting for the fluid-structure interactions and collective dynamics of the particles and microstructures building on our prior work on stochastic immersed boundary and related methods in [8, 9, 32, 33, 67].

In contrast to the flat Euclidean setting, the curvature of the fluid interface poses significant challenges for immersed boundary methods to obtain appropriate fluid-structure coupling operators for force spreading and velocity averaging [67]. We develop fluid-structure coupling operators that satisfy adjoint conditions to account consistently for inclusion particles within curved surfaces. These operators allow us to derive mobility tensors for the collective hydrodynamic coupling of particles and microstructures within the interface.

The curved geometry and topology of surfaces also pose some additional technical and numerical challenges for generating incompressible hydrodynamic fields with thermal fluctuations. For spherical topologies, this arises in part from the lack of a global coordinate chart. We develop techniques to handle incompressible hydrodynamics based on a generalized vector potential formulation of the fluid mechanics on the surface. In the quasi-steady regime, we further develop techniques based on a formulation of the mobility tensor in the embedding space to derive covariances to capture consistently the hydrodynamic correlations in the fluctuating hydrodynamic fields. Working in the embedding space introduces issues related to the expansion in dimension that results in null spaces for some of the linear operators. We introduce algorithms for stabilization allowing for computation of the stochastic driving forces for the in-plane drift-diffusion dynamics of microstructures within curved surfaces. Our introduced approaches provide in both the inertial and quasi-steady regimes methods that capture in a manner consistent with statistical mechanics the interface hydrodynamics, traction coupling with the surrounding bulk fluid, fluid-structure coupling, and thermal fluctuations.

We organize our paper as follows. We formulate fluctuating hydrodynamic equations and related immersed boundary methods for spherical fluid interfaces in Section 2. We then develop stochastic numerical methods for the drift-diffusion dynamics of particles and microstructures in Section 3. We use our approaches to investigate the statistical mechanics of surface fluctuating hydrodynamics and develop theory for explaining observed power-laws in Section 4. We further demonstrate our approaches by investigating the role of hydrodynamic coupling and related diffusive correlations in the kinetics of particles in Section 4. These results show some of the rich phenomena that can arise and be captured by our introduced fluctuating hydrodynamics approaches for curved fluid interfaces.
2. Fluctuating Hydrodynamics for Curved Fluid Interfaces

In the setting of curved fluid surfaces, physical quantities such as momentum must be treated carefully on the surface with an interpretation referenced to the physical ambient space [50]. This is done by deriving general conservation laws for fluids on curved surfaces by utilizing the invariances of the mechanical energy under different symmetries [32,50].

2.1. Conservation Laws for Curved Surfaces

The conservation of mass and momentum can be expressed as

\[
\begin{align*}
\rho \frac{\partial \mathbf{v}}{\partial t} + \nabla \cdot (\rho \mathbf{v}) &= \mathbf{b} \\
\rho \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) &= 0.
\end{align*}
\]

(1)

The stress tensor \( \sigma \) for an incompressible Newtonian fluid for a curved fluid interface can be expressed as

\[
\sigma = \mu_m \mathbf{D} - p \mathbf{I}.
\]

(3)

The D is the rate-of-deformation tensor, \( p \) is the pressure, and I is the metric associated identity tensor [50].

Tensors can be expressed in covariant or contravariant form [1,35]. For vectors in contravariant form we have \( t^i = t^a \partial_x a \) or in covariant form \( t_i = t_a dx^a \) [1]. The \( \partial_x a \) denotes the \( a^th \) coordinate basis vector. The \( dx^a \) denotes the \( a^th \) coordinate basis covector (differential 1-form) with \( dx^a[\partial_x a] = \delta^b_a \) [1]. We can convert between vectors and covectors by the mappings \( b : t^a \rightarrow t_a = g_{ab} t^b \) and \( \sharp : t_a \rightarrow t^a = g^{ab} t_b \). The \( g_{ab} \) denotes the metric tensor and \( g^{ab} \) the inverse metric tensor [1]. These maps \( b \) and \( \sharp \) between the tangent space and cotangent space correspond to lowering and raising indices in the coordinate expressions of the tensors [1,35].

We find it convenient in our calculations to express tensors in covariant form and use exterior calculus [1]. This allows us to generalize vector calculus and many techniques employed for fluid mechanics to the manifold setting [32,33,67]. For an incompressible Newtonian fluid interface, the stress \( \sigma \) is given in equation 3. The divergence of the stress tensor on the surface \( \nabla \cdot (\sigma) \) becomes in covariant form [32,50,67]

\[
\nabla \cdot (\sigma) = \mu_m \left( -\delta \mathbf{d} \mathbf{v}^\flat + 2K\mathbf{v}^\flat \right) - dp.
\]

(4)

The \( \mathbf{d} \) is the exterior derivative playing here a role similar to the gradient on the surface, \( \delta \) is the co-differential playing a role similar to the divergence on the surface, and \( K \) is the Gaussian curvature of the surface [1,60].
2.2. Fluctuating Hydrodynamics with Fluid-Structure Interactions

We introduce a fluctuating hydrodynamics description to account for the drift-diffusion motions of microstructures and their hydrodynamic coupling [8, 9, 67]. In covariant form, we introduce for curved fluid interfaces fluctuating hydrodynamic equations incorporating fluid-structure interactions. We show a schematic of our general approach in Figure 1.

The fluid dynamics are modeled by

\[ \rho \frac{d\mathbf{v}^b}{dt} = \mu_m \left( -\delta \mathbf{v}^b + 2K \mathbf{v}^b \right) - dp + t^b + \Lambda \left[ \gamma \left( \mathbf{V} - \Gamma \mathbf{v}^b \right) \right] + f_{thm} \]

\[ -\delta \mathbf{v}^b = 0. \]  

(6)

The drift-diffuson motions of microstructures are modeled by

\[ m \frac{d\mathbf{V}}{dt} = -\gamma \left( \mathbf{V} - \Gamma \mathbf{v}^b \right) - \nabla \phi + F_{thm} \]

\[ \frac{d\mathbf{X}}{dt} = \mathbf{V}. \]  

(8)

The \( \mathbf{v}^b \) denotes the fluid velocity. The \( \mathbf{X} \) and \( \mathbf{V} \) denotes the collective configuration and velocity of the microstructures immersed within the fluid. The \( \mu_m \) is the fluid shear viscosity, \( p \) is the pressure. As is commonly done in fluctuating hydrodynamics, we neglect the typically lower-order advection term contributions in equation 5 given the rapid oscillations of the fluid from the thermal fluctuations [71]. The \( \Lambda \) and \( \Gamma \) are fluid-structure coupling operators we shall discuss in more detail in Section 2.5. The \( \gamma \) is the drag coupling coefficient between microstructures and the fluid, \( -\nabla \phi \) are the conservative forces acting on microstructures, and \( f_{thm} \) and \( F_{thm} \) are stochastic forces accounting for thermal fluctuations of the system.
Surface Fluctuating Hydrodynamics with Fluid-Structure Interactions

Figure 1: Surface Fluctuating Hydrodynamics with Fluid-Structure Interactions. To model particles and microstructures embedded in curved fluid interfaces, we couple a Lagrangian description of the microstructures to an Eulerian description for the fluid mechanics. The coupling is modeled by the two operators $\Gamma$ and $\Lambda$. The operator $\Gamma$ gives a kinematic reference fluid velocity used to determine how the fluid exerts force upon microstructures in equation 7. The operator $\Lambda$ gives the related force density for how the microstructures exert force on the fluid in equation 5. We model the drift-diffusion dynamics of microstructures by the SELM fluctuating hydrodynamics description introduced in equations 5 - 8.

2.3. Traction Stress from Flow of the Surrounding Bulk Fluid

For the spherical geometry, we use Lamb’s solution [34, 43] to obtain the traction stresses $t^\flat = T_f v^\flat$ that arises from $v$ in entraining flow of the surrounding bulk fluid [67]. Our approach here makes the assumption that the bulk surrounding flow arises from an incompressible Newtonian fluid that reaches steady-state rapidly when contributing to the surface traction. Let the bulk fluid velocity be denoted by $u$ with values on the surface $u = v + v_n n$, where we shall assume $v_n = 0$ throughout. The solution can be expressed using the spherical harmonics expansion

$$ r \cdot \nabla \times u = \sum_{\ell=-\infty}^{\infty} Z_\ell. \quad (9) $$

We emphasize here the curl $\nabla \times$ is the usual operator in three dimensional Euclidean space. The $Z_\ell$ denotes the combined contributions of all of the solid spherical harmonic terms of degree $\ell$. We also expand the bulk surrounding fluid flows inside the sphere $u^-$ and outside the sphere $u^+$ as

$$ u^+ = \sum_{\ell=0}^{\infty} u^+_\ell, \quad u^- = \sum_{\ell=1}^{\infty} u^-_{\ell}. \quad (10) $$

The $u^+_\ell$ and $u^-_{\ell}$ are the solid spherical harmonic expansion terms combined for degree $\ell$. The Lamb solutions for the bulk fluid velocity fields are given by [34,43]

$$ u^+_\ell = \nabla \times (r \chi_{-(\ell+1)}), \quad u^-_{\ell} = \nabla \times (r \chi_{\ell}) \quad (11) $$

where

$$ \chi_\ell = \frac{1}{\ell(\ell+1)} \left( \frac{r}{R} \right)^\ell Z_\ell \quad (12) $$

$$ \chi_{-(\ell+1)} = \frac{1}{\ell(\ell+1)} \left( \frac{R}{r} \right)^{\ell+1} Z_\ell. \quad (13) $$

Page 5 of 29
The traction stress in contravariant form $t^\prime = t^+ + t^-$ is

$$
t^+ = \sigma^+ \cdot n^+ = \mu_+ \frac{\partial u^+}{\partial r} + \mu_+ \nabla (u^+ \cdot n^+) \quad \text{(14)}$$

$$
t^- = \sigma^- \cdot n^- = -\mu_- \frac{\partial u^-}{\partial r} + \mu_- \nabla (u^- \cdot n^-). \quad \text{(15)}$$

We emphasize in the above notation $n$ is evaluated at the fixed location of traction on the surface and does not change when taking the gradient $\nabla$. The $\sigma^\pm$ is the fluid shear stress and pressure from the bulk surrounding fluid arising at the fluid interface. We take $\mu^\pm = \mu_f$ throughout. The traction can be expressed in terms of the spherical harmonics expansion as

$$
t^+ = -\mu_+ \sum_{\ell=0}^{\infty} \frac{(\ell+2)}{R} u_\ell^+ =: \tilde{T}_f^+ \nu^+ \quad \text{(16)}$$

$$
t^- = -\mu_- \sum_{\ell=1}^{\infty} \frac{(\ell-1)}{R} u_\ell^- =: \tilde{T}_f^- \nu^- \quad \text{(17)}$$

The bulk fluid flow has $u^+ = u^- = v$ on the fluid interface and is completely determined by $v$. We define in covariant form the traction operators on the surface corresponding to equation 16 and 17 as $t^\flat = T_f \nu^\flat = \tilde{T}_f^+ \nu^\flat + \tilde{T}_f^- \nu^\flat$.

### 2.4. Thermal Fluctuations

To determine the associated stochastic driving terms $f_{\text{thm}}(x,t)$ and $F_{\text{thm}}(t)$ that account for thermal fluctuations, we use an approach related to our Stochastic Eulerian Lagrangian Method (SELM) framework [9, 71]. We use this in the setting of the curved fluid interface to derive stochastic driving terms $f_{\text{thm}}(x,t)$ and $F_{\text{thm}}(t)$. These are introduced as Gaussian processes that are $\delta$-correlated in time with mean zero and covariances

$$
\langle f_{\text{thm}}(t) f_{\text{thm}}(s)^T \rangle = -2k_B T L_{ff} \delta(t-s) \quad \text{(18)}$$

$$
\langle F_{\text{thm}}(t) F_{\text{thm}}(s)^T \rangle = 2k_B T \gamma L \delta(t-s) \quad \text{(19)}$$

$$
\langle F_{\text{thm}}(t) f_{\text{thm}}(s)^T \rangle = -2k_B T \gamma L \delta(t-s). \quad \text{(20)}$$

Here, the $\langle \cdot \rangle$ is to be interpreted as an expectation average taken over the probability distribution.

The first term involves the dissipative operator associated with the fluid $L_{ff} v^\flat$ where

$$
L_{ff} = L_f - \gamma_0 \Gamma \quad \text{(21)}$$

$$
L_f = \mu_m (-\delta d + 2K) + T_f. \quad \text{(22)}$$

The second term arises from the dissipative term of the microstructure degrees of freedom $L_v V = -\gamma_1 \dot{V}$. The third term gives the cross-correlation that arises from the coupling terms $L_{f} V = \gamma_2 \dot{V}$ and $L_{f} V = \gamma_3 \dot{V}$.

We shall also find it useful to express these thermal fluctuations using $g_{\text{thm}}$ which we take to be independent of $F_{\text{thm}}$ with covariance

$$
\langle g_{\text{thm}}(t) g_{\text{thm}}(s)^T \rangle = -2k_B T \gamma L \delta(t-s). \quad \text{(23)}$$

We can then express the thermal fluctuations for the hydrodynamics as $f_{\text{thm}} = g_{\text{thm}} - \Lambda [F_{\text{thm}}]$ to obtain the needed correlations.

Here, we have used that the fluid-structure coupling operators are adjoints $\Lambda = \Gamma^T$ in the sense $\int_S \langle \Lambda U, u^\flat \rangle dA = \langle U, \Gamma u^\flat \rangle$ for all choices of $U$ and $u^\flat$ [9, 67]. We discuss choices for the coupling operators and the adjoint conditions in more detail in Section 2.5. For the stochastic driving terms of equations 5– 8 and 18– 20, our SELM approach ensures when the system is at thermodynamic equilibrium that the Gibbs-Boltzmann distribution is invariant under the stochastic dynamics and satisfies detailed-balance [9, 63, 71]. The stochastic equations 5– 8 should be interpreted in the sense of Ito Calculus [28, 54].

We remark that the covariance operators in equations 18–20 are to be interpreted in the weak sense [9, 10, 48]. Consider

$$
\tilde{u}(x) = \int \alpha(z, r, x) \tilde{f}_{\text{thm}}(z, r) dr \text{ and } \tilde{u}(x) = \int \alpha(q, r) \tilde{f}_{\text{thm}}(q, r) dq \quad \text{and } U = \int A(r) F_{\text{thm}}(r) dr \text{ and } U = \int A(q) F_{\text{thm}}(q) dq.
$$

The $\alpha$, $\tilde{\alpha}$, $A$, $\tilde{A}$ are smooth fields and vectors playing the role of test functions. [48]. The asso-
ciated covariances are

\[ \langle u(x) \tilde{u}(y)^T \rangle = \] (24) \[ \langle \Gamma v, F \rangle = \sum_i \langle \Gamma v \rangle_i \cdot [F]_i \] (28)

\[
- \int \int \int \alpha(z,r,x)^T 2k_BT \mathcal{L}_{ff} \tilde{\alpha}(w,q,y) dw dz \cdot \\
\delta(r-q) dr dq.
\]

Here, the differential operator \( \mathcal{L}_{ff} \) acts in the parameter \( w \). We also have the covariances

\[ \langle U \tilde{U}^T \rangle = \int \int 2k_BT \gamma A(r)^T \tilde{A}(q) \delta(r-q) dr dq, \] (25)

\[ \langle U \tilde{u}(y)^T \rangle = - \int \int 2k_BT \gamma \mathcal{A}(r)^T \tilde{\mathcal{A}}(w,q,y) \cdot \\
\delta(r-q) dw dr dq. \] (26)

Here, the operator \( \Gamma \) acts in the parameter \( w \). Additional discussions on how to interpret these operator covariances also can be found in [9, 10].

Here, the differential operator \( \mathcal{L}_{ff} \) acts in the parameter \( w \). We also have the covariances

\[ \langle U \tilde{U}^T \rangle = \int \int 2k_BT \gamma A(r)^T \tilde{A}(q) \delta(r-q) dr dq, \] (25)

\[ \langle U \tilde{u}(y)^T \rangle = - \int \int 2k_BT \gamma \mathcal{A}(r)^T \tilde{\mathcal{A}}(w,q,y) \cdot \\
\delta(r-q) dw dr dq. \] (26)

Here, the operator \( \Gamma \) acts in the parameter \( w \). Additional discussions on how to interpret these operator covariances also can be found in [9, 10].

\[ \langle \Gamma v, F \rangle = \langle v, \Lambda F \rangle, \] (27)

where the inner-products are defined as

\[ \langle v, \Lambda F \rangle = \int_\Omega v(x) \cdot (\Lambda F)(x) dx. \] (29)

The \( \mathbf{X} \) denotes the collective vector of particle locations. The \( i \)th particle is at location \( [\mathbf{X}]_i \). The \( \cdot \) denotes the vector dot-product induced by the ambient physical space. For vector fields on the surface \( \mathbf{v} \) and \( \mathbf{u} \) we have \( \mathbf{v}(x) \cdot \mathbf{u}(x) = \langle \mathbf{v}(x), \mathbf{v}(x) \rangle_g = v^a g_{ab} u^b \). We use the notation \( \Gamma^T = \Lambda \) to denote the adjoint condition 27.

In the setting of curved surfaces the coupling operators \( \Gamma \) and \( \Lambda \) must be chosen carefully so that velocity averaging occurs over the surface and so that force densities provide well-controlled components in the directions of the normal and tangent space of the surface. We develop operators of the form

\[ \Gamma v = \int_\Omega \mathbf{W} [v](y) dy \] (30)

\[ \Lambda F = \mathbf{W}^* [F](x). \] (31)

We use a tensor \( \mathbf{W} \) to sample and weight values on the surface to perform velocity averaging. We use the adjoint tensor \( \mathbf{W}^* \) to produce a corresponding force density field on the surface compatible with our adjoint conditions 27.

For the curved surface, we use the geometrically motivated forms

\[ \mathbf{W} [v] = \sum_i w_{i,\alpha} [v] \partial_{x^\alpha} |_{\mathbf{X}[i]} \] (32)

\[ \mathbf{W}^* [F] = \sum_i \left( w_{i,\alpha} \right)^\gamma F^\alpha \partial_{x^\gamma}. \] (33)

The sum \( i \) runs over the particle indices and the \( \partial_{x^\alpha} |_{\mathbf{X}[i]} \) denotes the tangent basis vector in direction \( \alpha \) at location \( \mathbf{X}[i] \). We refer to the vector field \( w_{i,\alpha} \) as the probing vector field for direction \( \alpha \).

On the sphere, we have a lot of symmetry that can be utilized. For this case with the spherical
coordinates \((\theta, \phi)\), we take our probing vector fields to be of the form \(w^{[i],\theta} = \psi (x - X^{[i]}) \partial_\theta\) and \(w^{[i],\phi} = (\psi (x - X^{[i]}) / \cos(\theta)) \partial_\phi\), where \(\psi (r) = C \exp(-r^2/2\sigma^2)\). In practice, we truncate at length \(r_0 = 4\sigma\) and use \(C\) to normalize so that \(\psi (r)\) averages to one on the surface.

### 2.6. Overdamped Limit

In physical regimes corresponding to small Reynolds numbers \(Re \ll 1\) we can consider the overdamped limit of the the fluctuating hydrodynamic equations 5–7 \([9,71]\). In this regime the limiting fluctuating hydrodynamic equations can be expressed as

\[
\begin{align*}
\frac{dX}{dt} &= MF + k_BT \nabla \cdot M + F_{thm} \quad (34) \\
(F_{thm}(s)F_{thm}(t)^T) &= 2k_BT M \delta(t-s)
\end{align*}
\]

where

\[
M = \gamma^{-1}I + \Gamma \mathcal{S} \Lambda. \quad (35)
\]

Here, we take the overdamped limit while retaining the finite slip term \(-\gamma (\nabla - \Gamma v^b)\) in equation 5 and 7 resulting in the term \(\gamma^{-1}I\) in equation 35 \([71]\). In the strong-coupling limit \(\gamma \to \infty\) the mobility simplifies to

\[
M = \Gamma \mathcal{S} \Lambda. \quad (36)
\]

The velocity averaging operator \(\Gamma\) and force spreading operator \(\Lambda\) are as discussed in Section 2.5. The \(\mathcal{S}\) denotes the solution operator giving \(v^b = \mathcal{S} b^b\) for the following hydrodynamic equations

\[
(\mu_m (-\delta d + 2K) + T_f) v^b = -b^b \quad (37)
\]

\[
-\delta v^b = 0. \quad (38)
\]

The \(T_f\) corresponds to the traction stresses with the surrounding bulk fluid as discussed in Section 2.2. The \(v^b = \mathcal{S} \Phi F\) corresponds to the case with \(b = \Lambda [F]\) where in practice we will typically have \(F = -\nabla \phi\).

To simply expressions we have also taken here for equation 34 the limit of no-slip between the microstructure and the fluid which corresponds formally to \(\gamma/m \to \infty\). This yields \(dX/dt = \Gamma v^b\) throughout. Putting this together we arrive at the first term in equation 34.

For the full stochastic system, we perform related detailed dimensional analysis and asymptotics in \([9,67,71]\). In this physical regime, when equation 34 is given the Ito interpretation, the thermal fluctuations involve configuration dependent correlations resulting in the spontaneous drift term \(k_BT \nabla \cdot M\) \([9,28,54,71]\). Additional analysis of the Stochastic Eulerian Lagrangian Methods (SELM) and related regimes can be found in \([9,67,71]\).

### 2.7. Formulating Fluctuating Hydrodynamics on Surfaces using Vector Potentials \(\Phi\)

The hydrodynamic responses both in the inertial fluctuating hydrodynamics of equation 5 and in the overdamped regime of equation 37 require computation of the operator \(\mathcal{L}_f\) of equation 22. Since the hydrodynamic fields are incompressible, we can use the Hodge decomposition of the fluid velocity \(v^b = \delta \Phi + \delta \Psi + h\) where \(\Delta_H = \delta \delta + \delta \delta\) is the Hodge Laplacian and \(h\) is harmonic in the sense \(\Delta_H h = 0\). Using this in the case of spherical geometry with velocity tangential to the surface, we can express any incompressible flow as \(v^b = -\star d\Phi\) \([67]\). This allows us to reformulate the inertial hydrodynamics of equation 5 in terms of \(\Phi\) as

\[
\rho \Delta_{LB} \frac{\partial \Phi(t)}{\partial t} = (\star d) \mathcal{L}_f (\star d) - \star d \delta \Phi + \mu_m \Delta_{LB}^2 \Phi - 2 \star d \mu_m K (\star d) \Phi - \delta (d \mu K (\star d) \Phi) - \star d \delta \Phi + \star d (\Delta_{LB} (\mathcal{L}_f (\star \Phi) + c) - c) \Phi. \quad (39)
\]

The \(b^b = -\star dc\) denotes all of the forces acting on the fluid. The \(\Delta_{LB} = -\delta d\) denotes the Laplace-Beltrami operator \([1]\). The \(T_f\) denotes
The generalized curl commutes with the operator \( L \) which can be reformulated as \( \Delta_{LB} \). This yields for the steady-state hydrodynamics

\[
\Delta_{LB} \Phi = -c. \tag{40}
\]

Central to both the inertial fluctuating hydrodynamics and steady-state regimes is computation of the action of the operator \( \hat{L}_f \Phi \) which captures the hydrodynamic responses of the system. We expand \( \Phi \) using spherical harmonics to represent the vector potential as \( \Phi = \sum_s \Phi_s = \sum_s a_s Y_s \) where \( \Phi_s = a_s Y_s \) and \( s = (\ell, m) \) denotes the spherical harmonics index, see Appendix C. For the spherical geometry, we can express solutions using that the spherical harmonics are eigenfunctions of the Laplace-Beltrami operator \([32, 67]\).

The action of the operator can be expressed as

\[
\hat{L}_f \Phi_s = \Delta_{LB}^{-1}(- \star d) L_f (- \star d) \Phi_s = L_s a_s Y_s, \tag{41}
\]

where

\[
L_s = \frac{\mu_m}{R^2} \left[ 2 - \ell (\ell + 1) + \frac{R}{L^+} (\ell + 2) - \frac{R}{L^-} (\ell - 1) \right], \tag{42}
\]

with \( L^\pm = \mu_m/\mu \). In the case with \( \mu = \mu_f \) this can be simplified to

\[
L_s = \frac{\mu_m}{R^2} \left[ 2 - \ell (\ell + 1) - \frac{R}{L} \left( \ell + \frac{1}{2} \right) \right] \tag{43}
\]

where \( L = \mu_m/(\mu_+ + \mu) = \mu_m/2 \mu_f \). We see from this that the hydrodynamic flow on the sphere is characterized by the non-dimensional parameter \( \Pi_1 = L/R \), where \( L = \mu_m/2 \mu_f \) is the Saffman-Delbruck length-scale \([65]\) and \( R \) the radius of the sphere.

In the overdamped regime to obtain the steady-state hydrodynamics, we can solve the hydrodynamic equations to obtain directly the spherical harmonics coefficients as

\[
a_s = L_s^{-1} c_s. \tag{44}
\]

For the inertial fluctuating hydrodynamics of equation 5 and equation 39, we can express the dynamics in terms of the spherical harmonics coefficients \( a_s \) as

\[
\frac{\partial a_s(t)}{\partial t} = \rho^{-1} L_s a_s(t) + \rho^{-1} \bar{c}_s(t) + g_s(t) + h_s(t), \tag{45}
\]

where \( c_s = \bar{c}_s + g_s + h_s \). The stochastic driving terms \( \{g_s\} \) are associated with the hydrodynamics and are complex-valued Gaussian processes \( \delta \)-correlated in time with mean zero and covariance

\[
\langle g_s(t) \overline{g_s(r)} \rangle = -2k_B T \rho^{-2} |\lambda_s|^{-1} L_s \delta_{ss'} \delta(t - r). \tag{46}
\]

The stochastic driving terms \( \{h_s\} \) are associated with the fluid-structure coupling discussed in Section 2.5 that contributes dissipation to the system.
through $\tilde{c}$, see equation 5. The $h_s$ are complex-valued Gaussian processes having correlations with the microstructure stochastic dynamics in equation 7 which we can express as

$$h_s(t) = -\rho^{-1} \langle \Delta^{-1}_{LB}(-\ast \mathbf{d}) \Lambda[F_{thm}(t)](\mathbf{x}), Y_s(\mathbf{x}) \rangle_{L^2}.$$  \hspace{1cm} (47)

The $\lambda_s = -\ell(\ell+1)/R^2$ denotes the $s^{th}$ eigenvalue of the Laplace-Beltrami operator $\Delta_{LB} = -\delta \mathbf{d}$. The $\delta_{a,b}$ denotes the Kronecker $\delta$-function which is zero for $a \neq b$ and one for $a = b$.

The real-space fluctuating velocity field $\mathbf{v}^\circ$ can be recovered using $\mathbf{v} = (-\ast \mathbf{d}\Phi)^\circ$. This is derived from the stochastic force $F_{thm}$ acting on microstructures in equation 7. Together, these stochastic driving terms give in real-space $f_{thm}^\circ = -\ast \mathbf{d} \sum_s \rho(g_s + h_s)Y_s = g_{thm}^\circ - \Lambda[F_{thm}]$ which satisfy equations 18–20.

In summary, the equations 45–47 give a formulation of the SELM fluctuating hydrodynamics incorporating fluid-structure interactions in terms of the vector potential $\Phi$. The use of such Hodge decompositions and vector potentials is particularly convenient when representing velocity fields on surfaces. We give additional details on the derivation of these results in Appendix A.

3. Stochastic Numerical Methods

We develop numerical methods for the drift-diffusion dynamics of microstructures both in the inertial and over-damped regimes. To handle the incompressibility constraint for the surface hydrodynamics we make use of our generalized vector potential formulation discussed in Section 2.7.

3.1. Inertial Regime

In the inertial regime, we formulate the time-step integration of the fluctuating hydrodynamics of equation 5 in terms of stochastic dynamics of the vector potential $\Phi$ in equation 39 and 45. We use the time-step update in terms of the spherical harmonics coefficients of $\Phi$,

$$a_s^{n+1} = a_s^n + \Delta t\rho^{-1}L_s a_s^n + \Delta t\rho^{-1}c_s^n + g_s^n + h_s^n. \hspace{1cm} (48)$$

For the microstructure dynamics, we use the update

$$\begin{align*}
V^{n+1/2} &= V^n - \frac{\Delta t}{2m} \gamma(V^n - \Gamma^n V^n) + \frac{\Delta t}{2m} F_{thm}^n \\
X^{n+1} &= X^n + \Delta t V^{n+1/2} \\
V^{n+1} &= V^n - \frac{\Delta t}{2m} \gamma(V^n - \Gamma^n V^n) + \frac{\Delta t}{2m} F_{thm}^n \\
&\quad + \frac{\Delta t}{2m} F^{n+1}.
\end{align*} \hspace{1cm} (49)$$

We have $\Phi^n = \sum_s a_s^n Y_s$ with the fluid velocity obtained by $\mathbf{v}^n = (-\ast \mathbf{d}\Phi)^\circ$. Similarly, from the fluid-structure coupling $c^n = \Lambda^n[\gamma(V^n - \Gamma^n V^n)]$ we obtain the terms $c_s^n = \langle \Delta^{-1}_{LB}(-\ast \mathbf{d})c^n, Y_s(\mathbf{x}) \rangle_{L^2}$.

We account for thermal fluctuations of the microstructures over the time-step through the Gaussian term $F_{thm}^n$. This has mean zero and covariance

$$\langle F_{thm}^n F_{thm}^m \rangle = 2k_B T \gamma \Delta t^{-1} \delta_{m,n}. \hspace{1cm} (50)$$

The $g_s^n$ are complex-valued Gaussians with mean zero and covariance

$$\langle g_s^n g_{s'}^{n'} \rangle = -2\rho^{-1}L_s C_{ss'} \Delta t \delta_{nm}. \hspace{1cm} (51)$$

The $L_s$ are given by equation 43 or 42 and $C_{ss'}$ are the equilibrium fluctuations of the modes $a_s$ given by

$$C_{ss'} = \langle a_s a_{s'} \rangle = \rho^{-1} k_B T |\lambda_s|^{-1} \delta_{s',\bar{s}}. \hspace{1cm} (52)$$

The $\lambda_s = -\ell(\ell+1)/R^2$ are the eigenvalues of the Laplace-Beltrami operator $\Delta_{LB} = -\delta \mathbf{d}$ on the surface. For $s = (\ell, m)$ the $\bar{s} = (\ell, -m)$.

The $h_s^n$ are complex-valued Gaussians which we generate from $F_{thm}^n$ by

$$h_s^n = -\rho^{-1} \Delta t \langle \Delta^{-1}_{LB}(-\ast \mathbf{d}) \Lambda^n[F_{thm}^n](\mathbf{x}), Y_s(\mathbf{x}) \rangle_{L^2}. \hspace{1cm} (53)$$
This ensures proper correlations in the system between the microstructure and the fluctuating hydrodynamics. We note that in our derivation of $F_{thm}$ there were negative cross correlations with the fluid which we capture in our numerical methods consistent with equation 20. These cross-correlations play the important role of ensuring momentum conservation. They account for the spontaneous fluctuations that exchange momentum back and forth between the fluid and microstructures.

The integrator approach we have introduced works well when the time-scales are comparable between the microstructure evolution and hydrodynamics. When there is a disparity in these time-scales, stiff stochastic numerical time-step integrators can also be developed using our vector potential formulation. For instance, we can develop exponential time-stepping approaches similar to our prior works [8,76]. As an alternative, an asymptotic analysis of the stochastic dynamics of the fluid-structure system can also be performed as in [71]. This can be used to formulate equations in over-damped regimes and develop numerical methods for the drift-diffusion dynamics of the microstructures [71].

### 3.2. Overdamped Regime

For the overdamped regime, we develop numerical methods for simulations based on a stochastic variant of the Velocity-Verlet method [25, 73]. We account for the thermal drift term in the stochastic dynamics using an approach related to methods proposed in [18,23]. We update the collective configuration $X$ of the particles or microstructures of the system using

$$V^n = M(X^n)F^n + Q(X^n)\xi^n$$

$$\tilde{X}^{n+1} = X^n + V^n \Delta t$$

$$\tilde{V}^{n+1} = M(\tilde{X}^{n+1})\tilde{F}^{n+1} + Q(X^n)\xi^n$$

$$X^{n+1} = \frac{1}{2} \left( V^n + \tilde{V}^{n+1} \right) \Delta t$$

$$+ k_B T \left( \frac{\Delta t}{\delta} \right) \left( \mathbb{E} \left( M \left( X^n + \delta \xi \right) - M \left( X^n \right) \right) \right)_{\mathcal{N}} .$$

(54)

The thermal fluctuations have correlations generated by $Q(X^n)$ where $Q(X^n)Q(X^n)^T = 2k_B T M(X^n)/\Delta t$ with $\xi$ a standard Gaussian random variate with independent components having mean zero and variance one. The thermal drift $k_B TV \cdot M$ is approximated by numerically estimating an average by $\langle Z \rangle _\mathcal{N} = 1/N \sum_{k=1}^N Z^{[k]}$. For the random variable $Z$, the $Z^{[k]}$ denotes one of the $N$ independent samples. This probabilistic estimator provides an estimator for the divergence since for the random variables $p$ and $q$ satisfying $\langle p_i q_j \rangle = \delta_{ij}$ we have

$$\lim_{\delta \to 0} \delta^{-1} \langle (M (X + \delta p) - M(X)) q \rangle = \nabla \cdot M.$$

(55)

This follows an approach advocated by [18] and the validity follows readily from Taylor expansion of $M$ in $X$ [29].

The stochastic Velocity-Verlet scheme in equation 54 can be viewed in stages as follows. The $\tilde{X}^{n+1}$ gives the predictor part of the update of the configuration that is used to evaluate the force $\tilde{F}^{n+1}$ and mobility $M(\tilde{X}^{n+1})$. The $X^{n+1}$ gives the corrector part for the update of the configuration which makes use of the predictor data and additional contributions from the thermal drift term.

### 3.2.1. Generating Stochastic Forces from the Mobility Tensor

During numerical time-step integration of the drift-diffusion dynamics by equation 54, we
must generate the stochastic driving term $\mathbf{h}^n = Q(X^n)\xi^n$. A common way to do this is to determine from the mobility the square-root factor $Q$ satisfying $Q(X^n)Q(X^n)^T = 2k_B TM$. Cholesky factorization provides a convenient method for this for symmetric positive definite matrices [72]. However, in the current formulation this present challenges given that the mobility tensor for the surface hydrodynamics is singular since it only depends on the tangential component of the force, see equation 39. One may be tempted to work only with the surface coordinates. For the sphere, this presents challenges since there is no global coordinate chart for such topologies [67]. We have chosen instead to work in the embedding space resulting in a mobility tensor representation that is only positive semi-definite precluding the direct use of Cholesky factorization.

We remedy this situation by adding a block diagonal tensor to our grand mobility tensor of equation 36. We construct using rank-one stabalizations modified self-mobility tensor blocks $\tilde{M}_{ii} = M_{ii} + \alpha \mathbf{n}_i \mathbf{n}_i^T$, where $\alpha$ is any positive weight. The $\mathbf{n}_i$ denotes the normal vector on the sphere at the location of $X_i$. With this modified mobility tensor, we can now use Cholesky factorization to obtain $\tilde{Q}$ satisfying $\tilde{Q}(X^n)\tilde{Q}(X^n)^T = 2k_B TM$.

This is useful since the stabalizations constructed are orthogonal to the tangent directions of the surface and would only effect mobility responses in the dynamics of the particles in the directions normal to the surface. As a consequence, we can generate the needed tangential stochastic forces using $\tilde{\mathbf{h}} = \varphi \tilde{\mathbf{h}}^n$ where $\tilde{\mathbf{h}}^n = Q(X^n)\xi^n$ with $\xi^n$ a Gaussian vector with independent components having mean zero and variance one. The $\varphi$ here denotes projection of the stochastic driving vector $\tilde{\mathbf{h}}^n$ to the tangent space of the surface. In this manner, we obtain the needed stochastic terms to account for the thermal fluctuations in the drift-diffusion dynamics on the surface for the microstructures.

### 3.3. Computing Hydrodynamic Forces and Responses

To solve for the fluid velocity, we represent the force density term as $c = -\star \mathbf{db}^s$ with expansion $c = \sum_s c_s Y_s$. We compute this in practice by using the spherical harmonics representation of $\mathbf{b}$ obtained by $[b[a], Y_s]$ where the inner-product is approximated numerically by using Lebedev quadrature [44,45]. The $\mathbf{b} = b[a] \partial_{z^s}$ gives the representation of the force density $\mathbf{b}$ in the ambient physical space with coordinates $z^s$. We then compute $c = -\star \mathbf{db}^s = \sum_s (-\star \mathbf{d}) b_s$ using the finite spherical harmonics expansion of $\mathbf{b} = \sum_s \mathbf{b}_s$ with $\mathbf{b}_s$ denoting the term of the expansion associated with index $s$. We compute $c_s$ using $c_s = \langle c, Y_s \rangle$ where the inner-product is approximated numerically using Lebedev quadrature [44,45]. From the solution coefficients $a_s$, we obtain the fluid velocity on the surface from $\mathbf{v} = \sum_s a_s (-\star \mathbf{d} Y_s)^s$.

In practice, we numerically approximate $L^2$ inner-products by using Lebedev quadratures on the spherical surface [44,45,67]. We use $\langle u, v \rangle = \langle u, v \rangle_Q = \sum w_i u(x_i) v(x_i)$, where $\langle u, v \rangle_Q$ denotes the quadrature computed inner-product with $w_i$ the weights and $x_i$ the nodes [44,45,67]. This provides a finite spherical harmonics expansion of $-\star \mathbf{db}$. While other quadrature approaches could be used such as latitude and longitude sampling, the Lebedev quadrature nodes have octahedral symmetry and provide a better distribution of sampling nodes on the spherical surface [32,67].

### 4. Applications

We discuss a few applications of our introduce fluctuating hydrodynamics computational methods for investigating phenomena within curved fluid interfaces. We first discuss the hydrodynamic relaxation of fluctuating fluids and characterize scalings of the velocity autocorrelation function. We find different scalings can emerge de-
pending on the physical regimes associated with the interface geometry, surface viscosity, and bulk viscosity. We then investigate the mobilities associated with microstructures embedded within the interfaces in the quasi-steady regime. We further demonstrate the computational methods by studying the collective diffusion of particles embedded within curved fluid interfaces highlighting the roles played by the hydrodynamic coupling.

4.1. Autocorrelations of the Surface Fluctuating Hydrodynamics

We investigate the autocorrelation of the fluid velocity of interfacial fluctuating hydrodynamics introduced in equation 5. We find the velocity autocorrelations can exhibit power-law decay with scalings $\tau^{-1}$ and $\tau^{-2}$ depending on the physical regime. We also find in some regimes a plateau behavior can arise. This differs significantly from bulk fluctuating hydrodynamics that exhibits a characteristic $\tau^{-3/2}$ power-law decay [7, 8].

Interfacial fluctuating hydrodynamics involves both dissipation from the propagation of shearing motions within the interfacial fluid surface and from traction coupling with the bulk surrounding fluid. This results in two important time-scales. The first is the time-scale for shear stresses to propagate over the entire spherical surface $\tau_f = R^2/\mu_m$. The second is the timescale on which rigid-body rotation of the entire spherical interface dissipates energy significantly to the bulk surrounding fluid $\tau_r = RL/\mu_m$.

![Surface Fluctuating Hydrodynamics: Velocity of Spontaneous Flows](image)

**Figure 2:** Surface Fluctuating Hydrodynamics and Velocity of Spontaneous Flows. We show a few samples of the fluid velocity of the surface fluctuating hydrodynamics. We emphasize these results have an introduced correlation length-scale by use of a finite spherical harmonics expansion with modes up to degree $N = 20$. In the drift-diffusion dynamics of microstructures, similar correlations arise from the averaging operator $\Gamma$. The surface fluctuating hydrodynamics incorporates the dissipation from both the interfacial shear viscosity and the traction stresses with the inner and outer bulk surrounding fluids using equation 22. The incompressibility of the fluid and the spherical topology induces long-range correlated structures that manifest as recirculation patterns on the surface.

We explore these contributions to the velocity autocorrelations by varying the ratio $\tau_f/\tau_r = R/L$ involving the sphere radius $R$ to the Saffman-Delbruck length $L$. We show our results in Figure 3. We take as default parameter values $\rho = 1$, $\mu_m = 1$, $K_BT = 1$, $R = 1$, $L = 1$, and $\ell \leq N = \ell_*= 50$. We give details on our derivations analyzing these autocorrelations in Appendix B.

The velocity autocorrelations of the surface
fluctuating hydrodynamics can be expressed using an expansion in spherical harmonics as

\[
\langle v_\phi(0) v_\phi(t) \rangle = \sum_s \exp(tL_s) \frac{k_B T}{|g| \ell \rho (\ell + 1)} \left| \frac{\partial Y_s}{\partial \theta} \right|^2 \approx C \frac{k_B T}{|g| \rho} \sum_\ell \left( \ell + \frac{1}{2} \right) \exp(tL_\ell).
\]

The \(v_\phi\) denotes the \(\phi\)-directional component of the velocity, the \(Y_s\) denotes the spherical harmonic with mode \(s = (\ell, m)\), the metric factor on the sphere is \(|g| = R^2\). We also use that the velocity is isotropic and that \(\langle a_\phi^2 \rangle = k_B T R^2 / \rho (\ell + 1)\) and \(\langle a_\phi(0) a_\phi(t) \rangle = \langle a_\phi^2 \rangle \exp(tL_s)\), where \(L_s\) is given in equation 43. We derive scaling laws for different physical regimes using equation 56. We remark that all of our results use a truncated expansion with modes up to degree \(N = 50\). This introduces a regularization length-scale similar to our immersed boundary coupling approaches for determining responses of particles and microstructures. Details of our derivations can be found in Appendix B.

When \(R/L \ll 1\), we find the velocity correlations exhibit an initial decay to a power-law regime with scaling \(\tau^{-1}\) on time-scales \(\tau \ll \tau_f\). This is followed by a plateau regime that persists from \(\tau_f \ll \tau \ll \tau_r\). This eventually gives way to exponential decay for \(\tau \gg \tau_r\). The initial \(\tau^{-1}\) power law decay is associated with the propagation of shear stresses over the interface with negligible dissipation to the bulk. This persists until time-scale \(\tau_f\), see Figure 3.

A plateau arises in the case when \(\tau_r \gg \tau_f\) where there is an intermediate regime that exists. In the intermediate plateau regime the shear stress has already propagated to the entire surface, but the dissipation into the bulk fluid of the rigid-body rotational motion has not yet become significant. On time-scales \(\tau \gg \tau_r\), dissipation into the bulk fluid dominates through the rotational motions and gives exponential decay. As the \(R/L\) increases, the plateau regime disappears when \(\tau_r \sim \tau_f\), as seen when moving left to right in Figure 3.

In the \(R/L \gg 1\) regime, the time-scales for decay from intra-interface shearing motions becomes reversed and large relative to the time-scale for decay from the coupling to the bulk fluid \(\tau_f \gg \tau_r\). This results in a new regime with power law scaling \(\tau^{-2}\) for time-scales \(\tau \ll \tau_r\). When \(\tau \gg \tau_f\) this gives way again to exponential decay from the rotational motions of the entire interface. The \(\tau^{-2}\) arises from simultaneous dissipation from the shearing motions within the interface and dissipation from coupling to the bulk fluid. We give more details and derivations of these power-laws and related time-scales in Appendix B.

Figure 3: Velocity Autocorrelations of Surface Fluctuating Hydrodynamics. For the interfacial fluctuating hydrodynamics introduced in equation 5 we show the temporal autocorrelation \(\phi(\tau) = \langle \mathbf{v}(0) \cdot \mathbf{v}(t) \rangle / \langle \mathbf{v}^2(0) \rangle\). The curves left to right have \(R = 10^\alpha\) with integer values in range \(\alpha \in [-4, 4]\). We see the velocity autocorrelation exhibits regimes with power-law decay \(\tau^\beta\) with \(\beta = -1, -2\) (dotted lines) and plateaus. The surface fluctuating hydrodynamics where sampled with truncated expansion with modes up to degree \(N = 50\). We derive these power-laws for surface fluctuating hydrodynamics in Appendix B.
4.2. Mobility Tensor for Interacting Particles and Microstructures

We compute numerically the mobility of equation 36 as \( \tilde{M}(X) = \Gamma \tilde{S} \Lambda \). We obtain a numerical solver \( \tilde{S} \) for the fluid velocity \( \tilde{v} = \tilde{S}[F] \) with force distribution \( F(x) = \Lambda[F](x) \) on the spherical surface using equation 40 and Lebedev quadratures [44,45,67].

From the symmetry of the sphere the mobility of \( N \) particles can be determined from the canonical two particle mobility tensor. The two particle mobility obtained from equation 36 can be expressed as

\[
M = \begin{bmatrix}
M_{11} & M_{12} \\
M_{21} & M_{22}
\end{bmatrix}
\tag{57}
\]

with

\[
\tilde{M}_{12} = \begin{bmatrix}
M_{\parallel\parallel} & M_{\parallel\perp} \\
M_{\perp\parallel} & M_{\perp\perp}
\end{bmatrix}
\tag{58}
\]

The \( M_{ii} = \Gamma_i \tilde{S} \Lambda_i \) where we use notation \( \Gamma_i \tilde{v} = \Gamma_i[X_i]v^\phi \) and \( \Lambda_j[F](x) = \Lambda[X_j][F](x) \). The \( M_{ii} \) denote the self-mobilities and can be computed numerically once and stored.

The \( \tilde{M}_{12} \) give for a force \( F \) on the first particle the velocity response \( V \) at the second particle. We can express this as \( V = V_\parallel e_\parallel + V_\perp e_\perp \), where for the two particle displacement we split into the parallel \( \parallel \) and perpendicular \( \perp \) components. The \( V_\parallel = M_{\parallel\parallel} F_\parallel + M_{\parallel\perp} F_\perp \) and \( V_\perp = M_{\perp\parallel} F_\parallel + M_{\perp\perp} F_\perp \). Using the symmetry of the sphere we can tabulate numerically the two particle mobility tensor by using a canonical configuration of the two particles. We rotate the sphere so that the first particle is always situated at the north pole. We then align the geodesic displacement between the two particles in the \( xy \) -plane with tangent along the positive \( x \)-axis. We denote the rotation operation by \( R^T \) that moves any two particles into this canonical configuration \( \tilde{X} = R^T X \). We can convert our canonical tabulated two-particle mobilities to the specific mobility of two particles by \( M_{12} = R \tilde{M}_{12} R^T \).

We obtain the grand-mobility tensor \( M \) for \( n \) interacting particles by summing over all pairs of particles the two particle mobility tensors. We show the components of the two-particle mobility \( \tilde{M}_{12} \) when \( L/R = 0.13, 0.65, 6.5, 52 \) in Figure 4 and 5.

![Mobility Response](image)

**Figure 4:** Mobility Response \( V_\parallel = M_{\parallel\parallel} F_\parallel \). We show the mobility response component when a unit force is applied to the first particle in the direction parallel to the separation of the two particles. We scale the mobility by \( M_0 = 641 \) corresponding to a pure rotational response. The response \( V_\perp = M_{\perp\parallel} F_\parallel \) was found to be negligible with a magnitude smaller than 0.01% of \( M_0 \).
Figure 5: Mobility Response $V_\perp = M_\perp F_\perp$. We show the mobility response component when a unit force is applied to the first particle in the direction perpendicular to the separation of the two particles. We scale the mobility by $M_0 = 641$ corresponding to a pure rotational response. The response $V_\parallel = M_\parallel F_\perp$ was found to be negligible with a magnitude smaller than 0.01% of $M_0$.

4.3. Equilibrium Fluctuations

We validate our stochastic numerical methods by studying the drift-diffusion dynamics of interacting particles. A strong indication of the validity the methods is provided by consider how particles diffuse over time when subject to a conservative force. This requires the stochastic methods to capture both the drift dynamics accurately while also handling appropriately the thermal fluctuations of the system. From equilibrium statistical mechanics a configuration should have a probability distribution $\rho(X)$ of the Gibbs-Boltzmann form $[15, 63]$

$$\rho(X) = \frac{1}{Z} \exp \left[-\phi(X)/k_B T\right]. \quad (59)$$

The $Z$ denotes the partition function and $k_B T$ denotes the thermal energy of the system $[63]$.

We consider the drift-diffusion dynamics of two hydrodynamically coupled particles having the non-linear Lennard-Jones interaction

$$\phi(r) = 4\epsilon \left( \left( \frac{\sigma}{r} \right)^{12} - \left( \frac{\sigma}{r} \right)^6 \right). \quad (60)$$

The $r$ denotes the distance between the two particles. The $\sigma$ denotes the length-scale characterizing the radius of the particles. We find our stochastic numerical methods provide for the drift-diffusion dynamics very good agreement with the distribution predicted from equilibrium statistics mechanics from equation 59. We show these results for a few choices of $\sigma$ in Figure 6.

For parameters, we take throughout the thermal energy $k_B T = 2.48$ amu-mm$^2$/ps$^2$, the strength of the potential $\epsilon = 10 K_B T$, viscosity ratio $L/R = 0.65$. We use for the stochastic integrator in equation 54 the time-steps $\Delta t = 1.3 \times 10^5$ ps and drift estimator $\delta = 10^{-1}$, $\bar{N} = 10$. 

Figure 6: Gibbs-Boltzmann Distribution. We compute using our stochastic numerical methods of equation 54 the equilibrium fluctuations associated with the drift-diffusion motions of hydrodynamically coupled particles having Lennard-Jones interactions of equation 60. We test interactions for a few choices of $\sigma$ and find good agreement between our numerical results and the Gibbs-Boltzmann distribution predicted by equation 59.
4.4. Collective Diffusivity

Motivated by proteins in lipid bilayer membranes and recent results for synthetic colloidal systems [14, 17, 27, 52], we consider diffusion limited interactions by particles that interact within a curved fluid interface. We investigate the case with and without hydrodynamic coupling on the collective diffusivity and how this influences the time for particles to come into near contact.

**Figure 7:** Two Particle Diffusion. We show a schematic of our study of the distribution of times for two diffusing particles to come into contact. The two particles start respectively at the north and south poles (left). In the cases with and without hydrodynamic coupling, we investigate the distribution of times for when the particles come into diffusive contact (right).

We consider two particles initially at anti-podal locations on the sphere (north and south pole) and the amount of time it takes for them to come into contact with each other. We consider the distribution for this meeting time in the case of hydrodynamic coupling with mobility $M$ as in Section 4.1 and in the case without hydrodynamics with a local drag having mobility response $M = -\gamma L$. We report these results with and without hydrodynamic interactions in Figure 8. We use in our studies the parameter values in Table 1.

**Table 1:** Parameters used for the pair diffusivity study and simulations. We use SI units of atomic-mass-units (u), nanometers (nm), and picoseconds (ps).

We find in both cases that the meeting times remain on average on the same order of magnitude. However, the hydrodynamic coupling introduces significantly more variation in the meeting-time distribution producing a long-tail, see Figure 8. For systems where diffusive kinetics are important, we see the hydrodynamic coupling can significantly influence the distribution of encounters between particles.

**Figure 8:** Two Particle Pair-Meeting Time Distribution. For two particles starting at antipodal locations on the sphere, we show the distribution of times for the two particles to come into contact at critical distance $r \leq \tilde{r}_c = 3 R_{\text{particle}}$.

5. Conclusions

We have introduced general fluctuating hydrodynamics approaches for investigating the drift-
diffusion dynamics of particles and microstructures immersed within curved fluid interfaces. We introduced general computational methods for capturing fluid-structure interactions and collective dynamics driven by thermal fluctuations and active forces. We have used these approaches to investigate general phenomena associated with the autocorrelations of fluctuating hydrodynamics of interfaces finding there are different scalings that emerge in physical regimes depending on the interface geometry, surface viscosity, and bulk viscosities. We demonstrated how our methods can be used in practice to investigate the collective diffusion of particles and microstructures. These results show some of the rich phenomena that can arise for curved fluid interfaces that can be captured by our introduced fluctuating hydrodynamics approaches.

A. Derivations for Fluctuating Hydrodynamics on Surfaces using Vector Potentials \( \Phi \)

We discuss in more detail for fluctuating hydrodynamics on the surface derivation of the stochastic dynamics of the vector potential \( \Phi \). We express the dynamics in terms of complex-valued coefficients \( a_s \) of a spherical harmonics expansion as

\[
\rho \frac{\partial a_s}{\partial t} = L_s a_s + \bar{c}_s + g_s + h_s. \tag{61}
\]

The force expansion terms \( c^n_s \) are obtained from the real-space force \( f^n \) using equation 39. We obtain the stochastic driving fields \( g_s \) and \( h_s \) using a fluctuation-dissipation approach for the discretized system in a manner similar to our prior work \([8,9]\). We generate Gaussian driving terms with mean zero and covariance

\[
\langle g_s(t)g_s(r) \rangle = -2L_s C_{ss'} \delta(t-r). \tag{62}
\]

This requires determination of the covariance \( C_{ss'} \) for the equilibrium fluctuations of the modes \( a_s \).

The Gibbs-Boltzmann distribution \( \rho(\psi^s) = (1/Z) \exp(-E[\psi^s]/k_B T) \) for the equilibrium fluctuations depends on the kinetic energy of the fluid given by

\[
E[\psi^s] = \frac{\rho}{2} \int \langle \psi^s, \psi^s \rangle dA = \frac{\rho}{2} \int (\nabla \Phi, \nabla \Phi) dA = \frac{\rho}{2} \int (\Phi, \Delta \Phi) dA = \frac{\rho}{2} \int (\Phi, -\delta \Phi) dA = \frac{\rho}{2} \int \sum_{s,s'} a_s a_{s'} (\nabla Y_s, -\delta \nabla Y_{s'}) dA = \frac{\rho}{2} \sum_s |a_s|^2 L_s \|Y_s\|^2. \tag{63}
\]

The \( s = (\ell, m) \) where \( \ell \) is the degree and \( m \) the order. We used here the adjoint property of the co-differential \( \delta \) and the exterior derivative \( d \) \([1]\). The spherical harmonics modes \( Y_s \) have \( L^2 \)-norm given by \( \|Y_s\|^2 \) and are eignfunctions of the Laplace-Beltrami operator \(-\delta d Y_s = \lambda_s Y_s\) with eigenvalues \( \lambda_s = -\ell(\ell+1)/R^2\).

The quadratic form of the energy yields that the equilibrium fluctuations of the spherical harmonics coefficients are Gaussian with mean zero and covariance

\[
C_{ss'} = \langle a_s a_{s'} \rangle = \rho^{-1} k_B T |\lambda_s|^{-1} \delta_{s',\bar{s}}. \tag{64}
\]

The \( \delta_{s',\bar{s}} \) denotes the Kronecker \( \delta \)-function where we use notation \( \bar{s} = (\ell, -m) \) to denote the conjugate mode index. The spherical harmonics coefficients are complex-valued and the field \( \Phi \) must be real-valued. This requires for the coefficients \( a_s = a_s^* \).

We generate the stochastic driving terms using \( g_s = \eta_s + i \xi_s \) with \( i = \sqrt{-1} \) and \( \bar{g}_s = g_s \) throughout. From the conditions in equation 62, we have for \( m \neq 0 \) that

\[
\langle g_s g_{s'} \rangle = \langle g_s \bar{g}_s \rangle = \eta_s^2 + \xi_s^2 = -2L_s C_{s,s'}. \tag{65}
\]

\[
\langle g_s g_s \rangle = \langle \eta_s^2 - \xi_s^2 + 2i\eta_s \xi_s \rangle = 0. \tag{66}
\]

As a consequence, we must have that \( \langle \eta_s^2 \rangle = \langle \xi_s^2 \rangle \) and \( \langle \eta_s \xi_s \rangle = 0 \). This requires that \( \langle \eta_s^2 \rangle = \langle \xi_s^2 \rangle = -L_s C_{s,s'} \). The case with \( m = 0 \) is special since the mode is self-conjugate requiring

\[
\langle g_s g_{s'} \rangle = \langle g_s \bar{g}_s \rangle = \eta_s^2 + \xi_s^2 = -2L_s C_{s,s'}. \tag{67}
\]

\[
\langle g_s g_s \rangle = \langle \eta_s^2 - \xi_s^2 + 2i\eta_s \xi_s \rangle = -2L_s C_{s,s'}. \tag{68}
\]

As a consequence, we must have that \( \langle \xi_s^2 \rangle = 0 \) and \( \langle \eta_s^2 \rangle = -2L_s C_{s,s'} \).

Algorithmically, for modes \( s = (\ell, m) \) these results correspond to generating \( g_s \) for \( m > 0 \) by computing each of the components \( \eta_s \) and \( \xi_s \) as independent Gaussian random variates each having the covariance \(-L_s C_{s,s'}\), and for \( m < 0 \) setting \( g_s = \bar{g}_s \). The modes with \( m = 0 \) are special since they are self-conjugate and we have \( g_s = \bar{g}_s = \eta_s \) with covariance \(-2L_s C_{s,s'} \).
B. Derivation of Power-Laws for Fluctuating Hydrodynamics on a Sphere

We find the autocorrelation of the fluid velocity on the spherical interface has significantly different behaviors than bulk fluids. For bulk Newtonian fluids occupying a three dimensional volume the velocity autocorrelation function has a well-known characteristic long-tail with scaling $\tau^{-3/2}$. This is supported by continuum theory [7, 11], molecular simulations [3, 21], and experimental evidence [24, 57]. In contrast, we find from equation 5 and equation 44 the interfacial fluid velocity exhibits a few different intermediate power-law scalings and exponential decay depending on the considered parameter and temporal regimes, see Figure 3. As we shall show, this arises both from the spherical geometry and from the coupling between the two-dimensional hydrodynamics and bulk surrounding three-dimensional fluid which introduce additional time-scales.

The fluid velocity is obtained from $\Phi$ as $v = (-\star d\Phi)^s = v^\theta \partial_\theta + v^\phi \partial_\phi$ where $v^\theta = \sum_s \frac{\alpha_s}{\sqrt{gR}} \frac{\partial Y_s}{\partial \phi}$ and $v^\phi = - \sum_s \frac{\alpha_s}{\sqrt{gR}} \frac{\partial Y_s}{\partial \theta}$. The velocity autocorrelation function associated with fluctuating hydrodynamics on the sphere given in equation 5 can be expressed as

$$
\langle v^\theta(0)v^\theta(t) \rangle = \sum_s \sum_{s'} \frac{(a_s(0)a_{s'}(t))}{|g| R^2} \frac{\partial Y_s}{\partial \phi} \frac{\partial Y_{s'}}{\partial \phi}
\sum_s \exp(tL_s) \frac{k_BT}{|g| \rho \ell (\ell + 1)} \frac{\partial Y_s}{\partial \phi}^2
$$

$$
\langle v^\phi(0)v^\phi(t) \rangle = \sum_s \sum_{s'} \frac{(a_s(0)a_{s'}(t))}{|g| R^2} \frac{\partial Y_s}{\partial \phi} \frac{\partial Y_{s'}}{\partial \phi}
\sum_s \exp(tL_s) \frac{k_BT}{|g| \rho \ell (\ell + 1)} \frac{\partial Y_s}{\partial \theta}^2
$$

We consider the autocorrelation of the fluid at a point

$$
\langle v(x, 0) \cdot v(x, t) \rangle = \left\langle v^\theta(0)v^\theta(t) \right\rangle \|\partial_\theta\|^2 + \left\langle v^\phi(0)v^\phi(t) \right\rangle \|\partial_\phi\|^2.
$$

Given the $\delta$-spatial correlation of the fluctuating velocity field each of these series diverges in the limit $t \to 0$ when the full infinite expansion is taken. In practice in techniques such as the Stochastic Immersed Boundary Methods [8] the fluctuating velocity field is spatially averaged to model the dynamics of immersed particles and microstructures. This would result in fluid-structure interactions over the surface only having effectively a responses to fluid fluctuations above some critical length-scale (below some degree $\ell_*$) which is related to the object’s geometric size. We can obtain in practice a similar effect by working throughout with truncated series expansions with $\ell \leq \ell_* = 50$ [7].

We always consider fluctuations at a point $x_*$ on the equator for a given spherical coordinate chart which by symmetry yields

$$
\langle v(x_*, 0) \cdot v(x_*, t) \rangle = 2R^2 \left\langle v^\phi(0)v^\phi(t) \right\rangle
$$

and

$$
\left\langle v^\phi(0)v^\phi(t) \right\rangle = \sum_\ell \exp(tL_\ell) \frac{k_BT}{|g| \rho \ell (\ell + 1)}
\sum_{|m| \leq \ell} m^2 |Y_s|^2.
$$

We can express equation 69 as

For the spherical surface, we use that the metric $|g| = R^2$. We also use that $\left\langle a_s^2 \right\rangle = k_BT R^2 / \rho \ell (\ell + 1)$ and $\langle a_s(0)a_s(t) \rangle = \langle a_s^2 \rangle \exp(tL_s)$. We approximate these sums asymptotically to estimate significant time-scales governing different behaviors of the autocorrelation functions.
We have absorbed also the additional prefactor that we can treat the term \(|Y_s|^2 \sim C\). This gives

\[
\left\langle v^\phi(0)v^\phi(t) \right\rangle \approx C \sum_{|m| \leq \ell} m^2 \exp(tL_\ell) \sum_{\ell} \frac{k_B T}{|g| \rho \ell (\ell + 1)} \cdot C \sum_{|m| \leq \ell} m^2.
\]

We use that \(\sum_{|m| \leq \ell} m^2 = \ell(\ell+1)(2\ell+1)/3\). This very conveniently cancels the term \(\ell(\ell+1)\) in the denominator that arose from the eigenvalues of the Laplace-Beltrami operator discussed in Section 2.7. After some rearrangement, we have

\[
\left\langle v^\phi(0)v^\phi(t) \right\rangle \approx C \frac{k_B T}{|g| \rho} \sum_{\ell} \left( \ell + \frac{1}{2} \right) \exp(tL_\ell).
\]

We have absorbed also the additional prefactor constants into \(C\). The spherical motion corresponding to rigid-body rotation in the bulk fluid corresponds to the mode \(\ell = 1\). We see for \(L_\ell\) only the second term (traction stress term) persists in equation 43. This gives the decay time-scale \(\tau_r = 2RL/3\mu_m\) for energy dissipation through the rigid rotation of the entire spherical interface within the bulk fluid. There are two particularly interesting regimes. The first corresponds to when \(R/L \gg 1\) indicating localized hydrodynamics on the surface. The second to when \(R/L \ll 1\) indicating the hydrodynamics is strongly coupled nearly over the entire surface to give a response that is effectively a rigid-body rotation of the sphere.

We consider first the case when \(R/L \gg 1\) and make the approximation

\[
L_\ell \approx \frac{\mu_m}{RL} \left[ \left( \ell + \frac{1}{2} \right) + \epsilon \right].
\]

The \(\epsilon\) term includes the higher-order terms. We take \(\ell \ll R/L\) so that the \(\ell(\ell+1)\) term does not play a significant role. We approximate the sum using integration to obtain

\[
\sum_{\ell} \left( \ell + \frac{1}{2} \right) \exp \left( -\frac{\ell \mu_m}{RL} \left( \ell + \frac{1}{2} \right) \right) \approx \int_{1}^{\ell^*} \exp \left( -\frac{\ell \mu_m}{RL} \left( \ell + \frac{1}{2} \right) \right) \left( \ell + \frac{1}{2} \right) d\ell = \int_{\frac{3}{2}}^{\ell^*} e^{-\alpha t \tilde{\ell} \tilde{d} \tilde{d}} = \left[ \frac{-1}{\alpha} e^{-\alpha t \tilde{\ell} \tilde{d} \tilde{d}} \right]_{\frac{3}{2}}^{\ell^*} = \left( \frac{3}{2\alpha t} + \frac{1}{\alpha^2 t^2} \right) e^{-\frac{3}{2} \alpha t} \approx \frac{3}{2\alpha t} + \frac{1}{\alpha^2 t^2}.
\]

In this notation, we set \(\alpha = \mu_m/RL\). We also make the assumption that \(t \ll \tau_r = 2RL/3\mu_m\) so we can treat \(\exp(-\frac{3}{2} \alpha t) \approx 1\). In the case with \(R/L \gg 1\) and \(t \ll \tau_r = 2RL/3\mu_m\), we have that

\[
\left\langle v^\phi(0)v^\phi(t) \right\rangle \approx C \frac{k_B T}{|g| \rho} \sum_{\ell} \left( \ell + \frac{1}{2} \right) \exp \left( -\frac{\ell \mu_m}{RL} (\ell + \frac{1}{2}) \right) \\
\approx \frac{k_B T}{|g| \rho} \frac{C}{\alpha^2 t^2}.
\]

In the case approximating with \(R/L \gg 1\) followed by approximating with \(\alpha = \mu_m/RL \gg 1\), we have that

\[
\left\langle v^\phi(0)v^\phi(t) \right\rangle \approx C \frac{k_B T}{|g| \rho} \sum_{\ell} \exp \left( -\frac{t \mu_m}{RL} (\ell + \frac{1}{2}) (\ell + \frac{1}{2}) \right) \\
\approx \frac{k_B T}{|g| \rho} \frac{3C}{2\alpha t}.
\]

For the autocorrelation function, these results predict two distinct regimes that will exhibit different power law scalings. The first has power law \(t^{-2}\) and the second with power law scaling \(t^{-1}\). The \(t^{-1}\) power law is consistent with prior studies of pure two dimensional fluid interfaces.
predicting similar results for the long-time tail and divergence of the diffusion coefficient \([3, 11]\). Integrating the velocity autocorrelation functions with appropriate truncations given particle size one could obtain effective particle diffusivities within the interface using the Green-Kubo relations \([30, 42, 63]\).

Given the coupling to the bulk surrounding fluid our fluctuating hydrodynamics have additional time-scales mediating these effects. It is interesting that even though some of our parameter regimes exhibit a \(t^{-1}\) decay this in fact only persists for a finite amount of time and is eventually mitigated by our coupling to the bulk solvent fluid. Given that finite duration, our exhibited \(t^{-1}\) decay would result in finite logarithmic terms in the diffusivity, which is consistent with Saffman-Delbruck theory which considers a similar regime \([65]\). Our fluctuating hydrodynamics not only capture the classical Saffman-Delbruck results but also extend this to include geometric contributions from the spherical shape and other additional time-scales in regimes where the interfacial hydrodynamics and coupling to the bulk fluid could differ significantly. Further extensions could also be made to include the temporal dynamics of the bulk solvent fluid.

We next consider the regime with \(R/L \ll 1\) and make the approximation

\[
L_{\ell} \approx \frac{\mu_m}{R^2} [2 - \ell(\ell + 1) + \epsilon].
\] (78)

The \(\epsilon\) term includes the higher-order terms. We see a key term is \(\beta = \mu_m/R^2\). In this regime we have

\[
\sum_{\ell} \exp \left( \frac{t\mu_m}{R^2} (2 - \ell(\ell + 1) + \epsilon) \right) (\ell + \frac{1}{2}) \approx \int_{1}^{t_*} \exp \left( t\beta (2 - \ell^2 - \ell) \right) (\ell + \frac{1}{2}) d\ell
\]

\[
= \int_{1}^{t_*} \exp \left( -t\beta (\ell + \frac{1}{2})^2 \right) (\ell + \frac{1}{2}) d\ell \exp(t\beta \frac{9}{4})
\]

\[
= \exp(-t\beta \frac{9}{4}) \exp(t\beta \frac{9}{4}) \left( \frac{1}{2t\beta} + \text{(small terms)} \right)
\]

\[
\approx \frac{1}{2\beta t}.
\]

We obtained these results using completion of the square in the exponent.

In the regime with \(R/L \ll 1\), we see the velocity autocorrelation

\[
\langle v_{\phi}(0) v_{\phi}(t) \rangle \approx \frac{k_BT}{|g|\rho} \sum_{\ell} \exp \left( -t\frac{\mu_m}{R^2} (2 - \ell(\ell + 1) + \epsilon) \right) (\ell + \frac{1}{2}) \approx \frac{k_BT}{|g|\rho} \frac{C}{2\beta t}.
\] (80)

This predicts a power law decay with scaling \(t^{-1}\).

We see that the relaxation time-scale \(\tau_r\) for some systems can be quite large relative to the other time-scales. In these regimes, we find something interesting can occur where the velocity autocorrelation function plateaus. This is predicted by our theory to occur in the regime when the time \(t\) satisfies \(\tau_a = R^2/4\mu_m \ll t \ll \tau_r = 2RL/3\mu_m\). In this regime, the correlations associated with the internal flow of the hydrodynamics within the interfacial decays rapidly to zero. However, the rigid rotational motion of the entire fluid interface can still persist for awhile until the rotation reaches its decay time-scale that dissipates this motion. This leads to the interesting
plateaus seen in the velocity autocorrelation function in Figure 3. We also see that for all non-zero parameter choices the autocorrelation function will eventually exhibit an exponential decay when reaching time-scale \( t \gg \tau_e = 2RL/3\mu_\text{m} \). This is a consequence of the rigid-body rotational mode \( \ell = 1 \) being the longest lived mode and eventually dissipating energy from the interfacial fluid to the bulk surrounding fluid. Our calculations show that surface fluctuating hydrodynamics on quasi two dimensional fluid interfaces can exhibit significantly different phenomena relative to their bulk counter-parts in three dimensional space.

C. Spherical Harmonics

We expand functions \( \Phi \) on the surface using the spherical harmonics

\[
\Phi(\theta, \phi) = \sum_{n=0}^{\infty} \sum_{m=-n}^{n} \hat{\Phi}_n^m Y_n^m(\theta, \phi), \tag{81}
\]

where

\[
Y_n^m(\theta, \phi) = \sqrt{\frac{(2n+1)(n-m)!}{4\pi(n+m)!}} \cdot P_n^m(\cos(\phi)) \exp(i m \theta). \tag{82}
\]

The \( m \) denotes the order and \( n \) the degree for \( n \geq 0 \) and \( m \in \{-n, \ldots, n\} \). The \( P_n^m \) denote the Associated Legendre Polynomials. We denote by \( \theta \) the azimuthal angle and by \( \phi \) the polar angle of the spherical coordinates \([6]\). We work with real-valued functions and use that modes are self-conjugate in the sense \( Y_n^m = Y_{n,-m} \).

We can express the spherical harmonic modes as

\[
Y_n^m(\theta, \phi) = X_n^m(\theta, \phi) + i Z_n^m(\theta, \phi). \tag{83}
\]

The \( X_n^m \) and \( Z_n^m \) denote the real and imaginary parts. We use this splitting in our numerical methods to construct a purely real set of basis functions on the unit sphere with maximum degree \( N \) which consists of \( (N+1)^2 \) basis elements.

For the case \( N = 2 \) we have the basis elements

\[
\tilde{Y}_1 = Y_0^0, \quad \tilde{Y}_2 = Z_1^1, \quad \tilde{Y}_3 = Y_1^0, \quad \tilde{Y}_4 = X_1^1, \\
\tilde{Y}_5 = Z_2^2, \quad \tilde{Y}_6 = Z_2^1, \quad \tilde{Y}_7 = Y_2^0, \quad \tilde{Y}_8 = X_2^1, \\
\tilde{Y}_9 = X_2^2.
\]

Similar conventions are used for the basis for the other values of \( N \). We take final basis elements \( Y_i \) that are normalized as \( Y_i = \tilde{Y}_i/\sqrt{\langle Y_i, \tilde{Y}_i \rangle} \).

Derivatives are used within our finite expansions by evaluating analytic formulas whenever possible for the spherical harmonics in order to try to minimize approximation error \([6]\). Approximation errors are incurred when sampling the values of expressions involving these derivatives at the Lebedev nodes and when performing quadratures \([44]\). The derivative of the spherical harmonics in the azimuthal coordinate \( \theta \) is given by

\[
\partial_\theta Y_n^m(\theta, \phi) = \frac{\partial_\theta}{\frac{(2n+1)(n-m)!}{4\pi(n+m)!}} \cdot P_n^m(\cos(\phi)) \exp(i m \theta) \\
= im Y_n^m(\theta, \phi). \tag{85}
\]

We see this has the useful feature that the derivative in \( \theta \) of a spherical harmonic of degree \( n \) is again a spherical harmonic of degree \( n \). As a consequence, we have in our numerics that this derivative can be represented in our finite basis. This allows us to avoid additional \( L^2 \) projections allowing for computation of the derivative in \( \theta \) without incurring an approximation error. The derivative of the spherical harmonics in the polar angle \( \phi \) is given by

\[
\partial_\phi Y_n^m(\theta, \phi) = m \cot(\phi) Y_n^m(\theta, \phi) \tag{86}
\]

\[
+ \frac{\sqrt{(n-m)(n+m+1)}}{\sqrt{(n-m)(n+m+1)}} \cdot \exp(-i \theta) Y_{n+1}^{m+1}(\theta, \phi).
\]

We see that unlike derivatives in \( \theta \) the derivative in \( \phi \) can not be represented in general in terms of a finite expansion of spherical harmonics. In our
We expressed operators on the surface using expressions within each chart in the regions with \( \pi/4 \leq \phi \leq 3\pi/4 \) and \( \pi/4 \leq \tilde{\phi} \leq 3\pi/4 \). We give all expressions with generic polar coordinates \((\theta, \phi)\) which we subsequently use in practice in our numerical calculations by choosing the appropriate chart \( A \) or chart \( B \). More details on our approach can also be found in [67].

The exterior derivatives can be expressed for a 0-form \( f \) and 1-form \( \alpha \) as

\[
\begin{align*}
\text{d}f &\quad = \quad (\partial_\theta f)\,d\theta + (\partial_\phi f)\,d\phi = f_\theta d\theta + f_\phi d\phi \\
\text{d}\alpha &\quad = \quad (\partial_\theta \alpha_\phi - \partial_\phi \alpha_\theta) d\theta \wedge d\phi.
\end{align*}
\]

The generalized curl on the radial manifold of a 0-form and 1-form can be expressed as

\[
- \star \text{d}f = \text{curl}_M(f) = \sqrt{|g|} \left( f_\theta g^\phi_\phi + f_\phi g^\theta_\phi \right) d\theta \\
- \star \text{d}\alpha = \text{curl}_M(\alpha) = \frac{\partial_\phi \alpha_\theta - \partial_\theta \alpha_\phi}{\sqrt{|g|}}.
\]

In this notation we have taken the conventions that \( f_j = \partial_{x^j} f \) and \( \alpha_j \) such that \( \alpha = \alpha_j dx^j \) where \( j \in \{\theta, \phi\} \). The isomorphisms \( \sharp \) and \( \flat \) between vectors and co-vectors can be expressed explicitly as

\[
\begin{align*}
\nu^\flat &= (v^\theta \sigma_\theta + v^\phi \sigma_\phi)\,\frac{\partial}{\partial \theta} + (v^\phi g^\theta_\phi \sigma_\theta + v^\theta g^\phi_\phi \sigma_\phi)\,\frac{\partial}{\partial \phi} \\
&= v^\theta g_{\theta\theta} d\theta + v^\theta g_{\theta\phi} d\phi + v^\phi g_{\phi\theta} d\theta + v^\phi g_{\phi\phi} d\phi \\
&= (v^\theta g_{\theta\theta} + v^\phi g_{\phi\theta}) d\theta + (v^\theta g_{\theta\phi} + v^\phi g_{\phi\phi}) d\phi \\
\nu^\sharp &= (\alpha_\theta d\theta + \alpha_\phi d\phi)\,\frac{\partial}{\partial \theta} + (\alpha_\phi g^\theta_\phi \sigma_\theta + \alpha_\theta g^\phi_\phi \sigma_\phi)\,\frac{\partial}{\partial \phi} \\
&= \alpha_\theta g^{\theta\theta} \sigma_\theta + \alpha_\phi g^{\phi\phi} \sigma_\phi + \alpha_\theta g^{\theta\phi} \sigma_\phi + \alpha_\phi g^{\phi\theta} \sigma_\theta \\
&= (\alpha_\theta g^{\theta\theta} + \alpha_\phi g^{\phi\phi}) \sigma_\theta + (\alpha_\theta g^{\theta\phi} + \alpha_\phi g^{\phi\theta}) \sigma_\phi
\end{align*}
\]

We use the notational conventions here that for the embedding map \( \sigma \) for spherical coordinates in \( \mathbb{R}^3 \) we have \( \sigma_\theta = \partial_\theta \) and \( \sigma_\phi = \partial_\phi \). Combining the above equations we can express the generalized...
The scalar Laplace-Beltrami operator \( \Delta_{LB} \) that acts on 0-forms can be expressed in coordinates as

\[
\Delta_{LB} = -\delta d = \frac{1}{\sqrt{|g|}} \partial_i \left( g^{ij} \sqrt{|g|} \partial_j \right) .
\]

The \( g_{ij} \) denotes the metric tensor, \( g^{ij} \) the inverse metric tensor, and \( |g| \) the determinant of the metric tensor.

We also mention that the velocity field of the hydrodynamic flows \( \mathbf{v} \) is recovered from the vector potential \( \Phi \) as \( \mathbf{v}^\flat = -\delta d \Phi \). We obtain the velocity field \( \mathbf{v} = \mathbf{v}^\sharp = (-\delta d \Phi)^\sharp \) using equation 92. Similarly from the force density \( \mathbf{b} \) acting on the fluid, we obtain the data \( -\delta d \mathbf{b}^\flat \) for the vector potential formulation of the hydrodynamics using equation 93. Additional details and discussions of these operators also can be found in our related papers [31,67] and in [1,60,68].
