Abstract

Boosting variational inference (BVI) approximates an intractable probability density by iteratively building up a mixture of simple component distributions one at a time, using techniques from sparse convex optimization to provide both computational scalability and approximation error guarantees. But the guarantees have strong conditions that do not often hold in practice, resulting in degenerate component optimization problems; and we show that the ad-hoc regularization used to prevent degeneracy in practice can cause BVI to fail in unintuitive ways. We thus develop universal boosting variational inference (UBVI), a BVI scheme that exploits the simple geometry of probability densities under the Hellinger metric to prevent the degeneracy of other gradient-based BVI methods, avoid difficult joint optimizations of both component and weight, and simplify fully-corrective weight optimizations. We show that for any target density and any mixture component family, the output of UBVI converges to the best possible approximation in the mixture family, even when the mixture family is misspecified. We develop a scalable implementation based on exponential family mixture components and standard stochastic optimization techniques. Finally, we discuss statistical benefits of the Hellinger distance as a variational objective through bounds on posterior probability, moment, and importance sampling errors. Experiments on multiple datasets and models show that UBVI provides reliable, accurate posterior approximations.

1 Introduction

Bayesian statistical models provide a powerful framework for learning from data, with the ability to encode complex hierarchical dependence structures and prior domain expertise, as well as coherently capture uncertainty in latent parameters. The two predominant methods for Bayesian inference are Markov chain Monte Carlo (MCMC) [1, 2]—which obtains approximate posterior samples by simulating a Markov chain—and variational inference (VI) [3, 4]—which obtains an approximate distribution by minimizing some divergence to the posterior within a tractable family. The key strengths of MCMC are its generality and the ability to perform a computation-quality tradeoff: one can obtain a higher quality approximation by simulating the chain for a longer period [5, Theorem 4 & Fact 5]. However, the resulting Monte Carlo estimators have an unknown bias or random computation time [6], and statistical distances between the discrete sample posterior approximation and a diffuse true posterior are vacuous, ill-defined, or hard to bound without restrictive assumptions or a choice of kernel [7–9]. Designing correct MCMC schemes in the large-scale data setting is also a challenging task [10–12]. VI, on the other hand, is both computationally scalable and widely applicable due to advances from stochastic optimization and automatic differentiation [13–17]. However, the major disadvantage of the approach—and the fundamental reason that MCMC remains the preferred method in statistics—is that the variational family typically does not contain the posterior, fundamentally limiting the achievable approximation quality. And despite recent results in asymptotic theory [18–
it is difficult to assess the effect of the chosen family on the approximation for finite data; a poor choice can result in severe underestimation of posterior uncertainty [22, Ch. 21].

Boosting variational inference (BVI) [23–25] is an exciting new approach that addresses this fundamental limitation by using a nonparametric mixture variational family. By adding and reweighting only a single mixture component at a time, the approximation may be iteratively refined, achieving the computation/quality tradeoff of MCMC and the scalability of VI. Theoretical guarantees on the convergence rate of Kullback-Leibler (KL) divergence [23, 26, 27] are much stronger than those available for standard Monte Carlo, which degrade as the number of estimands increases, enabling the practitioner to confidently reuse the same approximation for multiple tasks. However, the bounds require the KL divergence to be sufficiently smooth over the class of mixtures—an assumption that does not hold for many standard mixture families, e.g. Gaussians, resulting in a degenerate procedure in practice. To overcome this, an ad-hoc entropy regularization is typically added to each component optimization; but this regularization invalidates convergence guarantees, and—depending on the regularization weight—sometimes does not actually prevent degeneracy.

In this paper, we develop universal boosting variational inference (UBVI), a variational scheme based on the Hellinger distance rather than the KL divergence. The primary advantage of using the Hellinger distance is that it endows the space of probability densities with a particularly simple unit-spherical geometry in a Hilbert space. We exploit this geometry to prevent the degeneracy of other gradient-based BVI methods, avoid difficult joint optimizations of both component and weight, simplify fully-corrective weight optimizations, and provide a procedure in which the normalization constant of $f$ does not need to be known, a crucial property in most VI settings. It also leads to the universality of UBVI: we show that for any target density and any mixture component family, the output of UBVI converges to the best possible approximation in the mixture family, even when the mixture family is misspecified. We develop a scalable implementation based on exponential family mixture components and standard stochastic optimization techniques. Finally, we discuss other statistical benefits of the Hellinger distance as a variational objective through bounds on posterior statistical benefits of the Hellinger distance as a variational objective through bounds on posterior uncertainty [22, Ch. 21], it is difficult to assess the effect of the chosen family on the approximation for finite data; a poor choice can result in severe underestimation of posterior uncertainty [22, Ch. 21].

2 Background: variational inference and boosting

Variational inference, in its most general form, involves approximating a probability density $p$ by minimizing some divergence $D(\cdot||\cdot)$ from $\xi$ to $p$ over densities $\xi$ in a family $Q$.

$$q = \arg \min_{\xi \in Q} D(\xi||p).$$

Past work has almost exclusively involved parametric families $Q$, such as mean-field exponential families [4], finite mixtures [28–30], normalizing flows [31], and neural nets [16]. The issue with these families is that typically $\min_{\xi \in Q} D(\xi||p) > 0$—meaning the practitioner cannot achieve arbitrary approximation quality with more computational effort—and a priori, there is no way to tell how poor the best approximation is. To address this, boosting variational inference (BVI) [23–25] proposes the use of the nonparametric family of all finite mixtures of a component density family $C$,

$$Q = \text{conv} C := \left\{ \sum_{k=1}^{K} w_k \xi_k : K \in \mathbb{N}, w \in \Delta^{K-1}, \forall k \in \mathbb{N}, \xi_k \in C \right\}.$$

Given a judicious choice of $C$, we have that $\inf_{\xi \in Q} D(\xi||p) = 0$; in other words, we can approximate any continuous density $p$ with arbitrarily low divergence [32]. As optimizing directly over the nonparametric $Q$ directly is intractable, BVI instead adds one component at a time to iteratively refine the approximation. There are two general formulations of BVI: Miller et al. [25] propose minimizing KL divergence over both the weight and component simultaneously,

$$q_n = \sum_{k=1}^{n} w_n \xi_k, \omega = \arg \min_{\xi \in C, \rho \in [0,1]} D_{KL}(\rho \xi + (1-\rho) q_n || p) \quad w_{n+1} = [(1-\omega) w_n \omega]^T,$$

while Guo et al. and Wang [23, 24] argue that optimizing both simultaneously is too difficult, and use a gradient boosting [32] formulation instead,

$$\xi_{n+1} = \arg \min_{\xi \in C} \left\{ D_{KL}(\xi||p) q_n \right\} \quad w_{n+1} = \arg \min_{\omega \in [1-\rho w_n \rho]^T, \rho \in [0,1]} D_{KL}(\sum_{k=1}^{n+1} \omega_k \xi_k || p).$$
Figure 1: (1a): Greedy component selection, with target \( f \), current iterate \( \bar{g}_n \), candidate components \( h \), optimal component \( g_{n+1} \), the closest point \( g^* \) to \( f \) on the \( \bar{g}_n \to g_{n+1} \) geodesic, and arrows for initial geodesic directions. The quality of \( g_{n+1} \) is determined by the distance from \( f \) to \( g^* \), or equivalently, by the alignment of the initial directions \( \bar{g}_n \to g_{n+1} \) and \( \bar{g}_n \to f \). (1b): BVI can fail even when \( p \) is in the mixture family. Here \( p = \frac{1}{2}N(0, 1) + \frac{1}{2}N(25, 5) \), and UBVI finds the correct mixture in 2 iterations. BVI (with regularization weight \( \{1, 10, 30\} \)) does not converge if \( \lambda < 5 \): the first component will have variance < 5, and the second component optimization diverges since the target \( N(25, 5) \) component has a heavier tail. Upon reweighting the second component is removed, and the approximation will never improve.

Both algorithms attain \( D_{KL}(q_N||p) = O(1/N) \)— the former by appealing to results from convex functional analysis [34, Theorem II.1], and the latter by viewing BVI as functional Frank-Wolfe optimization [26, 35, 36]. This requires that \( D_{KL}(q||p) \) is strongly smooth or has bounded curvature over \( q \in Q \), for which it is sufficient that densities in \( Q \) are bounded away from 0, bounded above, and have compact support [26], or have a bounded parameter space [27]. However, these assumptions do not hold in practice for many simple (and common) cases, e.g., where \( C \) is the class of multivariate normal distributions. Indeed, gradient boosting-based BVI methods all require some ad-hoc entropy regularization in the component optimizations to avoid degeneracy [23, 24, 27]. This addition of regularization has an adverse effect on performance in practice as demonstrated in Fig. 1b, and can lead to unintuitive behaviour and nonconvergence in general—even when \( p \in Q \)—as shown for the centered Gaussian case in Proposition 1.

**Proposition 1.** Suppose \( C \) is the set of 1D Gaussians with mean 0 parametrized by variance, let \( p = N(0, 1) \), and let the initial approximation be \( N(0, \tau^2) \). Then gradient-based BVI with entropy regularization weight \( \lambda > 0 \) returns a degenerate next component if \( \tau^2 \leq 1 \), and iterates infinitely without improving the approximation if \( \tau^2 > 1 \) and \( \lambda \tau^2 - \log \lambda \tau^2 > (\tau^2 - 1)(\tau^2 - \log \tau^2) \).

### 3 Universal boosting variational inference (UBVI)

#### 3.1 Algorithm and convergence guarantee

To design a BVI procedure without the need for ad-hoc regularization, we use a variational objective based on the Hellinger distance, which for any probability space \((X, \Sigma, \mu)\) and densities \( p, q \) is

\[
D_H^2(p, q) := \frac{1}{2} \int \left( \sqrt{p(x)} - \sqrt{q(x)} \right)^2 \mu(dx).
\]

Our general approach relies on two facts about the Hellinger distance. First, the metric \( D_H(\cdot, \cdot) \) endows the set of \( \mu \)-densities with a simple geometry corresponding to the nonnegative functions on the unit sphere in \( L^2(\mu) \). In particular, if \( f, g \in L^2(\mu) \) satisfy \( \|f\|_2 = \|g\|_2 = 1 \), \( f, g \geq 0 \), then \( p = f^2 \) and \( q = g^2 \) are probability densities and

\[
D_H^2(p, q) = \frac{1}{2} \|f - g\|_2^2.
\]

---

\(^1\)We assume throughout that nonconvex optimization problems can be solved reliably.
Algorithm 1 The universal boosting variational inference (UBVI) algorithm.

1: procedure UBVI(p, ℋ, N)
2: $f \leftarrow \sqrt{p}$
3: $\bar{g}_0 \leftarrow 0$
4: for $n = 1, \ldots, N$ do
5: $g_n \leftarrow \arg \max_{h \in \mathcal{H}} \left( f - \langle f, \bar{g}_{n-1} \rangle \bar{g}_{n-1}, h \right) / \sqrt{1 - \langle h, \bar{g}_{n-1} \rangle^2}$
6: Compute pairwise normalizations using Eq. (1)
7: $Z_{n,i} = Z_{i,n} \leftarrow \langle g_n, g_i \rangle$
8: end for
9: $d = (\langle f, g_1 \rangle, \ldots, \langle f, g_n \rangle)^T$
10: $\beta = \arg \min_{b \in \mathbb{R}^n, b \geq 0} b^T Z^{-1} b + 2b^T Z^{-1} d$
11: $\langle \lambda_{n,1}, \ldots, \lambda_{n,n} \rangle = \frac{\bar{g}_n}{Z^{T/2} \bar{g}_n Z^{T/2}}$
12: Update weights using Eq. (6)
13: $\bar{g}_n \leftarrow \sum_{i=1}^n \lambda_{n,i} g_i$
14: return $q = \bar{g}_n^2$
15: end procedure

One can thus perform Hellinger distance boosting by iteratively finding components that minimize geodesic distance to $f$ on the unit sphere in $L^2(\mu)$. Like the Miller et al. approach [25], the boosting step directly minimizes a statistical distance, leading to a nondegenerate method; but like the Guo et al. and Wang approach [23, 24], this avoids the joint optimization of both component and weight; see Section 3.2 for details. Second, a conic combination $q = \sum_{i=0}^N \lambda_i g_i$, $\lambda_i \geq 0$, $\|g_i\|_2 = 1$, $g_i \geq 0$ in $L^2(\mu)$ satisfying $\|g\|_2 = 1$ corresponds to the mixture model density

$$q = g^2 = \sum_{i,j=1}^N Z_{ij} \lambda_i \lambda_j \left( \frac{g_i g_j}{Z_{ij}} \right) \quad Z_{ij} := \langle g_i, g_j \rangle \geq 0.$$  \hspace{1cm} (1)

Therefore, if we can find a conic combination satisfying $\|f - q\|_2 \leq \sqrt{2\epsilon}$ for $p = f^2$, we can guarantee that the corresponding mixture density $q$ satisfies $D_H(p, q) \leq \epsilon$. The mixture will be built from a family $\mathcal{H} \subset L^2(\mu)$ of component functions for which $\forall h \in \mathcal{H}, \|h\|_2 = 1$ and $h \geq 0$. We assume that the target function $f \in L^2(\mu)$, $\|f\|_2 = 1$, $f \geq 0$ is known up to proportionality. We also assume that $f$ is not orthogonal to span $\mathcal{H}$ for expositional brevity, although the algorithms and theoretical results presented here apply equally well in this case. We make no other assumptions; in particular, we do not assume $f$ is in $\text{cl span } \mathcal{H}$.

The universal boosting variational inference (UBVI) procedure is shown in Algorithm 1. In each iteration, the algorithm finds a new mixture component from $\mathcal{H}$ (line 5); see Section 3.2 and Fig. 1a). Once the new component is found, the algorithm solves a convex quadratic optimization problem to update the weights (lines 9–11). The primary requirement to run Algorithm 1 is the ability to compute or estimate $\langle h, f \rangle$ and $\langle h, h' \rangle$ for $h, h' \in \mathcal{H}$. For this purpose we employ an exponential component family $\mathcal{H}$ such that $Z_{ij}$ is available in closed-form, and use samples from $h'$ to obtain estimates of $\langle h, f \rangle$; see Appendix A for further implementation details.

The major benefit of UBVI is that it comes with a computation/quality tradeoff akin to MCMC: for any target $p$ and component family $\mathcal{H}$, (1) there is a unique mixture $\hat{p} = f^2$ minimizing $D_H(\hat{p}, p)$ over the closure of finite mixtures $Q$; and (2) the output $q$ of UBVI($p$, $\mathcal{H}$, $N$) satisfies $D_H(q, \hat{p}) = O(1/N)$ with a dimension independent constant. No matter how coarse the family $\mathcal{H}$ is, the output of UBVI will converge to the best possible mixture approximation. Theorem 2 provides the precise result.

Theorem 2. For any density $p$ there is a unique density $\hat{p} = f^2$ satisfying $\hat{p} = \arg \min_{\xi \in \mathcal{H}} D_H(\xi, p)$; and if the component optimization Eq. (4) is solved with a $(1 - \delta)$-relative error, then the variational mixture approximation $q$ returned by UBVI($p$, $\mathcal{H}$, $N$) satisfies

$$D_H(\hat{p}, q)^2 \leq \frac{J_1}{1 + (1 - \delta)^2 J_1 (N - 1)} \quad J_1 := \left( 1 - \frac{\langle f, g_i \rangle}{\tau} \right)^2 \in [0, 1)$$

\hspace{1cm} $\tau := \text{Eq. (2)} < \infty$.  \hspace{1cm} (2)
The proof of Theorem 2 may be found in Appendix C, and consists of three primary steps. First, Lemma 8 guarantees the existence and uniqueness of the convergence target \( f \) under possible misspecification of the component family \( \mathcal{H} \). Then the difficulty of approximating \( \hat{f} \) with conic combinations of functions in \( \mathcal{H} \) is captured by the basis pursuit denoising problem \( \text{BP} \) \[ \begin{array}{ll}
\tau := \inf_{h_i \in \text{cone} \mathcal{H}} \quad (1 - x)^{-1} \sum_{i=1}^{\infty} \| h_i \|_2 \quad \text{s.t.} \quad \| \hat{f} - \sum_{i=1}^{\infty} h_i \|_2 \leq x, \quad \forall i, h_i \geq 0. \end{array} \] \[ (2) \]

Lemma 9 guarantees that \( \tau \) is finite, and in particular \( \tau \leq \frac{\sqrt{1 - \sqrt{1 - \| x \|_2^2}}}{1 - \| x \|_2} \), which can be estimated in practice using Eq. (8). Finally, Lemma 10 develops an objective function recursion, which is then solved to yield Theorem 2. Although UBVI and Theorem 2 is reminiscent of past work on greedy approximation in a Hilbert space \([33, 38–45]\), it provides the crucial advantage that the greedy steps do not require knowledge of the normalization of \( p \). UBVI is inspired by a previous greedy method \([45]\), but provides guarantees with an arbitrary, potentially misspecified infinite dictionary in a Hilbert space, and uses quadratic optimization to perform weight updates. Note that both the theoretical and practical cost of UBVI is dominated by finding the next component (line 5), which is a nonconvex optimization problem. The other expensive step is inverting \( Z \); however, incremental methods using block matrix inversion \([46, p. 46]\) reduce the cost at iteration \( n \) to \( O(n^2) \) and overall cost to \( O(N^3) \), which is not a concern for practical mixtures with \( n \leq 10^3 \) components. The weight optimization (line 10) is a nonnegative least squares problem, which can be solved efficiently \([47, \text{Ch. 23}]\).

3.2 Greedy boosting along density manifold geodetics

This section provides the technical derivation of UBVI (Algorithm 1) by exploiting the geometry of square-root densities under the Hellinger metric. Let the conic combination in \( L_2(\mu) \) after initialization followed by \( N - 1 \) steps of greedy construction be denoted

\[ \bar{g}_n := \sum_{i=1}^{n} \lambda_{ni} g_i, \quad \| \bar{g}_n \|_2 = 1, \]

where \( \lambda_{ni} \geq 0 \) is the weight for component \( i \) at step \( n \), and \( g_i \) is the component added at step \( i \). To find the next component, we minimize the distance between \( \bar{g}_{n+1} \) and \( f \) over \( h \in \mathcal{H} \) and position \( x \in [0, 1] \) along the \( \bar{g}_n \to h \) geodesic \( \bar{g}_n, x^* = \arg\min_{h \in \mathcal{H}, x \in [0, 1]} \left\| f - \left( x \cdot \frac{h - \langle h, \bar{g}_n \rangle \bar{g}_n}{\| h - \langle h, \bar{g}_n \rangle \bar{g}_n \|_2} + \sqrt{1 - x^2} \bar{g}_n \right) \right\|_2 \) \[ (3) \]

Intuitively, Eq. (4) attempts to maximize alignment of \( g_{n+1} \) with the residual \( f - \langle f, \bar{g}_n \rangle \bar{g}_n \) (the numerator) resulting in a ring of possible solutions, and among these, Eq. (4) minimizes alignment with the current iterate \( \bar{g}_n \) (the denominator). The first form in Eq. (4) provides an alternative intuition: \( g_{n+1} \) achieves the maximal alignment of the initial geodesic directions \( g_n \to f \) and \( \bar{g}_n \to h \) on the sphere. See Fig. 1D for a depiction. After selecting the next component \( g_{n+1} \), one option to obtain \( \bar{g}_{n+1} \) is to use the optimal weighting \( x^* \) from Eq. (3), in practice, however, it is typically the case that solving Eq. (4) is expensive enough that finding the optimal set of coefficients for \( \{g_1, \ldots, g_{n+1}\} \) is worthwhile. This is accomplished by maximizing alignment with \( f \) subject to a nonnegativity and unit-norm constraint:

\[ (\lambda_{(n+1)1}, \ldots, \lambda_{(n+1)(n+1)}) = \arg\max_{x \in \mathbb{R}^{n+1}} \left\{ f, \sum_{i=1}^{n+1} x_i g_i \right\} \quad \text{s.t.} \quad x \geq 0, \quad x^T Z x \leq 1, \]

Note that the \( \arg\max \) may not be unique, and when \( \mathcal{H} \) is infinite it may not exist; Theorem 2 still holds and UBVI works as intended in this case. For simplicity, we use \( (\ldots) = \arg\max (\ldots) \) throughout.
While the Hellinger distance has most frequently been applied in asymptotic analyses (e.g., [48]), where Theorem 6.9 under relatively weak conditions.

Theorem 6.9

...via Pinsker’s inequality (and at the very least is always in Hellinger distance as a variational objective

Proposition 4. Suppose \( X \) is a Polish space with metric \( d(\cdot, \cdot) \), \( \ell \geq 1 \), and \( p, q \) are densities with respect to a common measure \( \mu \). Then for any \( x_0 \),

\[
W_\ell(p, q) \leq 2D_H(p, q)^{1/\ell} \left( \mathbb{E} \left[ d(x_0, X)^{2\ell} \right] + \mathbb{E} \left[ d(x_0, Y)^{2\ell} \right] \right)^{1/2\ell},
\]

where \( Y \sim p(y)\mu(dy) \) and \( X \sim q(x)\mu(dx) \). In particular, if densities \( (q_N)_{N \in \mathbb{N}} \) have uniformly bounded \( 2\ell^\text{th} \) moments, \( D_H(p, q_N) \to 0 \implies W_\ell(p, q_N) \to 0 \) as \( N \to \infty \).

Figure 2: Forward KL divergence—which controls worst-case downstream importance sampling error—and importance-sampling-based covariance estimation error on a task of approximating \( \mathcal{N}(0, A^T A) \), \( A_{ij} \sim \mathcal{N}(0, 1) \) with \( \mathcal{N}(0, \sigma^2 I) \) by minimizing Hellinger, forward KL, and reverse KL, plotted as a function of condition number \( \kappa(A^T A) \). Minimizing Hellinger distance provides significantly lower forward KL divergence and estimation error than minimizing reverse KL.
Once a variational approximation \( q \) is obtained, it will typically be used to estimate expectations of some function of interest \( \phi(x) \in L^2(\mu) \) via Monte Carlo. Unless \( q \) is trusted entirely, this involves importance sampling—using \( I_n(\phi) \) or \( J_n(\phi) \) in Eq. (7) depending on whether the normalization of \( p \) is known—to account for the error in \( q \) compared with the target distribution \( p \). \[ \begin{aligned} I_n(\phi) &:= \frac{1}{N} \sum_{n=1}^{N} \frac{p(X_i)}{q(X_i)} \phi(X_i) & J_n(\phi) &:= \frac{I_n(\phi)}{I_n(1)} \quad X_i \sim q(x) \mu(dx). \end{aligned} \] (7)

Recent work has shown that the error of importance sampling is controlled by the intractable forward KL-divergence \( D_{KL}(p||q) \). This is where the Hellinger distance shines; Proposition 5 shows that it penalizes both positive and negative values of \( \log p(x)/q(x) \) and thus provides moderate control on \( D_{KL}(p||q) \)—unlike \( D_{KL}(q||p) \), which only penalizes negative values. See Fig. 2 for a demonstration of this effect on the classical correlated Gaussian example. While the takeaway from this setup is typically that minimizing \( D_{KL}(q||p) \) may cause severe underestimation of variance, a reasonable practitioner should attempt to use importance sampling to correct for this anyway. But Fig. 2 shows that minimizing \( D_{KL}(q||p) \) doesn’t minimize \( D_{KL}(p||q) \) well, leading to poor estimates from importance sampling. Even though minimizing \( D_H(p, q) \) also underestimates variance, it provides enough control on \( D_{KL}(p||q) \) so that importance sampling can correct the errors. Direct bounds on the error of importance sampling estimates are also provided in Proposition 6.

**Proposition 5.** Define \( R := \log \frac{p(X)}{q(X)} \) where \( X \sim p(x) \mu(dx) \). Then
\[
D_H(p, q) \geq \frac{1}{2} \mathbb{E} \left[ R^2 \left( \frac{1 + 1 [R \leq 0]}{1 + R} \right)^2 \right] \geq \frac{D_{KL}(p||q)}{2 \sqrt{1 + \mathbb{E}[(1 + R)^2]}}.
\]

**Proposition 6.** Define \( \alpha := \left( N^{-1/4} + 2 \sqrt{D_H(p, q)} \right)^2 \). Then the importance sampling error with known normalization is bounded by
\[
\mathbb{E} \left[ |I_n(\phi) - I(\phi)| \right] \leq \|\sqrt{p}\|_2 \alpha,
\]
and with unknown normalization by
\[
\forall t > 0 \quad \mathbb{P}(|J_n(\phi) - I(\phi)| > \|\sqrt{p}\|_2 t) \leq (1 + 4t^{-1}\sqrt{1 + t}) \alpha.
\]

Finally, the Hellinger distance between densities \( q, p \) can be estimated with high relative accuracy given samples from \( q \), enabling the use of the above bounds in practice. This involves computing either \( D^2_H(p, q) \) or \( D^2_H(p, q) \) below, depending on whether the normalization of \( p \) is known. The expected error of both of these estimates relative to \( D_H(p, q) \) is bounded via Proposition 7.
\[
D^2_H(p, q) := 1 - \frac{1}{N} \sum_{n=1}^{N} \frac{p(X_n)}{q(X_n)}, \quad D^2_H(p, q) := 1 - \frac{\frac{1}{N} \sum_{n=1}^{N} \sqrt{\frac{p(X_n)}{q(X_n)}}}{\sqrt{\frac{1}{N} \sum_{n=1}^{N} \frac{p(X_n)}{q(X_n)}}} \quad X_n \sim q(x) \mu(dx). \tag{8}
\]

**Proposition 7.** The mean absolute difference between the Hellinger squared estimates is
\[
\mathbb{E} \left[ |D^2_H(p, q) - D_H(p, q)^2| \right] \leq \frac{D_H(p, q) \sqrt{2 - D_H(p, q)^2}}{\sqrt{N}}
\]
\[
\mathbb{E} \left[ |D^2_H(p, q) - D_H(p, q)^2| \right] \leq \sqrt{2} \left( 1 + \sqrt{N^{-1}} \right) D_H(p, q).
\]

### 5 Experiments

In this section, we compare UBVI, BBVI, and standard VI on the standard Cauchy and banana (curvature \( b = 0.1 \)) distributions, as well as logistic regression with a multivariate-t prior on four real and two synthetic datasets. Detailed descriptions of the models and links to the datasets are provided in Appendix B. We used the Gaussian family for \( \mathcal{H} \) parametrized by mean and Cholesky covariance factor—full-rank for Cauchy and banana, and diagonal for logistic regression. We used ADAM \((10,000\) iterations, decaying step size \(1/\sqrt{1 + t})\) for optimization, with Monte Carlo...
gradients based on 1,000 samples. Each component optimization was initialized from the best of 1,000 trials involving sampling a component from the current mixture, inflating its covariance, and translating it by a random amount generated from itself—see Appendix A for details. Fully-corrective weight optimization was conducted via simplex-projected SGD for BBVI and nonnegative least squares for UBVI. Monte Carlo estimates of $\langle f, g \rangle_{n}$ in UBVI were based on 10,000 samples. Each experiment was run 20 times with an Intel i7 8700K processor and 32GB of memory. Code is available at www.github.com/trevorcampbell/ubvi.

Fig. 3 shows the results of these numerical tests. BBVI particularly struggles with heavy-tailed distributions, where its component optimization objective after the first is degenerate; and due to the necessary addition of regularization (we had to use a large regularization $\lambda = 10/(1 + n)$ in logistic regression to prevent divergence) it tends to overestimate variance. We also found that the behaviour of BBVI is very sensitive to the choice of regularization tuning schedule, and is difficult to tune well. UBVI, in contrast, approximates both heavy-tailed and complex distributions well with few components, and involves no tuning effort beyond the optimization learning rate / # of gradient estimate samples. Across both experiments, UBVI provides either a comparable or better posterior approximation than BBVI, with generally similar computation times—UBVI and BBVI took $55 \pm 5$ and $170 \pm 24$ seconds for Cauchy and $58 \pm 16$ and $141 \pm 36$ seconds for banana, respectively.

6 Conclusion

This paper developed universal boosting variational inference (UBVI). UBVI optimizes the Hellinger metric, avoiding the degeneracy, tuning, and difficult joint component/weight optimizations of other gradient-based BVI methods, while simplifying fully-corrective weight optimizations. Theoretical
guarantees on the convergence of Hellinger distance provide an MCMC-like computation/quality tradeoff, and experimental results demonstrate the advantages over previous variational methods.

A Component family and practical aspects of optimization

In order to use Algorithm 1 we need to compute or estimate \( \langle h, \phi \rangle \) for any \( \phi \in L^2(\mu) \) and \( \langle h, h' \rangle \) for any \( h, h' \in H \). For arbitrary \( \phi \), we use Monte Carlo estimates based on samples from \( h^2 \) via

\[
\forall \phi \in L^2(\mu), \quad \langle h, \phi \rangle = \int h^2(x) \frac{\phi(x)}{h(x)} \mu(dx) = \mathbb{E}_\mu \left[ \frac{\phi(X)}{h(X)} \right] \approx \frac{1}{S} \sum_{s=1}^S \frac{\phi(X_s)}{h(X_s)} \quad X_s \sim h^2,
\]

and employ an exponential component family \( H \) such that inner products \( \langle h, h' \rangle \) between members of \( H \) are available in closed-form. In other words, for some base density \( k(x) \), sufficient statistic \( T(x) \), and log-partition \( A(\eta) \), we let

\[
H = \left\{ \eta_i \in L^2(\mu) : h^2_i(x) = k(x) \exp \left( \eta^T T(x) - A(\eta) \right) \right\}.
\]

Denoting \( \eta_i \) to be the natural parameter for \( g_i \), then \( g_i = h_{\eta_i} \), and

\[
Z_{ij} = \langle g_i, g_j \rangle = \int h_{\eta_i}(x) h_{\eta_j}(x) \mu(dx) = \exp \left( A \left( \frac{\eta_i + \eta_j}{2} \right) \right), \quad (9)
\]

In practice, we use a few techniques to improve the stability and performance of UBVI:

**Component Initialization** The performance of variational boosting methods is often sensitive to the choice of initialization in each component optimization. The initialization used in this work is based on the intuition that after the first component optimization, each subsequent optimization will typically do one of two things: either it will find a new mode, or it will attempt to refine a previously found mode. If we wish to refine a previous mode, it is useful to initialize the optimization near that mode with a similar covariance structure. If we wish to discover a new mode, it is preferable to sample an initialization from the present distribution with significant added noise. In the experimental section of this work, we take the middle ground. We first sample a component from the current mixture approximation. Then, we generate an initialization for the Gaussian mean by sampling from that component with its covariance increased by a factor of 4. Finally, we initialize the covariance by using that component’s covariance multiplied by a standard log-normal random variable.

**Objective Transformation** We maximize \( \log(J(x)) \mathbb{1}_{[J(x) \geq 0]} - \log(-J(x)) \mathbb{1}_{[J(x) < 0]} \), where \( J(x) \) is the objective in Eq. [9], to avoid vanishing gradients and handle possible negativity; while this technically makes the Monte Carlo-based stochastic gradient estimates biased, it significantly improves performance in practice.

**Parametrization** The choice of parametrization can have a significant effect on the conditioning of the optimization problem. Although we exploit the properties of the exponential family for \( Z_{ij} \) evaluation in Eq. [9], we do not use the natural parametrization during optimization. In particular, for the multivariate Gaussian component family used throughout this work, we optimize over the mean and covariance Cholesky factor.

**Large-Scale Data** If the target density \( p \) arises from a Bayesian posterior inference problem with a large dataset, computing \( p \) and its gradients exactly in each component optimization iteration is expensive. Thus, we use a Monte Carlo minibatch approximation with uniformly subsampled data per [29]. Again, this provides biased gradient estimates, but works well in practice.

**Estimating \( \langle f, g \rangle \)** We use different numbers of samples for the component optimization stochastic gradient estimates and the estimates of \( \langle f, g_n \rangle \) (Line 9, Algorithm 1) required to solve the UBVI weight optimization. In particular, we use a relatively high number of samples (70,000 in our experiments) for estimating \( \langle f, g_n \rangle \), as these each need to be estimated only once, and they have a high impact on the choice of weights and thus future components; and for stochastic optimization, we use a relatively low number of samples (100 in our experiments) to avoid overly expensive component optimizations.

B Additional experimental details and results

The standard Cauchy distribution used in the synthetic experiment in Section 5 has density

\[
p(x) = \frac{1}{\pi} \frac{1}{1 + x^2},
\]

and can be simulated from by generating \( U, V \sim \mathcal{N}(0, 1) \) and setting \( X = U/V \). The banana distribution with curvature \( b \geq 0 \) in two dimensions has density

\[
p(x, y) \propto \exp \left( -x^2/200 - (y + bx^2 - 100b^2/2) \right),
\]
Figure 4: A comparison of the forward and reverse KL divergence vs. computation time for the Cauchy (4a) and banana (4b) distributions.

and can be simulated from by generating $U \sim \mathcal{N}(0, 100)$, $V \sim \mathcal{N}(0, 1)$, and setting $X = U$ and $Y = V - bU^2 + 100b$. The logistic regression model we used is as follows: for labelled data $(Y_n, X_n)$ with $Y_n \in \{-1, 1\}$ and $X_n \in \mathbb{R}^D$.

$$A_{ij} \sim \mathcal{N}(0, 1) \quad \Sigma = A^T A \in \mathbb{R}^{D+1} \quad \mu = 0 \quad \nu = 2$$

$$\theta \sim \mathcal{T}_\nu(\mu, \Sigma) \quad Y_n \sim \text{Bern}\left(\frac{1}{1 + e^{-Z_n^T \theta}}\right) \quad Z_n = \begin{bmatrix} X_n^T, 1 \end{bmatrix}^T.$$  

The choice of a multivariate-t prior on $\theta$ both reflects the fact that some features are far more relevant for prediction than others and yields a more complex posterior structure than that of a normal prior, making the problem better-suited to evaluating boosting variational methods. We used three different datasets in the logistic regression experiment: a synthetic dataset with $N = 10,000$ data points with covariate $x_n \sim \mathcal{N}(0, I)$, and label $y_n \in \{-1, 1\}$ generated from the logistic likelihood with parameter $\theta = [3, 3, 0]^T$; a phishing websites dataset with $N = 11,055$ data points reduced to $D = 10$ features via principal component analysis (available online at https://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/binary.html); and a chemical reactivity dataset with $N = 26,733$ data points each with $D = 10$ features (available online at http://komarix.org/ac/ds/).

Fig. 4 provides an additional comparison in the Cauchy and banana experiments with KL divergence plotted vs. computation time. The colors, dots, and whiskers have the same meaning as in Fig. 3.

C Proofs

C.1 Proof of gradient boosting BVI behaviour

Proof of Proposition 1. Let $\phi(x; \sigma^2)$ be the normal density with mean 0 and variance $\sigma^2$. Then given an initialization with a single component with variance $\tau^2$, the optimization solved at the next time step is [27]

$$\sigma^+ = \arg\min_{\sigma^2} \int \phi(x; \sigma^2) \log \frac{\phi(x; \sigma^2 \lambda \phi(x; \tau^2))}{\phi(x; 1)} dx$$

$$= \arg\min_{\sigma^2} -\lambda \log \sigma - \frac{\sigma^2}{2\tau^2} + \frac{\sigma^2}{2}$$

$$= \begin{cases} \infty & \tau^2 \leq 1 \\ \frac{\sigma^2}{\tau^2} & \tau^2 > 1 \end{cases}$$

Therefore, if the initialization has variance $\tau^2$ less than 1 the component optimization is degenerate. Note that for any two variances $\sigma_1^2$, $\sigma_2^2$, the weight optimization is

$$w^* = \arg\min_{w \in [0, 1]} \int \left( w\phi(x; \sigma_1^2) + (1 - w)\phi(x; \sigma_2^2) \right) \log \left( \frac{w\phi(x; \sigma_1^2) + (1 - w)\phi(x; \sigma_2^2)}{\phi(x; 1)} \right) dx$$

$$= \arg\min_{w \in [0, 1]} w \frac{\sigma_1^2}{2} - w \frac{\sigma_2^2}{2} + \int \left( w\phi(x; \sigma_1^2) + (1 - w)\phi(x; \sigma_2^2) \right) \log \left( \frac{w\phi(x; \sigma_1^2) + (1 - w)\phi(x; \sigma_2^2)}{\phi(x; 1)} \right) dx,$$
Proof of Proposition 5.\[\]

Rearranging the definition of Hellinger distance squared,
\[
\frac{d}{dw} = \frac{\sigma_1^2 - \sigma_2^2}{2} + \int (\phi(x; \sigma_1^2) - \phi(x; \sigma_2^2)) \log(w\phi(x; \sigma_1^2) + (1-w)\phi(x; \sigma_2^2)) \, dx
\]
\[
= \sigma_1^2 - \log \sigma_2^2 - \frac{\sigma_2^2 + \log \sigma_2^2}{2} - D_{\text{KL}}(\mathcal{N}_1 \| w\mathcal{N}_1 + (1-w)\mathcal{N}_2) - D_{\text{KL}}(\mathcal{N}_2 \| w\mathcal{N}_1 + (1-w)\mathcal{N}_2)
\]

In other words, if \(\sigma_2 > \sigma_1 > 1\) so that \(\sigma_1^2 - \log \sigma_2^2 > 0\), the derivative is always negative, and the optimization sets \(w = 1\) and forgets the new component. This holds if \(\sigma_1^2 = \tau^2 > 1, \sigma_2^2 = \lambda \tau^2 > \tau^2\), and
\[
\lambda \tau^2 - \log \lambda \tau^2 > (\tau^2 - 1)(\tau^2 - \log \tau^2).
\]

\[
\square
\]

C.2 Proofs of Hellinger distance properties

Proof of Proposition 3. This follows from
\[
D_H^2(p, q) = \frac{1}{2} \int (f(x) - g(x))^2 \mu(\,dx) \leq \frac{1}{2} \int |f(x) - g(x)| \, (f(x) + g(x)) \mu(\,dx)
\]
\[
= \frac{1}{2} \int |f^2(x) - g^2(x)| \, \mu(\,dx) = D_{\text{TV}}(p, q)
\]
and
\[
D_{\text{TV}}(p, q) = \frac{1}{2} \int |f^2(x) - g^2(x)| \, \mu(\,dx)
\]
\[
= \frac{1}{2} \sqrt{\int |f(x) - g(x)|^2 \mu(\,dx)} \sqrt{\int (f(x) + g(x))^2 \mu(\,dx)}
\]
\[
= \frac{1}{2} \sqrt{\int (f(x) - g(x))^2 \mu(\,dx)} \sqrt{\int (f(x) + g(x))^2 \mu(\,dx)}
\]
\[
= \frac{1}{\sqrt{2}} D_H(p, q) \sqrt{2 + 2 \int f(x)g(x) \mu(\,dx)}
\]
\[
= D_H(p, q) \sqrt{2 - D_H^2(p, q)}.
\]

\[
\square
\]

Proof of Proposition 7. Combining a bound on the \(\ell\)-Wasserstein distance [50 Theorem 6.15],
\[
W_\ell^2(p, q) \leq 2^\ell - 1 \int d(x_0, x)^\ell |p(x) - q(x)| \mu(\,dx),
\]
with \(|p(x) - q(x)| = |\sqrt{p(x)} - \sqrt{q(x)}| (\sqrt{p(x)} + \sqrt{q(x)})\), Cauchy-Schwarz, and Proposition 3 implies
\[
W_\ell^2(p, q) \leq 2^{\ell - 1/2} D_H(p, q) \sqrt{\int d(x_0, x)^{2\ell} \left(\sqrt{p(x)} + \sqrt{q(x)}\right)^2 \mu(\,dx)}.
\]
Finally, since \((a + b)^2 \leq 2a^2 + 2b^2\) for \(a, b \in \mathbb{R}\),
\[
W_\ell^2(p, q) \leq 2\ell D_H(p, q) \sqrt{\int d(x_0, x)^{2\ell} (p(x) + q(x)) \mu(\,dx)}.
\]

\[
\square
\]

Proof of Proposition 5. Rearranging the definition of Hellinger distance squared,
\[
D_H^2(p, q) = \frac{1}{2} \int \left(\sqrt{\frac{p(x)}{q(x)}} - \sqrt{\frac{q(x)}{p(x)}}\right)^2 \mu(\,dx)
\]
\[
= \frac{1}{2} \int p(x)\frac{q(x)}{p(x)} \left(\sqrt{\frac{p(x)}{q(x)}} - 1\right)^2 \mu(\,dx).
\]

14
For $x > 1$, $x^{-1} (\sqrt{x} - 1)^2 \geq \left( \frac{\log x}{1 + \log x} \right)^2$, and for $x \leq 1$, $x^{-1} (\sqrt{x} - 1)^2 \geq (\log x)^2$, so

$$D_H^2 (p, q) \geq \frac{1}{2} \int_{p > q} p(x) \left( \frac{\log \frac{p(x)}{q(x)}}{1 + \log \frac{p(x)}{q(x)}} \right)^2 \mu(\text{dx}) + \frac{1}{2} \int_{p < q} p(x) \left( \frac{\log \frac{p(x)}{q(x)}}{1 + \log \frac{p(x)}{q(x)}} \right)^2 \mu(\text{dx}).$$

Now using the relation $2a^2 + 2b^2 \geq (a + b)^2$,

$$D_H^2 (p, q) \geq \frac{1}{4} \int p(x) \left( [p > q] \frac{\log \frac{p(x)}{q(x)}}{1 + \log \frac{p(x)}{q(x)}} + [p \leq q] \log \frac{p(x)}{q(x)} \right)^2 \mu(\text{dx})$$

$$= \frac{1}{4} \int p(x) \left( \frac{[p > q] \log \frac{p(x)}{q(x)}}{1 + \log \frac{p(x)}{q(x)}} + [p \leq q] \log \frac{p(x)}{q(x)} \right)^2 \mu(\text{dx})$$

$$= \frac{1}{4} \int p(x) \left( \log \frac{p(x)}{q(x)} \right)^2 \left( 1 + \frac{1}{1 + \log \frac{p(x)}{q(x)}} \right)^2 \mu(\text{dx}).$$

This provides the first result. Using the reverse Hölder inequality $\|fg\|_1 \geq \|f\|_p \|g\|_q$, for $p = 2 \in (1, \infty)$,

$$D_H^2 (p, q) \geq \frac{1}{4} \left( \int p(x) \log \frac{p(x)}{q(x)} \mu(\text{dx}) \right)^2 \left( \int p(x) \left( \frac{1 + \log \frac{p(x)}{q(x)}}{1 + \log \frac{p(x)}{q(x)}} \right)^2 \mu(\text{dx}) \right)^{-1}$$

$$= \frac{1}{4} \mathcal{D}_{KL}^2 (p||q) \left[ \mathbb{P} \left( \log \frac{p(x)}{q(x)} \leq 0 \right) + \int p(x) \mathbb{I} \left[ \log \frac{p(x)}{q(x)} > 0 \right] \left( 1 + \log \frac{p(x)}{q(x)} \right)^2 \mu(\text{dx}) \right]^{-1}$$

$$\geq \frac{1}{4} \mathcal{D}_{KL}^2 (p||q) \left( 1 + \int p(x) \left( 1 + \log \frac{p(x)}{q(x)} \right)^2 \mu(\text{dx}) \right)^{-1}.$$

\[\square\]

**Proof of Proposition** This proof uses a technique adapted from \[33,\] Theorem 1.1. Let $Y \sim p(y)\mu(\text{dy})$, $X \sim q(x)\mu(\text{dx})$, and for $a \geq 0$,

$$\rho(x) := \left| 1 - \frac{q(x)}{p(x)} \right|^2$$

$$h(x) := \phi(x) \mathbb{I} [\rho(x) \leq a].$$

Then by Cauchy-Schwarz,

$$\mathbb{E} \left[ \|I_n(\phi) - I_n(h)\| \right] \leq \|\phi\|_{L^2(\mu)} \sqrt{\mathbb{P} (\rho(Y) > a)}$$

(10)

$$|I(\phi) - I(h)| \leq \|\phi\|_{L^2(\mu)} \sqrt{\mathbb{P} (\rho(Y) > a)}$$

(11)

$$\mathbb{E} \left[ \|I_n(h) - I(h)\| \right] \leq \sqrt{N}^{-1} \sqrt{\text{Var} \left( \frac{p(X)}{q(X)} \phi(X) \mathbb{I} [\rho(X) \leq a] \right)}.$$

(12)

Now note that

$$\text{Var} (\ldots) \leq \mathbb{E} \left[ \frac{p^2(X)}{q^2(X)} \phi(X)^2 \mathbb{I} [\rho(X) \leq a] \right]$$

$$= \mathbb{E} \left[ \frac{p(Y)}{q(Y)} \phi(Y)^2 \mathbb{I} [\rho(Y) \leq a] \right]$$

and for $a \in [0, 1)$, $\rho(x) \leq a$ implies

$$\sqrt{\frac{q(x)}{p(x)}} \geq 1 - \sqrt{a} \quad \Rightarrow \quad \frac{p(x)}{q(x)} \leq (1 - \sqrt{a})^{-2}$$

So

$$\text{Var} (\ldots) \leq \|\phi\|_{L^2(\mu)}^2 \left( \frac{1}{1 - \sqrt{a}} \right)^2.$$
and hence
\[ \mathbb{E} \| I_n(h) - I(h) \| \leq \| \phi \|_{L^2(p)} \sqrt{N^{-1} \frac{1}{1 - \sqrt{a}}} \]

By Markov’s inequality,
\[ \mathbb{P}(\rho(Y) > a) \leq e^{-1} \mathbb{E} [\rho(Y)] = 2a^{-1} D^2_h(p, q) \]

So substituting and combining the three bounds from Eqs. (10) to (12) using the triangle inequality,
\[ \mathbb{E} \| I_n(\phi) - I(\phi) \| \leq \| \phi \|_{L^2(p)} \left( \frac{1}{\sqrt{N(1 - \sqrt{a})}} + \sqrt{8a^{-1} D^2_h(p, q)} \right) \]

Optimizing over \( a \) yields
\[ \sqrt{a} = \frac{8^{1/4} D^2_h(p, q)^{1/2}}{8^{1/4} D^2_h(p, q)^{1/2} + N^{-1/4}} \]

and substituting with \( 8^{1/4} \leq 2 \)
\[ \mathbb{E} \| I_n(\phi) - I(\phi) \| \leq \| \phi \|_{L^2(p)} \left( N^{-1/4} + 2 \sqrt{D^2_h(p, q)} \right)^2 \]

Setting \( N = a^{-4} D^2_h(p, q)^{-2} \) yields the first result. For the second, note that \( |I_n(\phi) - I(\phi)| \leq \| \phi \|_{L^2(p)} \delta \) and \( |I_n(1) - 1| \leq \eta \) implies that
\[ |J_n(\phi) - I(\phi)| = \frac{|I_n(\phi) - I_n(1) I(\phi)|}{I_n(1)} \leq \frac{|I_n(\phi) - I(\phi)| + |I(\phi)| |I_n(1) - 1|}{1 - |I_n(1) - 1|} \leq \| \phi \|_{L^2(p)} \frac{\delta + \eta}{1 - \eta}, \]

so
\[ \mathbb{P} \left( |J_n(\phi) - I(\phi)| > \| \phi \|_{L^2(p)} \frac{\delta + \eta}{1 - \eta} \right) \leq \mathbb{P} \left( |I_n(\phi) - I(\phi)| > \| \phi \|_{L^2(p)} \delta \right) + \mathbb{P} \left( |I_n(\phi) - 1| > \eta \right), \]

which by Markov inequality and the previous bound,
\[ \mathbb{P} \left( |J_n(\phi) - I(\phi)| > \| \phi \|_{L^2(p)} \frac{\delta + \eta}{1 - \eta} \right) \leq \left( N^{-1/4} + 2 \sqrt{D^2_h(p, q)} \right) (\delta^{-1} + \eta^{-1}) \]

Minimizing \( \delta^{-1} + \eta^{-1} \) subject to the constraint that \( t = (\delta + \eta)/(1 - \eta) \) yields the result. \( \square \)

**Proof of Proposition 7** For the first bound, by Jensen’s inequality
\[ \mathbb{E} \left[ D_{\overline{h}}(p, q) - D_h^2(p, q) \right] \leq \sqrt{\frac{1}{N} \sum_{n=1}^{N} \sqrt{\frac{p(X_n)}{q(X_n)}}} \]
\[ = \sqrt{\frac{1}{N} \sum_{n=1}^{N} \sqrt{\frac{p(X_n)}{q(X_n)}}} \]
\[ = \sqrt{\frac{1}{N} \sum_{n=1}^{N} \sqrt{1 - \left( \int q(x)p(x)dx \right)^2}} \]
\[ = \sqrt{\frac{1}{N} \sum_{n=1}^{N} \sqrt{D^2_h(p, q)(2 - D^2_h(p, q))}} \]

For the second bound, using the triangle inequality, and cancelling out normalization constants
\[ \mathbb{E} \left[ D_{\overline{h}}(p, q) - D_h^2(p, q) \right] \leq \mathbb{E} \left[ \frac{1}{N} \sum_{n=1}^{N} \sqrt{\frac{p(X_n)}{q(X_n)}} \right] \left[ 1 - \sqrt{\mathbb{E} \left[ \frac{p(X_n)}{q(X_n)} \right]} \right] \]
\[ + \mathbb{E} \left[ \sqrt{\mathbb{E} \left[ \frac{p(X_n)}{q(X_n)} \right]} - \frac{1}{N} \sum_{n=1}^{N} \sqrt{\frac{p(X_n)}{q(X_n)}} \right] \]

By Jensen’s inequality on the left term and Cauchy-Schwarz on the right, and noting that \( \mathbb{E} [p/q] = 1 \),
\[ \mathbb{E} \left[ D_{\overline{h}}(p, q) - D_h^2(p, q) \right] \leq \mathbb{E} \left[ 1 - \sqrt{\frac{1}{N} \sum_{n=1}^{N} \frac{p(X_n)}{q(X_n)}} \right] + \sqrt{\frac{2}{N} D_h(p, q)} \]
The left term can be bounded via Cauchy-Schwarz and Jensen’s inequality:

$$E \left[ 1 - \sqrt{\frac{1}{N} \sum_{n=1}^{N} p(X_n)} \right] \leq \sqrt{2 \cdot 2E \left[ \frac{1}{N} \sum_{n=1}^{N} p(X_n) \right]}$$

$$\leq \sqrt{2 \cdot 2 \left[ \frac{1}{N} \sum_{n=1}^{N} \sqrt{p(X_n)} \right]}$$

$$= \sqrt{2D_H(p, q)}$$

Combining these results yields the second inequality.

\[\Box\]

C.3 Theoretical tools for establishing convergence of Algorithm 1

Lemma 8. Define $\hat{f} := \arg\min_{h \in \text{cl span } H} \|f - h\|_2$. Then $\hat{f}$ exists, is unique, and is nonnegative.

Proof of Lemma 8 Since cl span $H$ is a closed convex set, there exists a unique function $\hat{f}'$ of minimum distance to $f$. Note that $\hat{f}'$ is nonnegative since $f$ is nonnegative, so otherwise $\hat{f}'$ could be replaced with $\max\{0, \hat{f}'\}$ without increasing the distance to $f$. Furthermore, the error $\epsilon := f - \hat{f}'$ is orthogonal to cl span $H$. Since $f$ is not orthogonal to cl span $H$, $\hat{f}' \neq 0$, so set $\hat{f} = \frac{\hat{f}'}{\|\hat{f}'\|_2}$. Suppose there is another unit-norm function $g \in \text{cl span } H$ at least as close to $f$; then

$$0 \geq \langle f, \frac{\hat{f}'}{\|\hat{f}'\|_2} - g \rangle = \langle f + \epsilon, \frac{\hat{f}'}{\|\hat{f}'\|_2} - g \rangle = \langle \hat{f}', \frac{\hat{f}'}{\|\hat{f}'\|_2} - g \rangle$$

$$= \|\hat{f}'\|_2 - \langle \hat{f}', g \rangle.$$  

Dividing both sides by $\|\hat{f}'\|_2$ yields the inequality $\langle \hat{f}', g \rangle \geq 1$, implying that $g = \hat{f}$, and thus $\hat{f}$ is unique. \[\Box\]

Lemma 9. $\tau \leq \frac{(\hat{f}, g_1)}{1 - (\hat{f}, g_1)} < \infty$.

Proof of Lemma 9 Set $h_1 = \langle \hat{f}, g_1 \rangle g_1$ where $g_1$ is chosen from Eq. (4), and $\forall i > 1$, set $h_i = 0$. Since $\hat{f}$ is not orthogonal to cl span $H$, $\langle \hat{f}, g_1 \rangle > 0$, so $\tau < \infty$. \[\Box\]

Lemma 10. Suppose at each iteration, the optimization in Eq. (3) is solved with multiplicative error $(1 - \delta)$ relative to the optimal objective. Then

$$J_{n+1} \leq J_n(1 - J_n)$$

where $J_n := \left( \frac{1 - \delta}{\tau} \right)^2 \left( 1 - \langle \hat{f}, g_n \rangle \right)^2$.

Proof of Lemma 10. Taking the derivative of the objective in Eq. (3) with respect to $x$ and setting to zero, the solution is

$$x^* = \sqrt{\frac{\langle f, \frac{h - (h, g_n) g_n}{h - (h, g_n) g_n} \rangle^2}{\langle f, \frac{h - (h, g_n) g_n}{h - (h, g_n) g_n} \rangle^2 + (\hat{f}, g_n)^2}}.$$  

(13)

Suppose at iteration $n + 1$, instead of $g_{n+1}$ we obtain a function $h$ satisfying a $(1 - \delta)$-relative approximation to Eq. (4). Then using the optimal value for $x^*$ from Eq. (13), noting that the quadratic weight optimization provides at least as much error reduction as the geodesic update with $x^*$, and noting that $f = f' + \epsilon$ where $\epsilon \perp \text{cl span } H$ and $f'$ is from the proof of Lemma 8, we find the recursion

$$\|\hat{f}'\|_2^2 - \langle \hat{f}', g_n \rangle^2$$

$$= \left( \|\hat{f}'\|_2^2 - \langle \hat{f}', g_n \rangle^2 \right) \left( 1 - \frac{\hat{f}' \hat{f}'^T - \hat{f}' g_n \hat{g}_n^T}{\|\hat{f}' \hat{f}'^T - \hat{f}' g_n \hat{g}_n^T\|} \frac{h - (h, g_n) g_n}{\|h - (h, g_n) g_n\|^2} \right)^2.$$  

17
Denoting $J$ the definition of $J$, by [10, Lemma A.6], the recursion Lemma 10 satisfies the proof of Theorem 2.

Now again using the fact that $\epsilon \perp \text{cl span } \mathcal{H}$ as well as the fact that $g_{n+1}$ is the argmax of Eq. (4), we can replace $g_{n+1}$ with any convex combination of other elements of $\mathcal{H}$, so

$$
\parallel \hat{f}' \parallel^2 - \langle \hat{f}', \bar{g}_n \rangle^2
\leq (\parallel \hat{f}' \parallel^2 - \langle \hat{f}', \bar{g}_n \rangle^2)
\left(1 - (1 - \delta)^2 \left( \frac{\parallel \hat{f} - \langle \hat{f}, \bar{g}_n \rangle \bar{g}_n \parallel - \langle \hat{f}, \bar{g}_n \rangle \bar{g}_n \| g_{n+1} - \langle g_{n+1}, \bar{g}_n \rangle \bar{g}_n \| }{\| g_{n+1} - \langle g_{n+1}, \bar{g}_n \rangle \bar{g}_n \|} \right)^2 \right).
$$

where $D = \sum \parallel h_i \parallel \parallel h_i - \langle h_i, \bar{g}_n \rangle \bar{g}_n \parallel$. Define $\nu := \sum_i h_i - \hat{f}$. Again using $\epsilon \perp \text{cl span } \mathcal{H}$, and normalizing the left vector by $\parallel \hat{f}' \parallel$ yields

$$
\parallel \hat{f}' \parallel^2 - \langle \hat{f}', \bar{g}_n \rangle^2
\leq (\parallel \hat{f}' \parallel^2 - \langle \hat{f}', \bar{g}_n \rangle^2)
\left(1 - (1 - \delta)^2 \sup_{h_i \in \text{ cone } \mathcal{H}} \left( \frac{\parallel \hat{f} - \langle \hat{f}, \bar{g}_n \rangle \bar{g}_n \parallel - \langle \hat{f}, \bar{g}_n \rangle \bar{g}_n + \nu - \langle \nu, \bar{g}_n \rangle \bar{g}_n \| }{D} \right)^2 \right).
$$

Now noting that the inner term is minimized when $\nu = -\parallel \hat{f}\parallel$, we have that

$$
\leq (\parallel \hat{f}' \parallel^2 - \langle \hat{f}', \bar{g}_n \rangle^2)
\left(1 - \sup_{h_i \in \text{ cone } \mathcal{H}} \frac{(1 - \delta)^2 \parallel \nu \parallel^2}{D^2} (1 - \langle \hat{f}, \bar{g}_n \rangle^2) \right).
$$

Finally, dividing both sides by $\parallel \hat{f}' \parallel^2$ and noting that $D \leq \sum \parallel h_i \parallel$,

$$
1 - \langle \hat{f}, \bar{g}_{n+1} \rangle^2 \leq 1 - \langle \hat{f}, \bar{g}_n \rangle^2 \left(1 - \frac{(1 - \delta)^2}{\tau} \right) \left(1 - \langle \hat{f}, \bar{g}_n \rangle^2 \right).
$$

Denoting $J_n = \left(\frac{1 - \delta}{\tau}\right)^2 \left(1 - \langle \hat{f}, \bar{g}_n \rangle^2 \right)$, and multiplying both sides by $\left(\frac{1 - \delta}{\tau}\right)^2$ yields the recursion

$$
J_{n+1} \leq J_n (1 - J_n).
$$

Proof of Theorem 2. By [88] Lemma A.6, the recursion Lemma 10 satisfies $J_n \leq \frac{D}{1 + \rho_d m}$. Substituting the definition of $J_n$ and noting that $D_{\rho_d} (\hat{p}, \bar{q}_n)^2 = 1 - \langle \hat{f}, \bar{g}_n \rangle \leq 1 - \langle \hat{f}, \bar{g}_n \rangle^2$ yields the result.

\[ \square \]
