Abstract. The average residence time of energy in Earth’s atmosphere is estimated. It amounts to about 56 days. For the Sun, the residence time is about $2.6 \times 10^7$ yr, which agrees with the Kelvin-Helmholtz time scale.

Keywords: Residence time of energy, Kelvin-Helmholtz time scale, energy balance.
1. Introduction

When the inflow, $F_i$, of any substance into a box is equal to the outflow, then the amount of that substance in the box, $M$, is constant. This constitutes an equilibrium or steady state. Then the ratio of the stock in the box to the flow rate (in or out) is called the residence time and is a time scale for the transport of the substance in the box.

$$t = \frac{M}{F}. \quad (1)$$

We refer to a measurable and conserved substance. A good example of this type is the parameter defined in atmospheric chemistry as the average residence time of each individual gas, defined as (1). $M$ is the total average mass of a gas in the atmosphere and $F$ the total average influx or outflux. In time the averages for the whole atmosphere are equal. In this paper we want to extend the substance that flows from matter to energy, and estimate the average residence time of energy in Earth’s atmosphere and in the Sun. The first law of Thermodynamics guarantees that there is nothing improper in our purpose. Both cases correspond to steady state problems because the storage of energy in the atmosphere and in the Sun are not systematically increasing or decreasing.

We want to emphasize that the ideas used in this paper are familiar in undergraduate courses of atmospheric physics\cite{1} or astrophysics\cite{2}.

In section 2, we consider the Earth’s atmosphere as a big box and use the energy data to estimate (1). Then we compute the corresponding time of residence. Due to the educational nature of this journal, in section 3 we compute the static energy of an air column using two academic methods. This will likely increase the interest of this paper for the instructor in undergraduate courses of atmospheric or environmental science\cite{3}. In the first method we perform a numerical sum of the pressure data offered in the US Standard Atmosphere. In the second method, we assume that pressure varies with height exponentially.

Analogously to the process described in section 3, in section 4 we have used Standard Solar Model tables to compute the Sun’s global energy. Dividing by the solar luminosity, we estimate the residence time of energy in the Sun. This residence time agrees with the Kelvin-Helmholtz time scale. In section 5 we present a brief discussion and our conclusions.

2. Forms of energy in the atmosphere and time of residence.

In this section we use the energy data provided by Peixoto and Oort in \cite{4}. The most important forms of energy in the atmosphere are: the thermodynamic internal energy, $U$; the potential energy due to Earth’s gravity, $P$; the kinetic energy, $K$; and the latent energy, $L$, related to the phase transitions of water.

$$E = U + P + K + L. \quad (2)$$
The values quoted by these authors per unit surface in units of $10^7 \text{ J m}^{-2}$ are:

$$U = 180.3, \quad P = 69.3, \quad K = 0.123, \quad L = 6.38, \quad E = 256.1$$ (3)

Note that the sum $S = U + P = 249.6$, which constitutes the static energy of the atmosphere, is the main component.

For our purpose of computing the time of residence using (1), now we only need the inputs, or outputs, of energy in the atmosphere. For this, we use the data cited by Schneider [5]. It is common to express this data in units of $e = 3.45 \text{ W m}^{-2}$, because $e$ is a percentage of the solar irradiance out of the atmosphere. The atmosphere absorbs $25 \, e$ of solar energy, $29 \, e$ are absorbed at the surface as sensible and latent heats, and finally it absorbs $100 \, e$ long wave radiation emitted by the surface. The radiation emitted by the surface is $104 \, e$, but $4 \, e$ escapes to space through the so-called atmospheric window. Thus the total energy input in the atmosphere is:

$$F_i = 25 \, e + 29 \, e + 100 \, e = 154 \, e = 531 \text{ W m}^{-2}.$$ (4)

We identify two terms for the emitted energy flux, the component emitted into space, $66 \, e$, and that emitted to the planet surface, commonly denoted as the greenhouse effect, $88 \, e$. The sum of the outgoing terms coincides with that of the ingoing terms, $F_o = F_i = F$. Then, the estimation of the residence time of energy in our atmosphere, $t$, is:

$$t = \frac{E}{F} = \frac{256 \times 10^7 \text{ J m}^{-2}}{531 \text{ W m}^{-2}} = 4.82 \times 10^6 \text{ s} \approx 56 \text{ days.}$$ (5)

3. Estimation of the static energy in a column of air

As stated in section 2, the static energy $S = U + P$ is the main component of energy in the atmosphere. Here we show the link between $U$ and $P$.

$$P = \int_0^\infty g \rho z \, dz.$$ (6)

Pressure is denoted by $p$, $g$ is the acceleration of gravity; $\rho$, the mass density and $z$ the height. The upper limit $\infty$ stands for a height where pressure can be considered negligible. Using the differential relation of hydrostatic equilibrium and then integrating by parts:

$$dp = -\rho g \, dz,$$ (7)

$$P = \int_{p_0}^0 - z \, dp = 0 + \int_0^\infty p \, dz.$$ (8)

Regarding $U$,

$$U = \int_0^\infty c_v \rho T \, dz.$$ (9)

Using the equation of state of ideal gases in (8)

$$P = \int_0^\infty p \, dz = \int_0^\infty R \rho T \, dz.$$ (10)
Residence time of energy in Earth’s atmosphere and in the Sun

Then
\[
\int_0^\infty \rho T \, dz = \frac{P}{R}.
\] (11)

Thus,
\[
S = P + c_v \frac{P}{R} = \left( \frac{c_v + R}{R} \right) = \frac{c_p}{R} P.
\] (12)

\( R, c_v \) and \( c_p \) are the gas constant for dry air, and their specific heats at constant volume and constant pressure, respectively. Since for ideal diatomic gases the ratio \( c_p/R = 3.5 \), the computation of \( S \) requires only the calculation of the pressure integral, \( P \).

A first method (subindex 1) to estimate \( P \) is using the pressure data provided by the US Standard Atmosphere [6]. We have approximated the integral (8) as the sum:
\[
P_1 = \sum_{0}^{80 \text{Km}} p_i \Delta z_i.
\] (13)

The results for \( P_1 \) and \( S_1 \) are:
\[
P_1 = 7.55 \times 10^8 \text{ J m}^{-2}
\] (14)
\[
S_1 = 2.64 \times 10^9 \text{ J m}^{-2}.
\] (15)

An alternative second method (subindex 2) to compute \( P \) is to assume that pressure varies with height exponentially way:
\[
p(z) = p_0 \exp(-z/H).
\] (16)

We know that pressure is rigorously exponential with height only if the atmosphere is isothermal. Notwithstanding, using this exponential hypothesis with \( p_0 = 1.01325 \times 10^5 \) Pa, and a height scale \( H \approx 6.5 \text{ Km} \), the fit of the global data pressure (not only in the troposphere) is sufficiently good for our purposes. Thus, adopting (16), the results for \( P \) and \( E \) are:
\[
P_2 = p_0 H = 6.58 \times 10^8 \text{ J m}^{-2}
\] (17)
\[
S_2 = 3.5p_0 H = 2.3 \times 10^9 \text{ J m}^{-2}.
\] (18)

Note that both approximate methods provide the correct order of magnitude for the energy of a column of air but the first is an overestimation of \( E \).

4. Estimation of the solar energy and the time or residence of energy in the Sun

The order of magnitude of the solar energy, \( E \), can be estimated using the pressure data of a Standard Solar Model of the Sun [7].

The Virial Theorem provides the following relations:
\[
-E_{grav} = 3P
\] (19)
\[
E_{therm} = \frac{3}{2}P.
\] (20)
Where $P$ stands for
\[ P = \int_{0}^{R_{\odot}} p \, dr^3. \quad (21) \]

\[ E = E_{grav} + E_{therm} = \frac{-3}{2} P \]
\[ (22) \]

Note that the total energy, $E$, the gravitational energy, the thermal energy and the integral $P$ are all of the same magnitude. Using the data from a Standard Model of the Sun, we have carried out the sum:
\[ P = \sum_{0}^{R_{\odot}} \frac{4\pi}{3} (r_{i+1}^3 - r_i^3) \left( \frac{P_{i+1} + P_i}{2} \right). \quad (23) \]

Where the index $i$ runs from the center up to the surface of the Sun. The result of the sum (23) times 3/2, is the estimation of $\|E\| \approx 10^{41}$ J.

The ratio between $\|E\|$ and the solar luminosity, $L_{\odot} = 3.82 \times 10^{26}$ W, is our result for the energy residence time in the Sun:
\[ t_{\odot} \approx 2.6 \times 10^7 \text{ yr}. \quad (24) \]

The Kelvin-Helmholtz (K-H) time scale, see for example [2] for the Sun is:
\[ t_{KH} = \frac{GM_{\odot}^2}{R_{\odot}L_{\odot}} = 3 \times 10^7 \text{ yr}. \quad (25) \]

This time scale is roughly the time needed by the star to settle to equilibrium after a global thermal perturbation.

As mentioned above, for stars in equilibrium, the total energy and the gravitational energy are of the same order of magnitude. The K-H time scale is nothing but
\[ t_{KH} \approx \frac{\|E_{grav}\|}{L_{\odot}}. \quad (26) \]

Therefore the time of residence of energy computed for the Sun in (24) is basically the same thing as the classical K-H time scale. Stix also estimated the same order of magnitude in [11] for the time scale of energy transport in the Sun.

5. Discussion

In this paper, we have considered our atmosphere as a big box where energy is in equilibrium, and have estimated its residence time. It amounts to about 56 days. When the same idea is applied to the Sun, we obtain $t \approx 2.6 \times 10^7$ yr.

In astrophysics, the question: how long a photon might take to get from the core of the Sun to the surface has frequently been put forward. The answer of several authors was $\approx 10^4$ yr, see [8, 9], etc. In 1989, Mitalas and Sills [10] pointed out that the average step length assumed by previous authors for a photon diffusing through the Sun was too long. Correcting this step length, they obtained $1.7 \times 10^5$ yr. Finally, invoking the large heat capacity of the interior of the star, Stix [11] corrected the previous result up to a time scale of the order of $3 \times 10^7$ yr, i.e. the K-H time scale.
Bearing in mind the explanation given in section 4, our conclusion for the residence time of energy in Earth’s atmosphere ($t \approx 56$ days) is that this is the equivalent of the K-H time scale for the Sun. Thus, after a global thermal perturbation, the atmosphere would need about a couple of months to return to equilibrium.
