Abstract

Low rank approximation (LRA) of a matrix is a hot subject of modern computations. In application to Big Data mining and analysis the input matrices are so immense that one must apply sublinear cost algorithms, which only access a tiny fraction of the input entries and involve much fewer memory cells and flops\textsuperscript{1} than an input matrix has entries. Under this restriction the algorithms cannot compute accurate LRA of the worst case input matrix and even of the matrices of some small families specified in our Appendix\textsuperscript{A} but we recently prove that with a high probability (whp) some algorithms running at sublinear cost compute accurate LRA of a random matrix admitting LRA. This result is in good accordance with our tests and with more than a decade of worldwide computation of LRA by means of Cross-Approximation algorithms. A natural challenge is to complement such computations by the refinement of of an LRA at sublinear cost. We propose two algorithms for this task together with some heuristic recipes for a posteriori estimation of the errors of LRA at sublinear cost.

Key Words: Low-rank approximation, Sublinear cost, A posteriori error estimation, Iterative refinement

1 Introduction

(a) Accurate LRA at sublinear cost: the problem and our recent progress. LRA is a hot subject of Numerical Linear and Multilinear Algebra and Data Mining and Analysis, with applications ranging from machine learning theory and neural networks to term document data and DNA SNP data (see surveys [HMT11], [M11], and [KS16]). Matrices representing Big Data are

\textsuperscript{1}Flop is a floating point arithmetic operation.
usually so immense that realistically one can only access a tiny fraction of their entries, but quite typically these matrices admit LRA, that is, are close to low rank matrices \(^2\) with which one can operate by using sublinear memory space and arithmetic time, that is, much fewer memory cells and flops than an input matrix has entries.

Every LRA algorithm running at sublinear cost fails on a worst case input matrix and even on the small families of matrices of our Appendix A. In worldwide computational practice and in our extensive tests, however, some sublinear cost algorithms consistently compute reasonably accurate LRA of matrices admitting LRA, and the papers \[\text{PLSZ16, PLSZ17, Pl, PLSZa, PLSZb, and LPSa}\] provide some formal support for this empirical observation.\(^3\)

In various applications of LRA it is important to obtain as close LRA as possible, and then again we are challenged to achieve this at sublinear cost. In the present paper we propose two techniques for iterative refinement of a crude but reasonably close initial LRA at sublinear cost.

Our first approach naturally extends popular methods for iterative refinement of the solution as well as least squares solution of a linear system of equations (see \[\text{S98, Sections 3.3.4 and 4.2.5, H02, Chapter 12 and Section 20.5, DHK06, GL13 Sections 3.5.3 and 5.3.8, B15, Sections 1.4.6, 2.1.4, and 2.3.7}\]).

Such refinement algorithms are also known for other matrix computations, including nonlinear ones (see \[\text{S98, page 223 and the references on page 225}\]), but to the best of our knowledge have not been applied to LRA so far, possibly because the computation of LRA at sublinear cost has not been studied as much as it deserves. Our work seems to be the first attempt of this kind; our tests provide its empirical support.

Our second approach relies on recursive application of randomized algorithms of \[\text{DMM08}\], which compute LRA by means of random sampling of rows and columns of an input matrix. The probabilities directing random sampling are called leverage scores. The resulting LRA is nearly optimal whp, and the cost of its computation in \[\text{DMM08}\] is sublinear except for the auxiliary stage of computing the top right singular space of an input matrix.

If, however, we have a crude but reasonably close LRA of an input matrix, then we can approximate this space and leverage scores at sublinear cost. The approximations should be close if the LRA is close, and we can use these approximate scores in order to refine the LRA. We supply some relevant estimates for such heuristic refinement recipe; its formal support is a research challenge.

The proofs that LRA computed with using leverage scores are accurate are only known in the case where one samples a large number of rows and columns of an input matrix. Using large samples complicates practical use of these algorithms (see \[\text{TYUC17, Section 1.7.3}\]), but our simple Algorithm \[3.1\] provides a partial remedy at sublinear cost. Furthermore, empirically the algorithms of \[\text{DMM08}\], based on using leverage scores, output accurate LRA by means of sampling a reasonable number of rows and columns of an input matrix.

Formal support of this empirical observation and formal upper estimates for the distance of an input matrix to its initial LRA after which our algorithms refine these LRA are major research challenges. Our work seems to be the first step into a highly important research area and should motivate further efforts into this direction.

In order to develop our refinement algorithms we supply some recipes for a posteriori error estimation of LRA at sublinear cost; this can be of some independent interest.

**Organization of our paper.** In the next section we recall some background material. In Section 3 we transform any LRA into its SVD at sublinear cost. We propose some algorithms for iterative refinement of an LRA at sublinear cost in Sections 4 and 6 and study the problem of error

---

\(^2\)Here and throughout we use such concepts as “low”, “small”, “nearby”, etc. defined in context.

\(^3\)In the papers \[\text{PLSZ16 and PLSZ17}\] sublinear cost LRA algorithms are called “superfast”.

2
estimation for LRA at sublinear cost in Section 5. We devote Section 7, the contribution of the second author, to numerical tests. In Appendix A we specify some small families of matrices on which every LRA algorithm fails if it runs at sublinear cost, even though every matrix of these families admits LRA. In Appendix B we recall the known estimates for the output errors of LRA at sublinear cost in a very special but important case where an input matrix is filled with i.i.d. values of a single random variable.

2 Some background for LRA

Hereafter $|·|$ unifies definitions of the spectral norm $||·||$ and the Frobenius norm $||·||_F$. 

**Definition 2.1.** (i) An $m \times n$ matrix $\tilde{M}$ has rank at most $\rho$, rank($\tilde{M}$) $\leq$ $\rho$, if

$$\tilde{M} = AB, \ A \in \mathbb{C}^{m \times \rho}, \text{ and } B \in \mathbb{C}^{\rho \times n}. \quad (2.1)$$

(ii) Such a matrix $M$ has $\epsilon$-rank at most $\rho$ for a fixed tolerance $\epsilon$ if $M$ admits its approximation within an error norm $\epsilon$ by a matrix $\tilde{M}$ of rank at most $\rho$ or equivalently if there exist three matrices $A$, $B$ and $E$ such that

$$M = \tilde{M} + E \text{ where } |E| \leq \epsilon, \ \tilde{M} = AB, \ A \in \mathbb{C}^{m \times \rho}, \text{ and } B \in \mathbb{C}^{\rho \times n}. \quad (2.2)$$

The 0-rank is the rank; the $\epsilon$-rank of a matrix $M$ for a small positive tolerance $\epsilon$ is said to be its numerical rank, hereafter denoted $\text{nrank}(M)$. A matrix admits its close approximation by a matrix of rank at most $\rho$ if and only if it has numerical rank at most $\rho$.

A 2-factor LRA $AB$ of $M$ of (2.2) can be generalized to a 3-factor LRA

$$M = \tilde{M} + E, \ |E| \leq \epsilon, \ \tilde{M} = XTY, \ X \in \mathbb{C}^{m \times k}, \ T \in \mathbb{C}^{k \times l}, \ Y \in \mathbb{C}^{l \times n}, \quad (2.3)$$

$$\rho = \text{rank}(\tilde{M}) \leq k \leq m, \ \rho \leq l \leq n. \quad (2.4)$$

**Remark 2.1.** The pairs of the maps $XT \rightarrow A$ and $Y \rightarrow B$ as well as $X \rightarrow A$ and $TY \rightarrow B$ turn a 3-factor LRA $XTY$ of (2.3) into a 2-factor LRA AB of (2.2).

An important 3-factor LRA of matrix $M$ of rank at least $\rho$ is its $\rho$-top SVD $M^{(\rho)} = U^{(\rho)}\Sigma^{(\rho)}V^{(\rho)*}$ where $\Sigma^{(\rho)}$ is the diagonal matrix of the $\rho$ top (largest) singular values of $M$ and where $U^{(\rho)}$ and $V^{(\rho)}$ are the unitary (orthogonal) matrices of the associated top singular spaces of $M$. $M^{(\rho)}$ is said to be the $\rho$-truncation of $M$, obtained from $M$ by setting to zero all its singular values but the $\rho$ largest ones.

$$M^{(\rho)} = M \text{ for a matrix } M \text{ of rank } r, \text{ and then its } \rho\text{-top SVD is just its } \text{compact SVD}$$

$$M = U_M \Sigma_M V_M^*, \text{ for } U_M = U^{(\rho)}, \ \Sigma_M = \Sigma^{(\rho)}, \text{ and } V_M = V^{(\rho)}.$$

The $\rho$-top SVD of a matrix defines its optimal 3-factor LRA under both spectral and Frobenius norms:

**Theorem 2.1.** [GL13 Theorem 2.4.8]. Write $\tau_{\rho+1}(M) := |M^{(\rho)} - M| = \min_{N: \text{rank}(N) = \rho} |M - N|$. Then $\tau_{\rho+1}(M) = \sigma_{\rho+1}(M)$ under the spectral norm $|·|$ $= ||·||$ and $\tau_{\rho+1}(M) = \sigma_{F,\rho+1}(M) := \sum_{j \geq \rho} \sigma_j^2(M)$ under the Frobenius norm $|·|$ $= ||·||_F$.

**Lemma 2.1.** [GL13 Corollary 8.6.2]. For $m \geq n$ and a pair of $m \times n$ matrices $M$ and $M + E$ it holds that

$$|\sigma_j(M + E) - \sigma_j(M)| \leq ||E|| \text{ for } j = 1, \ldots, n.$$

**Lemma 2.2.** [The norm of the pseudo inverse of a matrix product.] Suppose that $A \in \mathbb{C}^{k \times r}$, $B \in \mathbb{C}^{r \times l}$ and the matrices $A$ and $B$ have full rank $r \leq \min\{k, l\}$. Then $|\,(AB)^+| \leq |A^+| \, |B^+|$. 
3 Computation of a $\rho$-top SVD of an LRA at sublinear cost

Algorithm 3.1. [Computation of a $\rho$-top SVD of an LRA.]

**Input:** Four integers $\rho, k, m,$ and $n$ such that $0 < \rho \leq k \leq \min\{m, n\}$ and two matrices $A \in \mathbb{C}^{m \times k}$ and $B \in \mathbb{C}^{k \times n}$.

**Output:** Three matrices $U \in \mathbb{C}^{m \times \rho}$ (unitary), $\Sigma \in \mathbb{R}^{\rho \times \rho}$ (diagonal), and $V \in \mathbb{C}^{n \times \rho}$ (unitary) such that $(AB)^{(\rho)} = U\Sigma V^*$ is a $\rho$-top SVD of $AB$.

**Computation:**
1. Compute SVDs $A = U_A\Sigma_AV_A^*$ and $B = U_B\Sigma_BV_B^*$ where $U_B \in \mathbb{C}^{m \times k}$, $V_B^* \in \mathbb{C}^{k \times n}$, and $\Sigma_A, V_A, U_B, \Sigma_B \in \mathbb{C}^{k \times k}$.
2. Compute $k \times k$ matrices $W = \Sigma_AV_A^*U_B\Sigma_B, U_W, \Sigma_W,$ and $V_W^*$ such that $W = U_W\Sigma_WV_W^*$ is SVD, $\Sigma_W = \text{diag}(\Sigma, \Sigma')$, and $\Sigma = \text{diag}(\sigma_j)_{j=1}^\rho$ and $\Sigma' = \text{diag}(\sigma_j)_{j=\rho+1}^k$ are the matrices of the $\rho$ top (largest) the $k - \rho$ trailing (smallest) singular values of the matrix $W$, respectively. Output the matrix $\Sigma$.
3. Compute and output the matrices $U$ and $V$ made up of the first $\rho$ columns of the matrices $U_AU_W$ and $V_BV_W$, respectively.

The algorithm involves $O((m+n)k^2)$ flops; it runs at sublinear cost if $k^2 \ll \min\{m, n\}$. Its correctness follows from equations $(3.1)$ and $(3.2)$.

4 Deterministic iterative refinement of an LRA at sublinear cost

Next we describe iterative refinement of a sufficiently close LRA of $M$. At the $i$th step we try to improve a current LRA $\tilde{M}^{(i)}$ by applying a fixed LRA algorithm to the current error matrix $E^{(i)} = \tilde{M}^{(i)} - M$. At every iteration the rank of the new tentative LRA is at least doubled, but we periodically cut it back to the value $\text{rank}(M)$ (see Remark 4.2).

Algorithm 4.1. (Iterative refinement of a CUR LRA at sublinear cost. See Remarks 4.2 and 4.3)

**Input:** Three integers $m, n,$ and $\rho$, $\rho \leq \min\{m, n\}$, an $m \times n$ matrix $M$ of numerical rank $\rho$, a Sub-algorithm APPROX$(r)$, which for a fixed positive integer $r$ computes a rank-$r$ approximation of its input matrix (this can be an algorithm running at sublinear cost such as MAXVOL of [GOSTZ10] or the algorithm of [TYUC17] using a pair of sparse multipliers $\Omega$ and $\Psi$), and a Stopping Criterion, which signals when the current candidate LRA is accepted as satisfactory (see the next section).

**Initialization:** $\tilde{M}^{(0)} = O^{m \times n}$. 

4
Computations: Recursively for $i = 0, 1, 2, \ldots$ do:

1. Apply Subalgorithm APPROX($r_1$) to the matrix $E^{(i)} = M - \tilde{M}^{(i)}$ for $r_i = \text{rank}(\tilde{M}^{(i)}) + \rho$.
2. Let $\Delta^{(i)}$ denote its output matrix of rank at most $r_i$. Compute a new approximation $\tilde{M}^{(i+1)} = \tilde{M}^{(i)} + \Delta^{(i)}$ of $M$ and the matrix $E^{(i+1)} = M - \tilde{M}^{(i+1)}$ of numerical rank at most $2^i \rho$.
3. Replace $i$ by $i + 1$ and repeat stages 1 and 2 until either $i$ exceeds the allowed limitation, and then stop and output FAILURE, or until Stopping Criterion is satisfied for some integer $i$, and then stop and output the matrix $\tilde{M} = \tilde{M}^{(i+1)}$.

Remark 4.1. Progress in refinement. Write $e_i = |E^{(i)}|$ for all $i$ and observe that $E^{(i)} = E^{(i-1)} - \Delta^{(i-1)}$, and so $e_i < e_{i-1}$ if $\Delta^{(i-1)}$ approximates $E^{(i-1)}$ closer than by the matrix $O$ filled with 0s. Furthermore equation $r_i = \text{rank}(\tilde{M}^{(i)}) + \rho$ at stage 1 implies that $\tau_{r_i}(M - \tilde{M}^{(i)}) \leq \tau_{\rho}(M)$.

Remark 4.2. Management of the rank growth. The bound on the rank of the matrix $E^{(i)}$ is doubled at every iteration of Algorithm 4.1 by allowing its increase we can obtain more accurate LRA. Fast growth of the rank, however, implies fast growth of the complexity of an iteration, and so we periodically compress the computed LRA $\tilde{M}^{(i)}$ into its $\rho$-truncation $(\tilde{M}^{(i)})^{(\rho)}$ by applying Algorithm 3.1. The error of LRA would grow in compression within bounds (3.1) and (3.2) for $AB = \tilde{M}^{(i)}$ and $\rho = r_i$, that is, less significantly if an LRA $\tilde{M}^{(i)}$ is close to an input matrix $M$.

Remark 4.3. Management of the precision of computing. As usual in iterative refinement we should apply the mixed precision technique, that is, perform the subtraction stage 2 with a higher precision than stage 1. Furthermore we can replace the summation $\tilde{M}^{(i)} = \tilde{M}^{(i-1)} + \Delta^{(i-1)}$ by the summation of more than two terms, by representing the matrix $\tilde{M}^{(i-1)} = \tilde{M}^{(i-2)} + \Delta^{(i-2)}$ by a pair of matrices $\tilde{M}^{(i-2)}$ and $\Delta^{(i-2)}$ and similarly representing the matrix $\tilde{M}^{(i-2)}$. The basic observation is that we need lower precision in order to represent each term than their sums.

5 Heuristic a posteriori error estimation for LRA at sublinear cost

Accurate a posteriori error estimation is impossible at sublinear cost even for the small input families of Appendix A but next we list some simple heuristic recipes for this task.

(i) Clearly the value $|e_{i,j}|$ for every entry $e_{i,j}$ of the LRA error matrix $E = (e_{i,j})_{i,j} = \tilde{M} - M$ is a lower bound on the norm $|E|$ of this matrix.

(ii) The above deterministic lower bound on the LRA error norm $|E|$ also implies its a posteriori randomized upper bounds if the error matrix $E$ is filled with i.i.d. values of a single random variable and has sufficiently many entries, e.g., 100 entries or more (see Appendix B).

(iii) By generalizing the technique of part (i) we obtain deterministic lower bounds on the error norm $|E|$ given by the ratios $|FE| / |F|$, $|EH| / |H|$ or $|F EH| / (|F| |H|)$ for any pair of matrices $F \in \mathbb{C}^{k \times n}$ and $H \in \mathbb{C}^{n \times l}$. The computation also defines randomized upper bounds on the error norm $|E|$ for random matrices $F$ and/or $H$ and sufficiently large integers $k$ and/or $l$ (see [87]) and runs at sublinear cost if the matrices $F$ and $H$ are sufficiently sparse, e.g., full rank submatrices of permutation matrices.

(iv) Suppose that we have computed a set of LRAs $\tilde{M}_1, \ldots, \tilde{M}_s$ for a matrix $M$, by applying to it various LRA algorithms running at sublinear cost or the same algorithm with distinct parameters, e.g., the algorithm of [TYUC17] with a distinct pair of sparse multipliers $F$ and $H$. Furthermore suppose that we have computed a median $\bar{M} = \tilde{M}_j$ for some $j$ in the range $1 \leq j \leq s$. Then we can consider this median a heuristic LRA of $M$ with an error norm $|\bar{M} - \bar{M}|$. 

For heuristic computation of a median at sublinear cost select the median index \( j = j(f, h) \) for the product \( f^T \tilde{M} j h \) over all subscripts \( j \) in the range \( 1 \leq j \leq s \) for a pair of fixed common vectors \( f \) and \( h \). For another heuristic but more dependable selection one may first compute such medians for a number of pairs of vectors \( f \) and \( h \) and then select a median of these medians.

All these recipes for a posteriori error estimation at sublinear cost apply to any LRA. In \cite{PLSZb} and \cite{PLSZa} we deduce such estimates for LRA output by some specific sublinear cost algorithms.

\section{Randomized iterative refinement of LRA at sublinear cost by means of refinement of leverage scores}

Suppose that we are given a crude but reasonably close LRA \( \tilde{M} = ATB \) such that \( ||\tilde{M} - M|| \ll \sigma_\rho(M) \). Next we propose its refinement at sublinear cost by extending the random subspace sampling algorithms of \cite{DMM08} by Drineas et al. and of various subsequent papers (see \cite{KS16}, \cite{BW17}, and the references therein). Such an algorithm first computes top right singular space of a matrix, then its so called leverage scores \cite{BW17}, and the references therein). Such an algorithm first computes top right singular space of a matrix, then its so called leverage scores, which serve as sampling probabilities that define random subspace sampling at sublinear cost, and finally outputs CUR LRA, which is nearly optimal whp. These computations are performed at sublinear cost if the top SVD of a matrix \( M \) is available.

Let us recall some details. Given \( \rho \)-top SVD \( M^{(\rho)} = U^{(\rho)} \Sigma^{(\rho)} V^{(\rho)*} \), with \( V^{(\rho)} = (v_j^{(\rho)})_{j=1}^n \) one can fix any real \( \beta \), \( 0 < \beta \leq 1 \), and then define the SVD-based leverage scores \( p_1, \ldots, p_n \) satisfying

\[
p_j \geq (\beta/\rho) ||v_j^{(\rho)}||^2 \text{ and } \sum_{j=1}^n p_j = 1 \text{ for } j = 1, \ldots, n. \tag{6.1}
\]

(6.1) turns into \( p_j = ||v_j^{(\rho)}||^2/\rho \) for \( j = 1, \ldots, n \) for \( \beta = 1 \), but for \( \beta < 1 \) we can use the same leverage scores \( p_1, \ldots, p_n \) in a small neighborhood of an input matrix.

\textbf{Remark 6.1.} The leverage scores are defined by the top right singular space but do not depend on the choice of its unitary basis; they stay invariant if the matrix \( V^{(\rho)*} \) is pre-multiplied by a unitary matrix. By virtue of Theorem 6.1 below, they change little in a small perturbation of that space.

We next recall a bound on the perturbation of singular spaces of the \( \rho \)-truncation \( M^{(\rho)} \) of a matrix \( M \) into those of a matrix \( M + E \). The bound is stated in terms of the minimal perturbation of unitary bases for the transition from the singular spaces of \( M \) to those of \( M + E \). Compare similar results by Davis–Kahan 1970 and Wedin 1972 and 1973 involving angles between singular spaces.

\textbf{Theorem 6.1.} (The impact of a perturbation of a matrix on its top singular spaces. \cite{GL13} Theorem 8.6.5). \footnote{\cite{GL13} Theorem 8.6.5} Suppose that

\[
g =: \sigma_\rho(M) - \sigma_{\rho+1}(M) > 0 \text{ and } ||E||_F \leq 0.2g.
\]

Then there exist unitary matrix bases \( B_{\rho,\text{left}}(M) \), \( B_{\rho,\text{right}}(M) \), \( B_{\rho,\text{left}}(M + E) \), and \( B_{\rho,\text{right}}(M + E) \) for the left and right top singular spaces of the matrices \( M \) and \( M + E \) such that

\[
\max\{||B_{\rho,\text{left}}(M + E) - B_{\rho,\text{left}}(M)||_F, ||B_{\rho,\text{right}}(M + E) - B_{\rho,\text{right}}(M)||_F\} \leq 4 ||E||_F / g.
\]

\footnote{\cite{GL13} Theorem 8.6.5} cites \cite{SY73} Theorem 6.4, which claims a slightly more optimistic bound.

\footnote{Recall that such bases are not unique even where all singular values are distinct.}
For example, if $\sigma_\rho(M) \geq 2\sigma_{\rho+1}(M)$, which implies that $g \geq 0.5 \sigma_\rho(M)$, and if $\|E\|_F \leq 0.1 \sigma_\rho(M)$, then the upper bound on the right-hand side is approximately $8\|E\|_F/\sigma_\rho(M)$.

The above observations and estimates combined lead us to a heuristic recipe for iterative refinement of LRA by means of updating the leverage scores of an input matrix.

Namely suppose that an LRA $\tilde{M}$ is sufficiently close to the matrix $M$. Then by virtue of Theorem 6.1 the top right singular spaces of the matrix $M$ and of its LRA $\tilde{M}$ are close to one another, and so the sets of their leverage scores are close or even identical to one another whp [DMM08]. At this point we propose to proceed as follows: (a) fix $\beta < 1$, (b) compute the leverage scores of the LRA at sublinear cost, and (c) apply the algorithm of [DMM08] to the matrix $M$ by using these leverage scores. For a proper choice of $\beta < 1$ the new LRA should improve $\tilde{M}$ whp if the norm $|E| = |M - \tilde{M}|$ is small enough. Recursively we arrive at a heuristic recipe for randomized iterative refinement of a crude but sufficiently close LRA.

For two research challenges consider

(i) the relevant estimates for an upper bound on the norm $|E|$ that would imply its decrease at every iteration, say, by twice with a probability at least $1/2$ and

(ii) numerical tests that would support these estimates.

7 Numerical Experiments for Algorithm 4.1

In this subsection we present the test results for Algorithm 4.1 on inputs of four types made up of synthetic and real-world data with various spectra. Our figures display the relative error ratio

$$r = \frac{\|M - \tilde{M}\|_F}{\|M - M^{(\rho)}\|_F}$$

(7.1)

where $M$ denotes the input matrix, $\tilde{M}$ denotes its approximation output by Algorithm 4.1, $M^{(\rho)}$ denotes the $\rho$ truncation of $M$, and $\rho$ is a rank value pre-determined for each input matrix. Unless the output of the algorithm was corrupted by rounding errors, the ratio $r$ was not supposed to be noticeably exceeded by 1, and it was not in our experiments.

The algorithm was implemented in Python, and we run all experiments on a 64bit MacOS Sierra 10.12.6 machine with 1.6GHz CPU and 4GB Memory. We called scipy.linalg version 0.4.9 for numerical linear algebra routines such as QR factorization with pivoting, Moore-Penrose matrix inversion, and linear least squares regression.

**Synthetic Input:** We used random synthetic $1024 \times 1024$ input matrices of two kinds – with fast and slowly decaying spectra. In both cases we generated these matrices as products $U \Sigma V^T$, where $U$ and $V$ were the matrices of the left and right singular vectors of a random Gaussian matrix.

By letting $\Sigma = \text{diag}(v)$, where $v_i = 1$ for $i = 1, 2, 3, \ldots, 40$, $v_i = \frac{1}{2}$ for $i = 41, \ldots, 100$, and $v_i = 0$ for $i > 100$, we generate input matrices with fast decaying spectra.

By letting $\Sigma = \text{diag}(u)$, where $u_i = 1$ for $i = 1, 2, 3, \ldots, 40$, and $u_i = \frac{1}{1+i}$ for $i > 40$, we generate input matrices with slowly decaying spectra.

**Real-world Input:** The input matrices of this category were $1000 \times 1000$ dense matrices with real values having low numerical rank. They represented discretization of Integral Equations, provided in the built-in problems of the Regularization Tools. We used two test matrices. One of them, called **gravity**, came from a one-dimensional gravity surveying model problem, and another one, called **shaw**, came from a one-dimensional image restoration model problem. We display

---

the distribution of their singular values in figure 1; we padded these matrices with 0s in order to increase their size to $1024 \times 1024$.

**Subalgorithm:** Our subalgorithm modifies the sketching approach of [TYUC17]. Namely, in the $i$th iteration step we fix two multipliers $F$ and $H$, then approximate the residual $R_i = M - \tilde{M}_{i-1}$ by $\tilde{R}_i = R_i H (FR_i H)^+ FR_i$, and finally compute the $i$th approximation $\tilde{M}_i = \tilde{M}_{i-1} + \tilde{R}_i$. In our tests, we used the *abridged* Hadamard multipliers defined in [PLSZ16] and [PLSZ17] and having size $5 \times 1024$ and recursion depth 3. We also included the results of similar tests with Gaussian multipliers for comparison (cf. [TYUC17]).

For each input matrix, we performed Algorithm 4.1 100 times for 100 random choices of pairs of multipliers $\Omega$ and $\Psi$ in the algorithm of [TYUC17]. We recorded the mean relative error ratio for every iteration step in figure 2.

The results of our tests with abridged SRHT multipliers were similar to the results with Gaussian multipliers and were only slightly worse in few places. This minor deterioration of the output accuracy was a reasonable price for using abridged (very sparse) Hadamard multipliers, with which we only access a small fraction of the input matrix at each iteration step.

Even in the tests for some random input matrices with slowly decaying spectrum the relative error ratio did not decrease below 1, which could be caused by the “heavy” tail in the spectrum. In our tests with some other inputs that were not “well-mixed” in some sense, it was necessary to increase the recursion depth of the abridged Hadamard multipliers in order to bring the relative error ratio close to 1.

**Appendix**

A Small families of hard inputs for sublinear cost LRA

Any sublinear cost LRA algorithm fails on the following small families of LRA inputs.

**Example A.1.** Let $\Delta_{i,j}$ denote an $m \times n$ matrix of rank 1 filled with 0s except for its $(i,j)$th entry filled with 1. The $mn$ such matrices $\{\Delta_{i,j}\}_{i,j=1}^{m,n}$ form a family of $\delta$-matrices. We also include the $m \times n$ null matrix $O_{m,n}$ filled with 0s into this family. Now fix any sublinear cost algorithm; it does not access the $(i,j)$th entry of its input matrices for some pair of $i$ and $j$. Therefore it outputs the same approximation of the matrices $\Delta_{i,j}$ and $O_{m,n}$, with an undetected error at least $1/2$. Arrive at the same conclusion by applying the same argument to the set of $mn + 1$ small-norm perturbations of the matrices of the above family and to the $mn + 1$ sums of the latter matrices with any fixed
$m \times n$ matrix of low rank. Finally, the same argument shows that a posteriori estimation of the output errors of an LRA algorithm applied to the same input families cannot run at sublinear cost.

The example actually covers randomized LRA algorithms as well. Indeed suppose that an LRA algorithm does not access a constant fraction of the entries of an input matrix with a positive constant probability. Then with a positive constant probability the algorithm misses an entry whose value greatly exceeds those of all other entries. Therefore whp the algorithm fails to approximate that entry closely. We have showed, however, that close LRA of a matrix that admits sufficiently close LRA can be computed at sublinear cost in two successive C-A iterations provided that we avoid choosing degenerating initial submatrix, which is precisely the problem with the matrix families of Example A.1. Thus we readily compute close LRA if we recursively perform C-A iterations and avoid degeneracy at any C-A step.

B A posteriori error estimation at sublinear cost for LRA of a matrix filled with i.i.d. values of a single variable

In our randomized a posteriori error estimation sublinear cost below we assume that the error matrix $E$ of an LRA has enough entries, say, 100 or more, and that they are the observed i.i.d.
values of a single random variable. This is realistic, for example, where the deviation of the matrix $W$ from its rank-$\rho$ approximation is due to the errors of measurement or rounding.

In this case the Central Limit Theorem implies that the distribution of the variable is close to Gaussian (see [EW07]). Fix a pair of integers $q$ and $s$ such that $qs$ is large enough (say, exceeds 100), but $qs = O((m + n)kl)$ and $qs \ll mn$; then apply our tests just to a random $q \times s$ submatrix of the $m \times n$ error matrix.

Under this policy we compute the error matrix at a dominated arithmetic cost in $O((m + n)kl)$ but still verify correctness with high confidence, by applying the customary rules of hypothesis testing for the variance of a Gaussian variable.

Namely suppose that we have observed the values $g_1, \ldots, g_K$ of a Gaussian random variable $g$ with a mean value $\mu$ and a variance $\sigma^2$ and that we have computed the observed average value and variance

$$\mu_K = \frac{1}{K} \sum_{i=1}^{K} |g_i| \quad \text{and} \quad \sigma^2_K = \frac{1}{K} \sum_{i=1}^{K} |g_i - \mu_K|^2,$$

respectively. Then, for a fixed reasonably large $K$, both

$$\text{Probability} \{|\mu_K - \mu| \geq t|\mu|\} \quad \text{and} \quad \text{Probability} \{|\sigma^2_K - \sigma^2| \geq t\sigma^2\}$$

converge to 0 exponentially fast as $t$ grows to the infinity (see [C46]).
