Abstract

To follow up recent work of Xiao-Song Yang on the Nosé-Hoover oscillator we consider Dettmann’s harmonic oscillator, which relates Yang’s ideas directly to Hamiltonian mechanics. We also use the Hoover-Holian oscillator to relate our mechanical studies to Gibbs’ statistical mechanics. All three oscillators are described by a coordinate $q$ and a momentum $p$. Additional control variables $(\zeta, \xi)$ vary the energy. Dettmann’s description includes a time-scaling variable $s$, as does Nosé’s original work. Time scaling controls the rates at which the $(q, p, \zeta)$ variables change. The ergodic Hoover-Holian oscillator provides the stationary Gibbsian probability density for the time-scaling variable $s$. Yang considered qualitative features of Nosé-Hoover dynamics. He showed that longtime Nosé-Hoover trajectories change energy, repeatedly crossing the $\zeta = 0$ plane. We use moments of the motion equations to give two new, different, and brief proofs of Yang’s long-time limiting result.

Keywords: Nosé-Hoover Oscillator, Dettmann Oscillator, Hoover-Holian Oscillator, Nonlinear Dynamics
I. BACKGROUND

Nosé-Hoover dynamics was developed in 1984 as a side benefit of a Centre Européen de Calcul Atomique et Moléculaire ("CECAM") Workshop on Constrained Dynamics organized by Carl Moser. The workshop was held at Orsay, about 20 miles southwest of Paris. Shuichi Nosé and Bill Hoover met by chance at the Orly airport a few days prior to the Orsay meeting and were able to spend several hours together near Notre Dame cathedral, discussing Nosé’s recent work on the thermal control of molecular dynamics simulations.

Seeking better to understand Nosé’s innovative work Hoover applied Nosé’s ideas to the one-dimensional harmonic oscillator problem, solving the nonlinear set of three ordinary differential equations of motion for the oscillator:

\[
\begin{align*}
\dot{q} &= p \\
\dot{p} &= -q - \zeta p \\
\dot{\zeta} &= \left[ \frac{p^2 - 1}{\tau^2} \right]
\end{align*}
\]

Provided that the mean value of \( \zeta \) is finite the last equation implies that the mean oscillator temperature \( \langle p^2 \rangle \) is unity for long times. Posch, Hoover, and Vesely explored the detailed nature of the oscillator solutions for a variety of response times \( \tau \). They found periodic, toroidal, and fat-fractal chaotic trajectories, depending upon \( \tau \) and the initial values of \((q, p, \zeta)\). In the present work we choose \( \tau = 1 \).

II. CONSEQUENCES OF TIME SCALING

Carl Dettmann discovered a vanishing Hamiltonian which precisely reproduces the time-dependence of the Nosé-Hoover flow where the Nosé-Hoover momentum becomes \( (p/s) \).

\[
\mathcal{H}_D(q, p, s, \zeta) \equiv \langle s/2 \rangle \left[ q^2 + (p/s)^2 + \zeta^2 + \ln(s^2) \right] \equiv 0.
\]

The “time-scaling variable” \( s \) has the conjugate momentum \( p_s = \zeta \). Evidently \( |s| \) must be less than unity for \( \mathcal{H}_D \) to vanish. We select positive values, \( 0 < s < 1 \), in our numerical work. The various resulting flows can occupy one-, two-, or three-dimensional subspaces of the full stationary solution, the Gaussian function:

\[
(2\pi)^{-3/2} \exp[-(q^2 + (p/s)^2 + \zeta^2)/2].
\]

With this Gaussian distribution known the normalized probability density for \( s \) follows easily,

\[
\sqrt{(2/\pi) \ln(s^{-2})}.
\]
FIG. 1: Analytic and numerical probability densities for the time-scaling variable $s$. Both are based on the three-dimensional Gaussian distribution with numerical values from the Hoover-Holian model.

Figure 1 compares this analytic distribution to a thousand-point histogram from a fourth-order Runge-Kutta solution of the (ergodic) Hoover-Holian oscillator equations:

$$
\{ \dot{q} = p ; \dot{p} = -q - \zeta p - \xi p^3 ; \dot{\zeta} = p^2 - 1 ; \dot{\xi} = p^4 - 3p^2 \} .
$$

For the Figure $q$ and $p$ were initially unity and the two control variables were zero. Ten million timesteps, $dt = 0.001$, were used. The stationary distribution for the Hoover-Holian equations is the four-dimensional Gaussian $(2\pi)^{-2} \exp[ (-q^2 - p^2 - \zeta^2 - \xi^2)/2 ]$. Because the model is ergodic, covering the entire four-dimensional Gaussian, we were able to use the three-dimensional Hoover-Holian subset $(q^2, p^2, \zeta^2)$ data as a model for the stationary Dettmann distribution $(q^2, (p/s)^2, \zeta^2)$ with $s$ determined from the condition $H_D \equiv 0$. These numerical data, confirming our analytic work, are shown in Figure 1.

Following up his earlier investigations of oscillator trajectories (including knots), Professor Xiao-Sung Yang has recently proved that the oscillator motion, independent of the chosen initial conditions, must nearly always cross the $\zeta = 0$ plane. The only exceptions are parallel lines at constant $p$ and $\zeta$:

$$
q(t) = q(0) \pm t ; \quad p(t) = p(0) = \pm 1 ; \quad \zeta(t) = \zeta(0) .
$$
In the present work we first consider oscillator trajectories from the standpoint of the continuity equation in \((q, p, \zeta)\) space. Because the Nosé-Hoover equations are not strictly Hamiltonian, except in the \(\mathcal{H}_D \equiv 0\) case discovered by Dettmann, the Nosé-Hoover flow is compressible – the three-dimensional divergence is locally nonzero, responding linearly to the control variable \(\zeta\):

\[
\left(\frac{\partial \dot{q}}{\partial q}\right) + \left(\frac{\partial \dot{p}}{\partial p}\right) + \left(\frac{\partial \dot{\zeta}}{\partial \zeta}\right) = 0 - \zeta + 0 \quad [\text{Dettmann} = \text{Nosé - Hoover}].
\]

Consider a longtime trajectory. Evidently a positive longtime average of \(\zeta\) would correspond to a vanishing of the comoving volume and a dimensionality loss. A negative average would correspond to divergence, a numerical instability. In fact, the continuity equation has been used to explain the fractal nature of chaotic flows with positive friction\(^{12}\).

In \((q, p, \zeta)\) space the continuity equation shows that the comoving volume element \(\otimes\) vanishes and can become fractal if the longtime-averaged control variable is positive. The volume diverges, and the simulation stops, if that averaged variable is negative. The motion equations for the oscillator, in either \((q, p, \zeta)\) space or \((q, p, s, p_s = \zeta)\) space, can also be used to prove Professor Yang’s zero-crossing result. We turn to that next.

III. PROOFS OF PROFESSOR YANG’S \(\zeta = 0\) PLANE RESULT

Yang’s recent contribution\(^{1}\) considers the three-variable Nosé-Hoover oscillator and shows algebraically that any longtime trajectory – other than the special constant \((p, \zeta)\) straight lines – must repeatedly cross the \(\zeta = 0\) plane. This is a handy result as the Poincaré sections at that plane are commonly used to diagnose the fractal character of nonlinear flows. Yang’s proof-of-crossing is relatively long, thirty pages, mainly algebra. Let us provide two simpler demonstrations of this result. Multiply the three motion equations by \(q\), \(p\), and \(\zeta\) respectively and compute the longtime averages \(\langle \ldots \rangle\) assuming that \(\langle q^2, p^2, \zeta^2 \rangle\) are finite (so that their time derivatives average to zero). The three Nosé-Hoover differential equations then give three identities:

\[
\{ \langle qp \rangle = 0 ; \langle qp \rangle = \langle -\zeta p^2 \rangle ; \langle \zeta \rangle = \langle \zeta p^2 \rangle \}.
\]

Combining the three shows that the mean value of \(\zeta\) vanishes, equivalent to Professor Yang’s result.
An even simpler demonstration follows from Nosé’s original Hamiltonian, \( H_N \equiv (1/s)H_D \), which gives a simple evolution equation for \( s : \dot{s} = p_s \). Because \( p_s \) and \( \zeta \) are identical, as shown by Dettmann, the time-average of the \( \dot{s} \) equation shows directly (assuming numerical convergence of the motion) that the control variable \( \zeta \) has mean value zero, again implying Yang’s result.

IV. AN AFTERWORD FOR YOUNG RESEARCHERS

Lingering questions remain where the chaotic sea is concerned. The sea is an enduring paradoxical concept. Is it a set of three-dimensional points? Is it a continuum? Is it a single chaotic trajectory? Is it an ill-defined limit? These questions remain at the research frontier.
