Quantum security of the Fiat-Shamir transform of commit and open protocols

André Chailloux*

October 29, 2019

Abstract

Applying the Fiat-Shamir transform on identification schemes is one of the main ways of constructing signature schemes. While the classical security of this transformation is well understood, it is only very recently that generic results for the quantum case has been proposed [DFMS19, LZ19]. In this paper, we show that if we start from a commit-and-open identification scheme, where the prover first commits to several strings and then as a second message opens a subset of them depending on the verifier’s message, then the Fiat-Shamir transform is quantum secure, for a suitable choice of commitment scheme. Unlike previous generic results, our transformation doesn’t require to reprogram the random function $H$ used in the Fiat-Shamir transform and we actually only require a quantum one-wayness property.

Our techniques can in some cases lead to a much tighter security reduction. To illustrate this, we apply our techniques to identifications schemes at the core of the MQDSS signature scheme, the Picnic scheme (both present in the round 2 of the post quantum NIST competition) and the Stern signature scheme. For all these schemes, we show that our technique can be applied with essentially tight results.

1 Introduction

There has been a strong interest in post-quantum cryptography in the last years. While we are still very far from having a full quantum computer, there are important technological advances each year and it is very possible that future quantum computers will be powerful enough to run Shor’s algorithm [Sho94] or other quantum algorithms devastating for current cryptography.

Post-quantum cryptosystems are based on computational problems which are not known to be broken by quantum computers like problems based on lattices, multivariate polynomials, isogenies or error correcting codes; and there is currently a standardization process of post-quantum cryptosystems organized by the NIST [Nis17].

*Inria de Paris, EPI SECRET. Email: andre.chailloux@inria.fr.
Quite surprisingly, while all the proposals are based on problems believed to be hard for quantum computers, many of the submissions, even the round 2 submissions, do not have a proper security proof against quantum computers. This is specially true for signature schemes where about half of the round 2 submissions do not have an explicit quantum security proof, even if the recent results of [DFMS19, LZ19] are quickly solving this problem. This shows how hard these quantum security proofs can be.

1.1 The quantum Fiat-Shamir transform for signature schemes

In this paper, we will be interested in some technical aspects related to proving the security of signatures schemes in the Quantum Random Oracle Model (QROM) using the Fiat-Shamir transform. An identification scheme is a 3 message interaction between a prover and a verifier where the prover first sends a message $x$, receives a random challenge $c$ from the verifier and then sends back a message $z$. The Fiat-Shamir transformation is a very important procedure that can transform (interactive) identification schemes into non-interactive ones. In order to do this, we replace the random challenge $c$ with the string $H(x)$ and the prover sends directly $(x, H(x), c)$ to the verifier. For a long time, nothing was known about the quantum security of the Fiat-Shamir transform. First impossibility results showed settings where, in all generality, the quantum Fiat-Shamir transform is not secure [DFG13, ARU14]. On the positive side, [DFG13] proved the security of the quantum Fiat-Shamir transform when oblivious commitments are used. Unruh [Unr15] then showed that it was possible to do a Fiat-Shamir like transform to remove the interaction from identification protocols. This transform is however rather inefficient and was hardly used in practice. More recently, there have been new exciting results related to the quantum security of the Fiat-Shamir transform. If an identification scheme is lossy, then [KLS18] showed that the Fiat-Shamir transform is quantum secure. They used this result to prove the security of the Dilithium signature [DKL+17], which is a NIST competitor. Another result is the security proof of $q$TESLA [ABB+19]. Unruh [Unr17] also showed the quantum security of the Fiat-Shamir transform for identification schemes with statistical security where the security of the underlying signature scheme with a dual-mode hard instance generator, a property closely related to the lossiness property.

Recently, 2 papers [DFMS19, LZ19] showed generic reduction for the quantum Fiat-Shamir transform. Unlike what was believed before, they show that it is actually possible to perform reprogramming of a quantum random oracle and to follow the classical proofs. Their results are not tight and lose at least a factor of $O(q^2)$ where $q$ is the number of queries to the random function.

1.2 Contributions and techniques

Motivated by the concrete security study of MQDSS and Picnic, two NIST candidate, we study commit-and-open identification schemes. In a commit-and-open identification scheme, the prover first commits to several strings and then as a second message opens
a subset of them depending on the verifier’s challenge. Our contributions are the following:

1. We prove that with a well chosen commitment scheme, namely a random function from \( \{0,1\}^l \) to \( \{0,1\}^{3l} \) we have quantum security of signature schemes constructed from a commit-and-open identification scheme with the Fiat-Shamir transform in the Quantum Random Oracle Model. While our results are not generic and can be applied only to commit-and-open identification schemes, they provide better bounds than the generic ones.

2. The above technique can even lead to tight reductions in some cases. In particular, we can apply our results to the Picnic (including the one that uses plain Fiat-Shamir) signature scheme [CDG+17] and to the Stern signature scheme [Ste93], for which we show an almost tight (i.e. tight up to log factors) quantum security. We also apply our results to the 3-pass identification scheme [SSH11]. The MQDSS signature [CHR+16] is actually based on the optimized 5-pass variant of [SSH11] so we essentially prove quantum security of the non-optimized variant of MQDSS. We leave the quantum security of the full scheme as an open question.

We present informally our 2 theorems

**Theorem 1** (Informal). Let \( \mathcal{IS} \) be a commit and open identification scheme that uses for commitment a random function from \( \{0,1\}^l \) to \( \{0,1\}^{3l} \), we have for each \( \delta \)

\[
QADV_{FS^H[\mathcal{IS}]}(t) \leq QADV_{\mathcal{IS}}^{RS,\delta}(t') + O(q_2^2\delta) + \varepsilon.
\]

with \( t' \approx t \) and \( \varepsilon \approx 0 \).

How to read this theorem? On the left hand side, we have the probability that a quantum attacker breaks the Fiat-Shamir transform of \( \mathcal{IS} \) in time \( t \). On the right hand side, we want some notion of soundness related to \( \mathcal{IS} \). In this theorem, we introduce the notion of \( \delta \)-rigid soundness and \( QADV_{\mathcal{IS}}^{RS,\delta}(t') \) is the \( \delta \)-rigid soundness advantage for a quantum attacker taking time \( t' \). There is an extra term that depends on the number of quantum queries to the random function \( H \) used in the Fiat-Shamir transform.

We will not explain the notion of \( \delta \)-rigid soundness but leave this for the preliminary section. What we want to say here is that if our identification scheme has some strong guarantees in terms of this rigid soundness then the quantum Fiat-Shamir reduction is essentially tight. The above theorem also implies results in terms of the standard soundness advantage.

**Proposition (Informal)**. Let \( \mathcal{IS} \) be a commit and open identification scheme that uses for commitment a random function from \( \{0,1\}^l \) to \( \{0,1\}^{3l} \), we have for each \( \delta \)

\[
QADV_{FS^H[\mathcal{IS}]}(t) \leq O(q_H\sqrt{QADV_{\mathcal{IS}}(t')}) + \varepsilon.
\]
with \( t' \approx t \) and \( \varepsilon \approx 0 \).

Here, \( QADV_{\mathcal{I}S}(t') \) is the commonly used soundness advantage of the identification scheme \( \mathcal{I}S \). This proposition already gives better results than those of [DFMS19, LZ19], even though it can be applied only to commit-and-open identification schemes. It is not tight however so if we want tight results, we should use Theorem 1.

To illustrate the power of Theorem 1, we present informally our second theorem, Theorem 2 (Informal). Let \( \mathcal{I}S \) be a commit and open identification scheme with challenge size 3 that uses for commitment a random function from \( \{0,1\}^l \) to \( \{0,1\}^{3l} \). Let \( \mathcal{I}S^{\otimes k} \) its \( k \)-fold parallel repetition. We have

\[
QADV_{FS[H_{\mathcal{I}S^{\otimes k}}]}(t) \leq QADV_{\mathcal{I}S}^{012}(t') + O(q_H^2 (2/3)^k) + \varepsilon.
\]

with \( t' \approx t \) and \( \varepsilon \approx 0 \).

The quantity \( QADV_{\mathcal{I}S}^{012}(t') \) is the probability to write down explicitly a strategy that will answer simultaneously the 3 challenges of the verifier in \( \mathcal{I}S \). The identification schemes used in MQDSS, Picnic and Stern are all of the form \( \mathcal{I}S^{\otimes k} \) and the computational assumption they use is tightly related to \( QADV_{\mathcal{I}S}^{012} \). So the way to read the above theorem is that for these identification schemes, the quantum Fiat-Shamir reduction is tight as long as the number of repetitions \( k \) is large enough.

Another aspect is that we force in the above theorems to use as a commitment scheme a random function from \( \{0,1\}^l \) to \( \{0,1\}^{3l} \). If we want to use those identification schemes to construct signatures then this can greatly increase the size of the signature. In order to prevent this, we show how to replace this random function with a sponge function. Their quantum security was proven in [CHS19] and we can show how to regain size efficiency using these sponges and this is the purpose of Section 4.5.

In terms of technical contributions, on top of defining and analyzing the above concepts, our main contribution is to strengthen a result of Zhandry about his QRO framework. Let us discuss briefly what it is. In Zhandry’s framework of the QROM, the description of the random function is coherently stored in an extra quantum register. This register is huge and can’t be efficiently manipulated. However, Zhandry showed that there is a way to store a compressed version of this database that can be efficiently manipulated and stored, and which has essentially all the useful information of the large database. Informally, Zhandry showed that if an algorithm querying the random function outputs some pairs \((x_1, y_1), \ldots, (x_k, y_k)\) with \( H(x_i) = y_i \) such that these pairs satisfy an extra property \( P \) then we can with high probability retrieve these pairs in the compressed database. What we show is that if the algorithm only outputs \( y_1, \ldots, y_k \) but there exist \( x_1, \ldots, x_k \) such that \( H(x_i) = y_i \) and these pairs satisfy \( P \) then those pairs will also appear in the compressed database with high probability. This can have many applications in the quantum setting, as only having those values \( y_1, \ldots, y_k \) is usually hard to manipulate when we don’t have access to the preimages. This result, formally introduced in Proposition 10, is at the core of our results.
1.3 Organization of the paper

In Section 2, we present some preliminaries on quantum information. In Section 3, we present different definitions for identification schemes and signature schemes. In Section 4, we show our 2 theorems, as well as variants, discussions and the use of sponge functions. We only omit a crucial proposition that involves Zhandry’s framework. In Section 5, we present Zhandry’s framework and finish the proof of our theorem.

2 Preliminaries

2.1 Quantum query algorithms and the quantum random oracle model

For any quantum algorithm $A$, we denote by $|A|$ its total running time. We will also consider query algorithms $A^O$ that will make a certain amount of calls to an oracle $O$. The Quantum Random Oracle Model (QROM) is a model where we model a certain function with a random function $H$. Since we are in the quantum setting, we have a black box access to $H$ but also to the unitary $O_H(|x⟩|y⟩) = |x⟩|H(x) + y⟩$. Zhandry presented in [Zha18] an alternative way at looking at the QROM that we present in Section 5.

2.2 Quantum lower bounds

We will use a generalization of Grover’s lower bound.

**Lemma 1.** Let $\mathcal{F}^Y_X$ be the set of random functions from $X$ to $Y$. For each $x \in X$, we associate a set $U_x \subseteq Y$ such that $\frac{|U_x|}{|Y|} \leq \varepsilon$. For any quantum query algorithm $A^O$ making $q$ queries to $O$, we have

$$\Pr[H(x) \in U_x : H \leftarrow \mathcal{F}^Y_X, x \leftarrow A^O(\cdot)] \leq O(q^2 \varepsilon).$$

The above lemma was implicitly stated and proven in [Unr17, Theorem21]. The idea is to construct a function $H_2(x) = H(x) + u(x)$ where $u(x)$ is a random element from $U_x$ and use standard lower bounds for Grover search on random functions. It is also possible to directly use the recent framework of recording of quantum queries [Zha18, Theorem 4.1] to obtain exactly the same result.

3 Identification schemes and signature schemes

Throughout the paper, $x \leftarrow S$ means that $x$ is chosen uniformly at random from $S$. For a string $x = x_1, \ldots, x_n$ and $I = (i_1, \ldots, i_k) \subseteq \{1, \ldots, n\}$, we define $x_I = (x_{i_1}, \ldots, x_{i_k})$.

3.1 Identification schemes

An identification scheme $\mathcal{IS} = (\text{Keygen}, P, V, S_{ch})$, consists of the following:
• A key generation algorithm \( \text{Keygen}(1^\lambda) \rightarrow (pk, sk) \).

• The prover’s algorithm \( P = (P_1, P_2) \) for constructing his messages. We have \( P_1(sk) \rightarrow (x, St) \) where \( x \) corresponds to the first message and \( St \) is some internal state. \( P_2(sk, x, c, St) \rightarrow z \) where \( c \in S_{ch} \) is the challenge from the verifier and \( z \) the prover’s response (second message).

• A verification function \( V(pk, x, c, z) \) used by the verifier that outputs a bit, 0 corresponds to ‘Reject’ and 1 to ‘Accept’.

We do not specify here the different string lengths of \( x \) and \( z \) to not make notations too heavy. We explicit the challenge space \( S_{ch} \) as it will often appear in our definitions and statements. We want all the different algorithms presented above to be efficient and we will usually omit their running times (i.e. fix them to 1), again to significantly reduce the amount of notations we introduce. Even though we deal with concrete security parameters in this paper, we kept the notation \( \text{Keygen}(1^\lambda) \) with a unary representation of a security parameter to remind this implicit efficiency requirement.

We present below more precisely the different steps of an identification scheme.

<table>
<thead>
<tr>
<th>Identification scheme ( I\mathcal{S} = (\text{Keygen}, P = (P_1, P_2), V, S_{ch}) )</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Initialization.</strong> ((pk, sk) \leftarrow \text{Keygen}(1^\lambda)). The prover has ((pk, sk)) and the verifier (pk).</td>
</tr>
</tbody>
</table>

1. \( P \) generates \((x, St) \leftarrow P_1(sk)\) and sends \( x \) to the verifier.
2. The verifier sends a uniformly random \( c \in S_{ch} \).
3. \( P \) generates \( z \leftarrow P_2(sk, x, c, St) \) and sends \( z \) to the verifier.

| Verification. The verifier accepts iff. \( V(x, c, z) = 1 \). |

We denote by \( I\mathcal{S}^{\otimes k} \) the \( k \)-fold parallel repetition of \( I\mathcal{S} \), which consists of the following

---

6
Identification scheme $\mathcal{IS}^{\otimes k}$

**Initialization.** ($pk, sk) \leftarrow \text{Keygen}(1^\lambda$). The prover has ($pk, sk$) and the verifier $pk$.

**Interaction.**

1. $P$ generates $(x^1, \ldots, x^k, St) \leftarrow P_1(sk)$ and sends $x = x^1, \ldots, x^k$ to the verifier.

2. The verifier picks a random $c = c^1, \ldots, c^k$ where each $c^i \in S_{ch}$ and sends $c$ to the prover.

3. $P$ generates $z = (z^1, \ldots, z^k) \leftarrow P_2(sk, x, c, St)$ and sends $z$ to the verifier.

**Verification.** The verifier accepts iff. $\forall i \in \{1, \ldots, k\}, V(x_1, c_1, z_1) = 1$.

We will write $\mathcal{IS}^{\otimes k} = (\text{Keygen}, P^\times k, G, V^\times k, S_{ch}^\times k, nk)$ for this parallel repetition.

Now, let’s present the properties we want an identification scheme to verify. The first property we want from an identification scheme is that the verifier accepts if a prover runs the scheme honestly.

**Definition 1** (Completeness). An identification scheme $\mathcal{IS} = (\text{Keygen}, P, V, S_{ch})$ has perfect completeness if

$$\Pr[V(x, c, z) = 1 : (pk, sk) \leftarrow \text{Keygen}(1^\lambda), (x, St) \leftarrow P_1(sk), c \leftarrow S_{ch}, z \leftarrow P_2(sk, x, c, St)] = 1.$$ 

The second property we want is honest-verifier zero-knowledge, meaning that an honest verifier cannot extract any information (in particular about the secret key $sk$), from its interaction with an honest prover.

**Definition 2** (HVZK). An identification scheme $\mathcal{IS} = (\text{Keygen}, P, V, S_{ch})$ is $\varepsilon$-HVZK if there exists an efficient simulator $S$ such that the 2 distributions:

- $D_1 : (pk, sk) \leftarrow \text{Keygen}(1^\lambda), (x, St) \leftarrow P_1(sk), c \leftarrow S_{ch}, z \leftarrow P_2(sk, x, c, St)$, return $(x, c, z)$.

- $D_2 : (x', c', z') \leftarrow S(pk, 1^\lambda), \text{ return } (x', c', z')$.

have statistical distance at most $\varepsilon$.

Finally, the third property that we require is soundness. We don’t want a cheating prover that doesn’t know the secret key $sk$ to make the verifier accept.

### 3.2 Different flavors of soundness

There are different notions of soundness and the interplay between them will play an important role in our proofs. We put directly the running time of the attacker $t$ in those definitions instead of just putting a polynomially bounded prover. This type of definition is better suited when dealing with concrete security bounds.

We first define the notions of soundness advantage and special-soundness advantage for a cheating adversary $\mathcal{A}$.
Definition 3. Let $\mathcal{S} = (\text{Keygen}, P, V, S_{ch})$ be an identification scheme. For any quantum algorithm (a quantum cheating prover) $\mathcal{A} = (A_1, A_2)$, we define

$$QADV_{\mathcal{S}}(\mathcal{A}) = \Pr[V(x, c, z) = 1 : (pk, sk) \leftarrow \text{Keygen}(1^\lambda),$$

$$(x, St) \leftarrow A_1(pk), c \leftarrow S_{ch}, z \leftarrow A_2(pk, x, c, St)]$$

$$QADV_{\mathcal{S}}^{sp}(\mathcal{A}) = \Pr[V(x, c, z) = 1 \land V(x, c', z') = 1 :$$

$$(pk, sk) \leftarrow \text{Keygen}(1^\lambda) ; (x, c, z, c', z') \leftarrow \mathcal{A}(pk)].$$

Remark: Special soundness corresponds usually to the existence of an efficient extractor $E$ such that $E(pk, x, c, z, c', z')$ produces a valid secret key $sk$ from a pair of accepting transcripts $(x, c, z)$ and $(x, c', z')$. In the context of identification schemes, it is always coupled with the hardness of generating a valid secret key. If such an extractor $E$ exists then our quantity $QADV_{\mathcal{S}}^{sp}(\mathcal{A})$ is upper bounded by the probability of outputting a valid secret key. Therefore, these 2 notions of special soundness play the same role and are essentially equivalent.

From these definitions, we can define the notion of advantage related to respectively computational soundness, statistical soundness and special soundness.

Definition 4. Let $\mathcal{S} = (\text{Keygen}, P, V, S_{ch})$ be an identification scheme. We define

$$QADV_{\mathcal{S}}(t) = \max_{\mathcal{A} = (A_1, A_2)} QADV_{\mathcal{S}}(\mathcal{A})$$

$$QADV_{\mathcal{S}}^{st}(t) = \max_{\mathcal{A} = (A_1, A_2)} QADV_{\mathcal{S}}(\mathcal{A})$$

$$QADV_{\mathcal{S}}^{sp}(t) = \max_{\mathcal{A} = (A_1, A_2)} QADV_{\mathcal{S}}^{sp}(\mathcal{A})$$

The relationship between those different notions is the following, for all $t$

$$QADV_{\mathcal{S}}(t) \leq QADV_{\mathcal{S}}^{cs}(t) \leq QADV_{\mathcal{S}}^{st}(t) \leq QADV_{\mathcal{S}}^{sp}(t).$$

Finally, we define the notion of strict soundness which says that for the second message, there is at most one valid message $z$ that the verifier will accept.
Definition 6. Let $\mathcal{IS} = (\text{Keygen}, P, V, S_{ch})$ be an identification scheme. We say that $\mathcal{IS}$ has strict soundness iff.

$$\forall x, \forall c, |\{z : V(x, c, z) = 1\}| \leq 1.$$ 

3.3 Soundness vs. special soundness

The reason why we have to deal with special soundness is that in many cases, we can construct identification schemes for which the special soundness can be directly reduced to a computationally hard problem. However, when we want to use identification schemes for instance for signature schemes, we require them to have computational soundness. Therefore, we need to find ways to relate them.

In the classical setting, we can actually interpret the use of the forking lemma [PS96] as a way to relate the soundness and the special soundness of the underlying protocols. In the quantum setting, we don’t have equivalents of such powerful theorems. In the context of Fiat-Shamir constructions of signature schemes, many of these problems can be seen as a way to relate the soundness and the special soundness of identification schemes (or more generally $\Sigma$-protocols).

We present here the relation we will use between those soundness notions in the quantum setting.

Proposition 1. Let $\mathcal{IS} = (\text{Keygen}, P, V, S_{ch})$ be an identification scheme with strict soundness. For any $t$,

$$QADV_{\mathcal{IS}}(t) \leq \frac{1}{|S_{ch}|} + 4 (QADV_{\mathcal{IS}}^{sp}(2t))^{1/3}.$$ 

In order to prove our proposition, we restate a (slightly modified) version of Theorem 3 of [CL17].

Proposition 2 (Theorem 3, [CL17]). Consider $n$ projectors $P_1, \ldots, P_n$ and a quantum mixed state $\sigma$. Let $V := \frac{1}{n} \sum_{i=1}^{n} \text{tr}(P_i \sigma)$ and let

$$E := \frac{1}{n(n-1)} \sum_{i,j\neq i} \text{tr}(P_i P_j \sigma P_j P_i).$$

Then it holds that $V \leq \frac{1}{n} + 4E^{1/3}$.

Proof of Proposition 1. Fix an identification scheme $\mathcal{IS}$ and consider a cheating $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$ running in time $t$. Now consider the following algorithm $\mathcal{B}(pk)$: run $(x, St) \leftarrow \mathcal{A}_1(pk)$, choose random $c, c' \in S_{ch}$ with $c \neq c'$. Run $z \leftarrow \mathcal{A}_2(pk, x, c, St)$ and $z' \leftarrow \mathcal{A}_2(pk, x, c', St)$. Output $(x, c, z, c', z')$. For a fixed $x, c$, $\mathcal{A}_2(pk, x, c, St)$ can be modeled as a quantum projective measurement $M^c = \{M^c_1, \ldots, M^c_\nu\}$ where $\nu$ is the output of the measurement. Let also $\sigma_{x, St}$ be the state conditioned on $\mathcal{A}_1$ outputting $x, St$.

For each $c$, from strict soundness, there is at most 1 value $\nu$ such that $V(x, c, \nu) = 1$. We define $P_c = M^c_\nu$ such a $\nu$ exists and $P_c = 0$ otherwise. Let $V_{x, St} = \frac{1}{|S_{ch}|} \sum_{c} \text{tr}(P_c \sigma_{x, St})$ that corresponds to $\mathcal{A}_2$ outputting a valid $z = \nu$ given that $\mathcal{A}_1$ outputs $x, St$. 

9
Let also $E_{x,St} = \frac{1}{|S_{ch}|(|S_{ch}| - 1)} \sum_{c, c' \neq c} tr(P_c P_c' \sigma_{x,St} P_c P_c')$, which corresponds to the probability that $B$ outputs a valid $(x, c, z, c', z')$ given that his run of $A_1$ outputs $(x, St)$.

By definition, we have $QADV_{\mathcal{IS}}(A) = E_{(pk, sk) \leftarrow \text{Keygen}(1^\lambda)} [V_{x,St}]$ and

$$QADV_{\mathcal{IS}}^{sp}(B) = E_{(pk, sk) \leftarrow \text{Keygen}(1^\lambda)} [E_{x,St}].$$

Using Proposition 2, we have $V_{x,St} \leq \frac{1}{|S_{ch}|} + 4E_{x,St}^{1/3}$. From there, we can conclude

$$QADV_{\mathcal{IS}}(A) = E_{(pk, sk) \leftarrow \text{Keygen}(1^\lambda)} [V_{x,St}] \leq E_{(pk, sk) \leftarrow \text{Keygen}(1^\lambda)} [E_{x,St}] \leq \frac{1}{|S_{ch}|} + 4E_{x,St}^{1/3}$$

$$\leq \frac{1}{|S_{ch}|} + 4 \left( E_{(pk, sk) \leftarrow \text{Keygen}(1^\lambda)} [E_{x,St}] \right)^{1/3} \quad \text{by concavity of } x \rightarrow x^{1/3}$$

$$\leq \frac{1}{|S_{ch}|} + 4 \left( QADV_{\mathcal{IS}}^{sp}(B) \right)^{1/3}.$$

Finally, to conclude, notice that $B$ runs $A_1$ once and $A_2$ twice so takes at most twice the time as $A$.

**Remark:** There are other similar bounds that can be derived, see for example [CSST11] and [Unr12].

### 3.4 The Fiat-Shamir transform for identification schemes

The Fiat-Shamir transform [FS87] is a major cryptographic construction that converts any $\Sigma$-protocol into an non-interactive protocol. The idea is to use a function $H$, modeled as a random function, and to replace the verifier’s challenge $c \in S_{ch}$ by the string $H(x)$ where $x$ is the prover’s first message. Since the prover can compute $H(x)$ himself, there is no need for interaction anymore. For any identification scheme $\mathcal{IS}$, we denote by $\text{FS}^H[\mathcal{IS}]$ its Fiat-Shamir transform.

**Running $\text{FS}^H[\mathcal{IS}]$ for an identification scheme $\mathcal{IS} = \text{(Keygen, P, V, S_{ch})}$**

**Initialization.** $(pk, sk) \leftarrow \text{Keygen}(1^\lambda)$. The prover has $(pk, sk)$ and the verifier $pk$.

**One-way communication.** $P$ generates $(x, St) \leftarrow P_1(sk)$, computes $c = H(x)$ and generates $z \leftarrow P_2(sk, x, c, St)$. He sends the pair $(x, z)$ to the verifier.

**Verification.** The verifier accepts iff. $V(x, H(x), z) = 1$.

The Fiat-Shamir transform is very useful as it can be used (among other things) to construct signature schemes from identification schemes. As for identification schemes,
we can define soundness properties. Here we will only present computational soundness.

**Definition 7.** Let $\mathcal{IS} = (\text{Keygen}, P, V, S_{ch})$ be an identification scheme and $\text{FS}^H[\mathcal{IS}]$ its Fiat-Shamir transform. Let $\mathcal{A}_H$ be a query algorithm. We define

$$QADV_{\text{FS}^H[\mathcal{IS}]}(\mathcal{A}_H) = \Pr[V(x, H(x), z) = 1 : (pk, sk) \leftarrow \text{Keygen}(1^\lambda), (x, z) \leftarrow \mathcal{A}_H].$$

$$QADV_{\text{FS}^H[\mathcal{IS}]}(t) = \max_{|\mathcal{A}_H| = t} QADV_{\text{FS}^H[\mathcal{IS}]}(\mathcal{A}_H)$$

This advantage notion will be directly related to the security of the associated signature scheme.

### 3.5 Commit and open identification schemes

A commit-and-open identification scheme is a specific kind of identification schemes where, for the first message, $P$ commits to some values $y_1, \ldots, y_n$ and after the verifier’s challenge, he reveals a subset of those values. More precisely, a commit-and-open identification scheme $\mathcal{IS} = (\text{Keygen}, P, G, V', S_{ch}, n)$ consists of the following

- A key generation algorithm $\text{Keygen}(1^\lambda) \rightarrow (pk, sk)$.
- A function $G : \{0, 1\}^l \rightarrow \{0, 1\}^m$ that will act as a commitment scheme.
- $P_1(sk) \rightarrow (x, St)$ has to output $x = (G(y_1), \ldots, G(y_n))$ for some values $y_i$ and $St = y_1, \ldots, y_n$.
- The challenge $c$ corresponds to a subset $I_c$ of $\{1, \ldots, n\}$.
- $P_2$ always outputs $z = y_{I_c}$ where $y_{I_c} = y_i_1, \ldots, y_{i|I_c|}$ for $I_c = \{i_1, \ldots, i_{|I_c|}\}, i_1 < i_2 < \cdots < i_{|I_c|}$.
- The verification function $V$ must satisfy

$$V(pk, x, c, z) = 1 \iff (\forall i \in I_c, G(z_i) = x_i) \land V'(pk, c, z) = 1.$$

Here, we explicitly mention three parameters $l, m, n$: each $y_i \in \{0, 1\}^l$, each $x_i = G(y_i) \in \{0, 1\}^m$ and the prover commits to $n$ values. Notice that in the above verification function, we require $V'$ to be independent of $x$, this captures the fact that $x$ is only used as a commitment and will rule out some unwanted cases. All the real life identification schemes we will consider have this property.
Commit-and-open Identification scheme \( IS = (\text{Keygen}, P, G, V', S_{ch}, n) \)

**Initialization.** \((pk, sk) \leftarrow \text{Keygen}(1^\lambda)\). The prover has \((pk, sk)\) and the verifier \(pk\).

**Interaction.**
1. \(P\) generates \((G(y_1), \ldots, G(y_n), y_1, \ldots, y_n) \leftarrow P_1(sk)\) and sends \(x_1, \ldots, x_n = G(y_1), \ldots, G(y_n)\) to the verifier.
2. The verifier sends a random \(c \in S_{ch}\) that corresponds to a subset \(I_c \subseteq \{1, \ldots, n\}\).
3. \(P\) sends \(z = y_{I_c}\) to the verifier.

**Verification.** The verifier accepts iff. \((\forall i \in I_c, G(y_i) = x_i) \land V'(pk, c, z) = 1\).

**Definition 8.** Let \( IS = (\text{Keygen}, P, G, V', S_{ch}, n) \) be a commit-and-open identification scheme. For any quantum algorithm \( \mathcal{O}^{\mathcal{O}_G} \) running in time \( t \) and performing \( q_G \) queries to \( \mathcal{O}_G \), we define

\[
QADV_{IS}^{RS\delta}(\mathcal{O}^{\mathcal{O}_G}) = \Pr\left[ 1 \left| \frac{1}{|S_{ch}|} \{ c : I_c \subseteq J \text{ and } V(pk, x, c, z_{I_c}) = 1 \} \right| \geq \delta : (pk, sk) \leftarrow \text{Keygen}(1^\lambda), (x, J, z_J) \leftarrow \mathcal{O}^{\mathcal{O}_G}(pk) \right].
\]

Notice that if we have \((x, J, z_J)\) such that \(\frac{1}{|S_{ch}|} \{ c : I_c \subseteq J \text{ and } V(pk, x, c, z_{I_c}) = 1 \} \geq \delta\), we can easily extract a quantum strategy that wins \( IS \) with probability \( \delta \). Indeed, take \( \mathcal{A}_1(pk) = x \) (and anything in \( St \)) and \( \mathcal{A}_2(pk, c) = z_{I_c} \) when \( I_c \subseteq J \) and anything otherwise. Therefore, we have for any \( \delta \)

\[
QADV_{IS}(\mathcal{O}^{\mathcal{O}_G}) \geq \delta QADV_{IS}^{RS\delta}(\mathcal{O}^{\mathcal{O}_G}).
\]

This bound is quite loose and there are many cases where we can prove a much tighter bound.

### 3.6 Signature schemes

A signature scheme \( S \) consists of 3 algorithms \((\text{S.KEYGEN}, \text{S.SIGN}, \text{SVERIFY})\):

- \(\text{S.KEYGEN}(1^\lambda) \rightarrow (pk, sk)\) is the generation of the public key \( pk \) and the secret key \( sk \) from the security parameter \( \lambda \).
- \(\text{S.SIGN}(m, pk, sk) \rightarrow \sigma_m\) : generates the signature \( \sigma_m \) of a message \( m \) from \( m, pk, sk \).
- \(\text{SVERIFY}(m, \sigma, pk) \rightarrow \{0, 1\}\) verifies that \( \sigma \) is a valid signature of \( m \) using \( m, \sigma, pk \). The output 1 corresponds to a valid signature.
**Correctness.** A signature scheme is correct iff. when we sample \((pk, sk) \leftarrow \text{S.keygen}(1^\lambda)\), we have for each \(m\)

\[ \text{S.verify}(m, \text{S.sign}(m, pk, sk), pk) = 1. \]

**Security definitions** We consider the standard EUF-CMA security for signature schemes. To define the advantage of an adversary \(\mathcal{A}\), we consider the following interaction with a challenger:

**Initialize.** The challenger generates \((pk, sk) \leftarrow \text{S.keygen}(1^\lambda)\) and sends \(pk\) to \(\mathcal{A}\).

**Query phase.** \(\mathcal{A}\) can perform sign queries by sending each time a message \(m\) to the challenger who generates \(\sigma = \text{S.sign}(m, pk, sk)\) and sends \(\sigma\) to \(\mathcal{A}\). Let \(m_1, \ldots, m_{qs}\) the (not necessarily distinct) queries made by \(\mathcal{A}\). The adversary can also make \(q_H\) queries to \(\mathcal{H}\).

**Output.** \(\mathcal{A}\) outputs a pair \((m^*, \sigma^*)\). The advantage \(\text{Adv}(\mathcal{A})\) for \(\mathcal{A}\) is the quantity

\[ Q_{\text{ADV}}^{\text{EUF-CMA}}_S(\mathcal{A}) = \Pr[\mathcal{A} \text{ outputs } (m^*, \sigma^*) \text{ st. } \text{S.verify}(m^*, \sigma^*, pk) = 1 \land m^* \neq m_1, \ldots, m_{qs}], \]

where \(m^* \neq m_1, \ldots, m_{qs}\) means \(\forall i, m^* \neq m_i\).

**Definition 9.** Let \(S = (\text{S.keygen}, \text{S.sign}, \text{S.verify})\) be a signature scheme. We define

\[ Q_{\text{ADV}}^{\text{EUF-CMA}}_S(t, q_H, q_S) = \max_{\mathcal{A}} Q_{\text{ADV}}^{\text{EUF-CMA}}_S(\mathcal{A}). \]

where we maximize over an adversary running in time \(t\), performing \(q_H\) hash queries and \(q_S\) sign queries.

We can directly construct a signature scheme from an identification scheme via the Fiat-Shamir transform. From an identification scheme \(IS = (\text{Keygen}, P = (P_1, P_2), V, S_{ch})\), we define the following signature scheme

\(S_{IS} = (S_{IS}.\text{keygen}(1^\lambda), S_{IS}.\text{sign}, S_{IS}.\text{verify})\) that uses a random function \(\mathcal{H}\):

- \(S_{IS}.\text{keygen}(1^\lambda) = \text{Keygen}(1^\lambda)\)
- \(S_{IS}.\text{sign}(m, pk, sk) : (x, St) \leftarrow P_1(pk), c \leftarrow \mathcal{H}(x, m), z \leftarrow P_2(sk, x, c, St), \text{output } \sigma = (x, z)\)
- \(S_{IS}.\text{verify}(m, \sigma = (x, z), pk) = V(pk, x, \mathcal{H}(x, m), z)\).

**Proposition 3.** \([KLS18]\) Let \(IS\) be an identification scheme which is \(\varepsilon\)-HVZK and has \(\alpha\) bits of min-entropy. Let \(S_{IS}\) the corresponding signature scheme. We have

\[ Q_{\text{ADV}}^{\text{EUF-CMA}}_{S_{IS}}(t, q_H, q_S) \leq Q_{\text{ADV}}^{\text{Fiat Shamir}}_{IS}(t + q_H q_S, q_H) + q_S 2^{-\alpha} + q_S \varepsilon. \]
The min-entropy here is the min-entropy of the prover’s first message when he is honest. All schemes we consider will have very large min-entropy so the $q_S 2^{-\alpha}$ will be negligibly small. Notice that in [KLS18], they prove a more general result where the identification scheme IS allows some aborts. The above proposition shows that we only need to focus on the soundness of the Fiat-Shamir transform in order to build signature schemes, which is what we will do in the next section.

4 The Fiat-Shamir reduction for commit-and-open identification schemes

In this section, we present our main theorem

Theorem 1. Let IS = (Keygen, P, G, V’, S_ch, n) be a commit-and-open identification scheme where G is modeled as a random function from $\{0, 1\}^l$ to $\{0, 1\}^{3l}$. Let $FS^H[IS_G]$ its Fiat-Shamir transform that uses a function H modeled as a random function. For any quantum adversary $\mathcal{A}^{G,H}$ running in time $t$ making $q_G$ queries to $G$ and $q_H$ queries to $H$, we have for each $\delta$

$$QADV_{FS^H[IS]}(A^{G,H}) \leq 2^n QADV_{IS}^{RS,\delta}(t + q_G, n) + \frac{2n^2}{2^t} + O(q_H^2 \delta).$$

In this theorem the security of the quantum Fiat-Shamir reduction is phrased in terms of rigid soundness. The reason we do this is that it will allow us to have a tighter security reduction in Section 4.3. We will however, show variants of this theorem using more standard soundness notions.

4.1 Proof of Theorem 1

In this Section, we will prove Theorem 1 with the exception of a key proposition that will be proven in Section 5.

of Theorem 1 Fix IS = (Keygen, P, G, V’, S_ch, n). Fix $\delta$. For any $x = x_1, \ldots, x_n \in \{0, 1\}^{3l}$, let

$$V_x = \{c \in S_{ch} : \exists z_{I_c} \text{ s.t. } \forall i \in I_c, G(z_i) = x_i \land V'(pk, c, z_{I_c}) = 1\}$$

$$= \{c \in S_{ch} : \exists z_{I_c}, V(pk, x, c, z_{I_c}) = 1\}.$$ 

where the second equality uses the definition of V from section 3.5. Let also $S = \{x : |V_x| \geq \delta\}$. Consider an adversary $\mathcal{A}^{G,H}$ that runs in time $t$ and performs respectively $q_G$ queries to $G$ and $q_H$ queries to $H$ that outputs $(x, z)$.

$$QADV_{FS^H[IS_G]}(A^{G,H}) = Pr[V(x, H(x), z) = 1 : (pk, sk) \leftarrow \text{Keygen}(1^\lambda), (x, z) \leftarrow A^{G,H}].$$
Let

$$P_1 = \Pr[V(x, H(x), z) = 1 \land x \in S : (pk, sk) \leftarrow \text{Keygen}(1^\lambda), (x, z) \leftarrow \mathcal{A}^{O_{G, O_H}}]$$

$$P_2 = \Pr[V(x, H(x), z) = 1 \land x \notin S : (pk, sk) \leftarrow \text{Keygen}(1^\lambda), (x, z) \leftarrow \mathcal{A}^{O_{G, O_H}}].$$

We clearly have $QADV_{FS^H[IS_G]}(\mathcal{A}^{O_{G, O_H}}) = P_1 + P_2$. Notice that $V(x, H(x), z) = 1$ implies $H(x) \in V_x$. Using Lemma 1, we immediately have

$$P_2 \leq O(q_H^2 \delta)$$

In order to conclude, we need to prove the following proposition

**Proposition 4.** $P_1 \leq 2QADV^H_{IS}(\tilde{O}(t), q_G) + 2n^2/2$.

This is the main technical part of the proof. Let us just discuss the difficulty in proving this proposition. Suppose our algorithm $\mathcal{A}^{O_{G, O_H}}$ outputs $(x, z)$ such that $V(x, H(x), z) = 1$ and $x \in S$. We can show that there exists $J, z'_J$ such that $\delta$. Also, we find such a couple satisfying $\forall j \in J, G(z'_J) = x_j$. If we could extract those $J, z'_J$ then we would have constructed an algorithm for the $\delta$-rigid soundness. What we will show is that we can perform this extraction using Zhandry’s model for the QRO, and in particular the compressed random oracle framework. In this framework, we can emulate calls to $O_G$ and keep track of a compressed database that contains all the couples $(z_i, x_i)$ such that $G(z_i = x_i)$ which have been fixed by the queries. This database is maintained coherently and we can show that the values $z'_J$ will appear there with high probability. Presenting Zhandry’s framework and proving formally this proposition will be the object of Section 5.

In the remainder of Section 4, we will present variants and discussions around Theorem 1. We will also see how we can apply it to commit-and-open identification schemes which are a parallel repetition of identification schemes with challenge size 3. We show in Theorem 2 essentially a tight security reduction for those schemes.

### 4.2 Variants of Theorem 1

We now present a variation of theorem 1 that uses standard soundness.

**Proposition 5.** Let $\mathcal{IS} = (\text{Keygen}, P, G, V', S_{ch}, n)$ be a commit-and-open identification scheme where $G$ is modeled as a random function from $\{0,1\}^l$ to $\{0,1\}^{3l}$. Let $\text{FS}^H[\mathcal{IS}_G]$ its Fiat-Shamir transform that uses a function $H$ modeled as a random function. For any quantum adversary $\mathcal{A}^{O_{G, O_H}}$ running in time $t$ making $q_G$ queries to $O_G$ and $q_H$ queries to $O_H$, we have for each $\delta$

$$QADV_{FS^H[IS_G]}(\mathcal{A}^{O_{G, O_H}}) \leq O(q_H\sqrt{QADV_{\mathcal{IS}_G}(t + q_G, n)}) + \frac{2n^2}{2}.$$
Proof. Fix a quantum adversary $\mathcal{A}^{\mathcal{O}_G,\mathcal{O}_H}$ running in time $t$ making $q_C$ queries to $\mathcal{O}_G$ and $q_H$ queries to $\mathcal{O}_H$. For each $\delta$, we have $\delta QADV_{\mathcal{I}_G}^{RS,\delta}(t + q_G, n) \leq QADV_{\mathcal{I}_G}^{RS,\delta}(t + q_G, n)$. Putting this into Theorem 1, we get that for any $\delta$,

$$QADV_{\mathcal{I}_G}^{RS,\delta}(t + q_G, n) \leq \frac{2}{\delta} QADV_{\mathcal{I}_G}(t + q_G, n) + \frac{2n^2}{2^t} + O(q_H^2 \delta).$$

Now, take $\delta = \sqrt{QADV_{\mathcal{I}_G}(t + q_G, n)}$. Plugging this in the above equation, we obtain the desired result.

As we mentioned in Section 3.3, the bound between soundness and rigid soundness we use here is quite loose. If one wants to have a relation with soundness, we still recommend to start from Theorem 1 and try to obtain the best bound possible and not go through the above proposition.

We now present a variant including special soundness. It is quite often the case, we only know a bound on the special soundness of $\mathcal{I}_G$. In order to relate the security of the quantum Fiat-Shamir transform with the special soundness of the scheme, we can combine the above Proposition with a bound relating special soundness and soundness such as Proposition 1. Notice that all commit-and-open identification schemes we consider have strict soundness because $G$ is injective with overwhelming probability.

By doing this, we obtain the following statement.

**Proposition 6.** Let $\mathcal{I}_G = (\text{Keygen}, P, G, V', S_{ch}, n)$ be a commit-and-open identification scheme where $G$ is modeled as a random function from $\{0,1\}^l$ to $\{0,1\}^{3l}$. Let $\mathcal{F}_H^{\mathcal{I}_G}$ its Fiat-Shamir transform that uses a function $H$ modeled as a random function. For any quantum adversary $\mathcal{A}^{\mathcal{O}_G,\mathcal{O}_H}$ running in time $t$ making $q_C$ queries to $\mathcal{O}_G$ and $q_H$ queries to $\mathcal{O}_H$, we have for each $\delta$

$$QADV_{\mathcal{F}_H^{\mathcal{I}_G}}(\mathcal{A}^{\mathcal{O}_G,\mathcal{O}_H}) \leq O\left(q_H \sqrt{\frac{1}{|S_{ch}|}} + 4 \left(QADV_{\mathcal{I}_G}^{sp}(2t + 2q_G, 2n)\right)^{\frac{1}{3}}\right) + \frac{2n^2}{2^t}.$$  

### 4.3 A concrete example: commit-and-open identification schemes with challenge size 3 repeated in parallel

In this section, we will do a practical analysis of identification schemes which are a parallel repetition of commit-and-open identification schemes with challenge size 3. MQDSS, Picnic/Fish and the Stern signature are all based on an identification scheme which satisfies this property so the theorem below applies to these schemes. We will use Theorem 1 to get much tighter bounds than if we used those of [DFMS19] and [LZ19].

First, for identification schemes with challenge space $S_{ch} = \{0,1,2\}$, we define the following security definition.
Definition 10. Let $\mathcal{I}S = (\text{Keygen}, P, G, V', \{0, 1, 2\}, n)$ be a commit-and-open identification scheme. For any quantum algorithm $\mathcal{A}$, we define

$$QADV_{\mathcal{I}S}^{012}(\mathcal{A}) = \Pr\left[V'(pk, 0, z_{I_0}) = 1 \land V'(pk, 1, z_{I_1}) = 1 \land V'(pk, 2, z_{I_2}) = 1: (pk, sk) \leftarrow \text{Keygen}(1^\lambda); (x, z) \leftarrow \mathcal{A}(pk)\right]$$

and $QADV_{\mathcal{I}S}^{012}(t, q_G) = \max_\mathcal{A} QADV_{\mathcal{I}S}^{012}(\mathcal{A})$, where the maximum is over algorithms $\mathcal{A}$ running in time $t$ and performing $q_G$ queries to $G$.

The security of the 3 signature schemes we consider are based on the above quantity. 

In order to prove the quantum Fiat-Shamir reduction for these schemes, we just need to relate $QADV_{\mathcal{I}S}^{012}$ to $QADV_{\mathcal{I}S^{\otimes 3}}^{RS, \delta,k}$ and apply Theorem 1. This is done via the following proposition:

Proposition 7. Let $\mathcal{I}S = (\text{Keygen}, P, G, V', \{0, 1, 2\}, n)$ be a commit-and-open identification scheme where $G$ is modeled as a random function from $\{0, 1\}^l$ to $\{0, 1\}^{3l}$. Let $\mathcal{I}S^{\otimes 3}_G$ be its parallel repetition $k$ times. We have

$$QADV_{\mathcal{I}S^{\otimes 3}_G}^{RS, \delta,k}(t, q_G) \leq QADV_{\mathcal{I}S}^{012}(t + O(nk), q_G) \quad \text{when} \quad \delta \geq \frac{2^k + 1}{3^k}.$$

Proof. We write $\mathcal{I}S^{\otimes 3}_G = (\text{Keygen}, P^{\otimes k}, G, V'^{\otimes k}, \{0, 1, 2\}^{3k}, kn)$. For each $J \subseteq \{1, \ldots, kn\}$ and $z_J$, let $T(J, z_J) = \{c : I_c \subseteq J \text{ and } V'(pk, c, z_L) = 1\}$. Let $\varepsilon = QADV_{\mathcal{I}S^{\otimes 3}_G}^{RS, \delta,k}(t, q_G)$. Choose an algorithm $\mathcal{A}$ running in time $t$ and performing $q_G$ queries to $\mathcal{G}$ such that

$$\Pr\left[|T(J, z_J)| \geq \frac{2^k + 1}{3^k} : (pk, sk) \leftarrow \text{Keygen}(1^\lambda); (x, J, z_J) \leftarrow \mathcal{A}(pk)\right] = \varepsilon.$$

Let $(J, z_J)$ such that $|T(J, z_J)| \geq \frac{2^k + 1}{3^k}$. This means that there exists 3 strings $c^0, c^1, c^2$ each in $\{0, 1, 2\}^k$ and a position $d \in \{1, \ldots, k\}$ such that $c^b \in T(J, z_J)$ and $c^b_d = b$ for $b \in \{0, 1, 2\}$.

It will be easier to consider $J$ as a set of couples and to match $\{1, \ldots, kn\}$ with $\{1, \ldots, k\} \times \{1, \ldots, n\}$. So for each $J \subseteq \{1, \ldots, k\} \times \{1, \ldots, n\}$, we define sets $I_i \subseteq \{1, \ldots, n\}$ such that $J = \{(i, j) : i \in \{1, \ldots, k\} \text{ and } j \in I_i\}$. This allows us also to write $z_J = z^1_{I_1}, z^2_{I_2}, \ldots, z^k_{I_k}$, for some strings $z^i$. With these notations, we also have for each string $c = c_1, \ldots, c_n$, $I_c = \{(i, j) : i \in \{1, \ldots, k\} \text{ and } j \in I_{c_i}\}$ and we can write $z_c = z^1_{I_{c_1}} z^2_{I_{c_2}} \cdots z^k_{I_{c_k}}$.

In order to conclude, using our strings $c^0, c^1, c^2$ such that $c^b \in T(J, z_J)$ and $c^b_d = b$ for $b \in \{0, 1, 2\}$, we have for each $b \in \{0, 1, 2\}$:

$$\{(d, j) : j \in I_b\} = \{(d, j) : j \in I_{c^b_d}\} \subseteq I_{c^b} \subseteq J.$$

This implies that $I_b \subseteq J_d$ for each $b \in \{0, 1, 2\}$. Moreover, $V^{\otimes k}(pk, c^b, z_{I_b}) = 1$ for $b \in \{0, 1, 2\}$ which implies, when looking at position $d$ that
\[ V(pk, c^b_d, z^d_{I_b}) = V(pk, b, z^d_{I_b}) = 1 \quad \text{for } b \in \{0, 1, 2\}. \] (1)

Notice also that it is efficient to construct \( z^d \) from \((J, z_J)\). Indeed, one can try all the positions \( d \in \{1, \ldots, k\} \) and find the one such that \( I_b \subseteq J_d \) for \( b \in \{0, 1, 2\} \) and Equation (1) is satisfied.

Now, let us conclude. We start from an algorithm \( \mathcal{A} \) that outputs \((J, z_J)\) such that \( |T(J, z_J)| \geq \frac{2^k+1}{3^k} \) with probability \( \varepsilon \). If \( |T(J, z_J)| \geq \frac{2^k+1}{3^k} \), we showed how to construct in time \( O(nk) \) a string \( z^d \) such that \( V(b, z^d_{I_b}) = 1 \) for \( b \in \{0, 1, 2\} \) and Equation 1 is satisfied.

Combining this with Theorem 1, we immediately get

**Theorem 2.** Let \( \mathcal{IS} = (\text{Keygen}, P, G, V', \{0, 1, 2\}, n) \) be a commit-and-open identification scheme where \( G \) is modeled as a random function from \( \{0, 1\}^l \) to \( \{0, 1\}^{3l} \). Let \( \mathcal{IS} \otimes k \) be its parallel repetition \( k \) times. We have

\[ QADV_{FS^k}[\mathcal{IS} \otimes k] (\mathcal{A}^G, \mathcal{H}^G) \leq 2QADV_{\mathcal{IS}}^{012}(t + O(nk), q_G) \geq \varepsilon \] which allows us to conclude the proof.

Combining this with Theorem 1, we immediately get

\[ QADV_{FS^k}[\mathcal{IS} \otimes k] (\mathcal{A}^G, \mathcal{H}^G) \leq 2QADV_{\mathcal{IS}}^{012}(t + O(nk), q_G) + 2k^2 + O(q_c^2 2^k + 1). \]

4.4 Comparison with previous work and tightness of Theorem 2

The work of [DFMS19] and [LZ19] showed respectively

\[ QADV_{\mathcal{IS}}(t) \lesssim O(q_c^2 QADV_{\mathcal{IS}}(t')) \quad [DFMS19] \]
\[ QADV_{\mathcal{IS}}(t) \lesssim O(q_c^2 QADV_{\mathcal{IS}}(t')) \quad [LZ19] \]

with \( t' \approx t \)

To the best of our knowledge, the parameters are not explicit so we leave them in the \( \approx \) form. These results are presented in terms of standard soundness. Already, we can see that Proposition 5 will give better bounds. Of course, the results of [DFMS19] and [LZ19] are general while our results only apply to commit and open identification schemes.

In the case of the schemes studied in Section 4.3 things become even more interesting. Here, we need to relate \( QADV_{\mathcal{IS}}(t) \) with \( QADV_{\mathcal{IS}}^{012}(t) \). We could use the above combined with a relation between \( QADV_{\mathcal{IS}}^{012}(t) \) and \( QADV_{\mathcal{IS}}(t) \). However, quantum generic relations between soundness and 3-special soundness gives only \( QADV_{\mathcal{IS}}(t) \leq (QADV_{\mathcal{IS}}^{012}(t))^{1/5} \). Putting this together, we would have

\[ QADV_{\mathcal{IS}}^{012}(t) \lesssim O(q_c^2 (QADV_{\mathcal{IS}}^{012}(t'))^{1/5}) \quad [DFMS19] \]
\[ QADV_{\mathcal{IS}}^{012}(t) \lesssim O(q_c^2 (QADV_{\mathcal{IS}}^{012}(t'))^{1/5}) \quad [LZ19] \]

with \( t' \approx t \)
which is here significantly less tight than the results of Theorem 2.

Another thing we want to mention is that in many cases, including the identification schemes from MQDSS, Picnic/Fish and the Stern signature, the term $O(q^2 H^2 k)$ is necessary (up to some $\text{poly}(k,n)$ factors) and correctly identifies an attack on $\text{FS}^H[\mathcal{I S}_{G}^{\otimes k}]$. Indeed, suppose there is an adversary for $\mathcal{I S}$ such that for any pair of challenges $(c_1^*, c_2^*)$, can produce $x,z$ such that

$$V'(pk, x, c_1^*, z_{c_1^*}) = V'(pk, x, c_2^*, z_{c_2^*}) = 1.$$  

Using $O(n)$ queries to $O_H$ MQDSS, Picnic/Fish and the Stern signature have this property.

By applying this strategy $k$ times on $\text{FS}^H[\mathcal{I S}_{G}^{\otimes k}]$ each time choosing a random pair $(c_1^*, c_2^*)$, we construct a $x,z$ such that

$$|\{c : V(pk, x, c) = 1\}| = 2^{k/3}.$$  

If $H(x)$ is in this set, then we get an attack on $\text{FS}^H[\mathcal{I S}_{G}^{\otimes k}]$. This happens with probability $(2/3)^k$ using $O(k)$ queries to $\mathcal{O}_H$. Now, we can perform quantum amplitude amplification with $q_H$ steps - so that the total number of $\mathcal{O}_H$ queries is $q_H$ - and the total success probability will be amplified to $O(q_H^2 (2/3)^k)$ which is the term we have in Theorem 2 up to $k$ and $n$ factors.

### 4.5 Compressing the commitments

Theorems 1 and 2 show the security of the Fiat-Shamir transform but the resulting non-interactive scheme (hence the resulting signature scheme) still requires a random permutation as a hash function. Signature schemes based on commit-and-open identification already have a quite high signature length (i.e. communication cost) and using a random function from $\{0,1\}^l$ to $\{0,1\}^{3l}$ can even more increase the signature length. Our idea is to replace $G$ with a sponge function.

We consider sponge functions from $\{0,1\}^l \rightarrow \{0,1\}^{3l}$. We can see a sponge function $Sp$ as 2 functions, an absorb and a squeeze function ($S_{abs}$, $S_{sq}$) such that $S_{abs} : \{0,1\}^l \rightarrow \{0,1\}^{r+c}$ and $S_{sq} : \{0,1\}^{r+c} \rightarrow \{0,1\}^{3l}$ where $r$ is the rate and $c$ is the capacity of the sponge. The whole sponge function $S$ will then be $S = S_{sq} \circ S_{abs}$ (this includes eventual padding operations) where $f$ is underlying function of.

In [CHS19], it is shown that random sponges are indistinguishable from random functions.

**Proposition 8.** For any quantum query algorithm $\mathcal{A}^f$, we have

$$\Pr_{H \leftarrow \mathcal{F}_{\{0,1\}^l}} [\mathcal{A}^{f_H}() = 1] - \Pr_{S \leftarrow Sp} [\mathcal{A}^{f_S}() = 1] \leq \frac{8\pi^2(q + 6l)^3}{3 \cdot 2^c}.$$  

where $Sp$ is the set of random sponges (for a randomly chosen internal function). This shows that we require a bit more than $2^{c/3}$ queries to distinguish both settings.

We now show how to modify a commit-and-open identification scheme using sponge functions to reduce the commitment costs.

19
Running FS\(^H\)[\(\mathcal{LS}\)] for a commit-and-open identification scheme where the commitment function is a sponge \(Sp = (S_{abs}, S_{sq})\)
\[\mathcal{LS} = (\text{Keygen}, P, Sp, V', S_{ch}, n)\]

**Initialization.** \((pk, sk) \leftarrow \text{Keygen}(1^\lambda)\). The prover has \((pk, sk)\) and the verifier \(pk\).

**One-way communication.** \(P\) generates \((Sp(y_1), \ldots, Sp(y_n), y_1, \ldots, y_n) \leftarrow P_1(sk)\).
Let \(x = Sp(y_1), \ldots, Sp(y_n)\) and \(z = y_1, \ldots, y_n\). He computes \(c = H(x)\) and sends the pair \((x, z, c)\) to the verifier.

**Verification.** The verifier accepts iff. \(V(x, H(x), z) = 1\).

From the quantum security of sponge functions, we can use \(Sp\) instead of \(G\). We haven’t yet reduced the communication because each \(Sp(y_i) \in \{0,1\}^{3l}\). In order to reduce the communication, the prover can send \(S_{abs}(y_i)\) instead of \(Sp(y_i)\). Since \(S_{sq}\) is public, the verifier can compute \(Sp(y_i)\) himself from \(S_{abs}(y_i)\).

With this transformation, each commitment (i.e. each \(S_{abs}(y_i)\)) has size \(c + r\) which can be made small. For example, we can take \(c = 400, r = 64\) (to not have a too big number of rounds) and from the above proposition, we would have more than 128 bits of quantum security, for reasonable values of \(l\).

5 Proving Proposition 4

In order to prove our lemma, we will need to dive in Zhandry’s formulation of the QROM.

5.1 The Quantum Random Oracle Model, reminder

The Quantum Random Oracle Model (QROM) is a model where we model a certain function with a random function \(H : \{0,1\}^n \rightarrow \{0,1\}^m\). Since we are in the quantum setting, we have a black box access to \(H\) but also to the unitary \(\mathcal{O}_H(|x\rangle|y\rangle) = |x\rangle|H(x) + y\rangle\).

**Notation:** When we write a state of \(n\) qubits in the Hadamard basis, we will write \(|b\rangle^H\) which will correspond to the state \(\frac{1}{\sqrt{2^n}} \sum_y (-1)^{b \cdot y} |y\rangle\).

5.2 Zhandry’s oracles

One difficulty when dealing with the QROM is to deal with inherent randomness in the choice of \(H\). In [Zha18], Zhandry proposed another way at looking at the QROM, where the choice of \(H\) is encoded in a quantum register \(D\) (for database) which is a purification of the working register. This framework is quite elaborate and we present here some of the ideas and a small subset of the results presented in [Zha18]. We sometimes will go a little fast and we refer to [Zha18] for more details and explanations.
It is good for now to think of \(D\) as an internal register of the oracle function. This approach allows us to work on a single quantum state instead of dealing with a random choice of \(H\).

**The standard oracle.** The internal database of the oracle is initialized at

\[
|D_0\rangle_D = \frac{1}{\sqrt{2^m 2^n}} \sum_{H \in \mathcal{F}^{m \times \{0,1\}^n}} \mathbf{1} \otimes |x\rangle |H(x)\rangle
\]

which stores in a uniform superposition over all functions \(H : \{0,1\}^n \rightarrow \{0,1\}^m\) all the input/output pairs \((x, H(x))\). If \(|D_0\rangle\) is measured in the computational basis, we obtain the full specification of a random function \(H\).

How do we query \(O_H\) in this framework? By applying the unitary \(O^{St} : \langle x | \left| H(x) \right\rangle_D \left\rightarrow \left| x \right\rangle_X \left| y \right\rangle_Y \left| H \right\rangle_D\) where \(X, Y\) are the input registers to the oracle and \(D\) is its internal quantum register containing the description of \(H\). Notice that this unitary only uses \(D\) as a classical control so even if it can entangle \((X, Y)\) and \(D\), measuring \(D\) in the computational basis will still yield a uniformly chosen \(H \in \mathcal{F}^m\). Using \(O^{St}\) with an internal register \(D\) is actually equivalent from an adversary’s point of view to applying \(O_H\) for a randomly chosen \(H\).

At any point, we say that \((x, y)\) is in the database if when measuring the whole register \(D\) in the computational basis, we get an element \(x, H(x) = y\).

It seems that this is just a rewriting technique and that not much has been done. However, having access to this extra register \(D\) allows us to control the different possibilities of \(H\) after some queries done by an algorithm. It is shown in [Zha18] how to use this to (re)prove tight lower bounds for both the search and the collision problem for random functions.

**The compressed standard oracle.** One problem with the standard oracle described above is that the database register \(D\) is of exponential size so we cannot efficiently manipulate it and hence cannot emulate efficiently the whole QRO. The idea will be to store a compressed version of this database. We now define some quantum states that will allow us to define the compressed oracle.

Fix an integer \(t\) and let \(S_t = \{(x_1, \ldots, x_t) : \forall i, x_i \in \{0,1\}^n \text{ and } x_i < x_{i+1}\}\). Let \(X \in S_t\) and let \(R = (r_1, \ldots, r_t)\) be a tuple of values in \(\{0,1\}^m\) each different from 0. We define the state \(|\psi^S_{X,R}\rangle\) on register \(D\) as:

\[
|\psi^S_{X,R}\rangle = \bigotimes_{x \in \{0,1\}^n} |x\rangle |y(x)\rangle^H.
\]

where \(y(x) = r_i\) if \(x = x_i\) and \(y(x) = 0\) otherwise. This state corresponds to the standard database where we associate to each \(x_i\) the value \(r_i\) in the Hadamard basis and
associate the uniform distribution \(i.e.\) the value 0 in the Hadamard basis to other values. Zhandry showed that after \(t\) queries, the database register is in \(\text{span}\{|\psi_{X,R}^S\rangle\}_{X,R}\) where the set is over all the \(X, R\) defined above of size at most \(t\).

Let us rewrite \(|\psi_{X,R}^S\rangle\). For each \(X \in S_t\), let \(D_X\) the subset of register of \(D\) containing the values \(|x\rangle|y(x)\rangle^H\) for \(x \in X\) and \(D_X^c\) the subset of register of \(D\) containing the values \(|x\rangle|y(x)\rangle^H\) for \(x \notin X\). By reordering the registers, we write

\[
|\psi_{X,R}^S\rangle = \left( \bigotimes_{i \in \{1, \ldots, t\}} |x_i\rangle|r_i\rangle^H \right)_{D_X} \left( \bigotimes_{x \notin X} |x\rangle|0\rangle^H \right)_{D_X^c}.
\]

The idea of the compressed database is that after \(q\) queries, the register \(D_X\) contains at most \(q\) pairs \(|x_i\rangle|r_i\rangle^H\) and that they are enough to construct the full state \(|\psi_{X,R}^S\rangle\).

For a fixed number of queries \(q\), we define the state \(|\psi_{X,R}^{C,q}\rangle\) on register \(D^{C,q}\) as:

\[
|\psi_{X,R}^{C,q}\rangle_{D^{C,q}} = \bigotimes_{i \in \{1, \ldots, t\}} |x_i\rangle|r_i\rangle^H \bigotimes_{j \in \{t+1, \ldots, q\}} |\perp\rangle|0\rangle^H.
\]

with the convention that \(\{q+1, \ldots, q\} = \emptyset\). Similarly, for each \(X\), we decompose register \(D^{C,q}\) into \(D_X^{C,q}\) and \(D_X^{c,q}\) such that

\[
|\psi_{X,R}^{C,q}\rangle_{D^{C,q}} = \left( \bigotimes_{i \in \{1, \ldots, t\}} |x_i\rangle|r_i\rangle^H \right)_{D_X} \left( \bigotimes_{j \in \{t+1, \ldots, q\}} |\perp\rangle|0\rangle^H \right)_{D_X^c}.
\]

There is a (not necessarily efficient) isometry \(E\) that goes from \(|\psi_{X,R}^S\rangle\) to \(|\psi_{X,R}^{C,q}\rangle\) so this compression is lossless. The idea of the compressed database is to store states \(|\psi_{X,R}^{C,q}\rangle\) instead of \(|\psi_{X,R}^S\rangle\). The compressed oracle (for a defined total of queries \(q\)) is the unitary

\[
\mathcal{O}^C : |x\rangle_X|y\rangle_Y E(|\mathcal{H}\rangle)_D \to |x\rangle_X|y + \mathcal{H}(x)\rangle_Y E(|\mathcal{H}\rangle)_D.
\]

**Proposition 9** (Zha18). Consider any quantum algorithm \(\mathcal{A}^O\). We have

\[
\Pr[\mathcal{A}^{O^{S,t}}(\cdot) = 1] - \Pr[\mathcal{A}^{O^{C}}(\cdot) = 1] = 0.
\]

In order words, applying \(O^C\) is indistinguishable to applying \(O^S\).

How efficiently can we emulate \(\mathcal{A}^{O^C}\) efficiently by keeping track of the compressed database register \(D^C\)? For each call to \(O_C\), Zhandry showed a procedure that achieves this using a constant number of membership, insertion or deletion steps in the database registers \(D^C\). These steps must be done coherently so it’s not a priori clear if you can perform them efficiently. Fortunately, we know quantum data structures that can achieve these operations in time \(O(\text{polylog}(q))\) where \(q\) is the size of the database. One can use for example the skip list + hash table data structure used by Ambainis to perform quantum random walks [Amb07] or quantum radix trees [BJLM13] used for quantum subset sum algorithms. Therefore, we can emulate each query in time \(O(\text{polylog}(q))\) and the \(q\) queries in time \(\tilde{O}(q)\). Note that these efficient quantum data structures need to use quantum RAM.
5.3 Main technical lemma

The above proposition shows that the working registers of an algorithm using the standard oracle or the compressed oracle are indistinguishable. An interesting feature is to be able to recover information about $H$ from $D_C$ efficiently. Lemma 5 of [Zha18] shows that if an algorithm $A_{O_C}$ outputs $(x,y)$ st. $H(x) = y$ then it can retrieve efficiently $(x,y)$ in $D_C$ with very high probability (while it always appears in $D$).

Here, we extend this lemma when to the case where the algorithm outputs a value $y$ but without knowing a preimage $x$. We fix here $n = l$ and $m = 3l$ for some integer $l$ so we consider random functions $H : \{0,1\}^l \to \{0,1\}^{3l}$.

**Proposition 10.** Consider a quantum algorithm $A_{O_S}$ that does $q$ quantum queries to a random oracle $O$ acting on registers $U = XYZ$ where $X, Y$ are the query registers to $O$. Fix a function $f$ and consider the following scenarios:

1. Run an algorithm $A_{O_S}$ on registers $UD$ where $D$ is the database register. For each $y = (y_1, \ldots, y_n)$, we define

   $$p_y = \Pr[\exists J \subseteq \{1, \ldots, n\}, \exists x_J = \{x_i\}_{i \in J}, \text{ st. } \forall i \in J, (x_i, y_i) \in D \text{ and } f(J, x_J, y_J) = 1 | A_{O_S} \text{ outputs } y].$$

2. Run an algorithm $A_{O_C}$ on registers $UD_{C,q}$ where $D_{C,q}$ is the compressed database register. For each $y = (y_1, \ldots, y_n)$, we define

   $$p'_y = \Pr[\exists J \subseteq \{1, \ldots, n\}, \exists x_J = \{x_i\}_{i \in J}, \text{ st. } \forall i \in J, (x_i, y_i) \in D_{C,q} \text{ and } f(J, x_J, y_J) = 1 | A_{O_C} \text{ outputs } y].$$

For any tuple $y = (y_1, \ldots, y_n)$, we have $p_y \leq 2p'_y + 2^{2n}$.

**Proof.** Fix a tuple $\tilde{y} = (\tilde{y}_1, \ldots, \tilde{y}_n)$ where each $\tilde{y}_i \in \{0,1\}^{3l}$ and let $p = p_{\tilde{y}}$ and $p' = p'_{\tilde{y}}$. Our proof will have 4 steps.

**Step 1: characterize $p$.** Consider the first scenario and let $|\Phi_1\rangle$ be the state in UD conditioned on the algorithm $A_{O_S}$ outputting $\tilde{y}$. We have

$$|\Phi_1\rangle = \sum_{u} \alpha_{u, X, R} |u\rangle_U |\psi^{S}_{X, R}\rangle_{D_C}.$$

We define

$$\Lambda = \{(u, t, X, R) : t \in \{0, \ldots, q\}, X = (x_1, \ldots, x_t) \in S_t, R = (r_1, \ldots, r_t) : 0 \notin R\}.$$
so that we can rewrite $|\Phi_1\rangle = \sum_{(u,t,X,R) \in \Lambda} \alpha_{u,X,R} |u\rangle U |\psi^S_{X,R}\rangle_D$. For any $Y = (y_0, \ldots, y_{2^l-1})$, let $|\eta^S_Y\rangle = \bigotimes_{x \in \{0,1\}^n} |x\rangle |y_x\rangle$. $Y$ is considered here as a total description of the function $\mathcal{H}_Y : x \rightarrow y_x$ and $|\eta^S_Y\rangle$ is the standard database state corresponding to $\mathcal{H}_Y$. Let also

$$|\eta^S_Y\rangle = \bigotimes_{x \in \{0,1\}^n} |x\rangle |y_x\rangle.$$  

We have

$$p = \left\| \sum_{Y \in \text{VALID}} (I_U \otimes |\eta^S_Y\rangle \langle \eta^S_Y|) |\Phi_1\rangle \right\|_2^2. \quad (2)$$

We define $|\Omega_p\rangle = \sum_{Y \in \text{VALID}} (I_U \otimes |\eta^S_Y\rangle \langle \eta^S_Y|) |\Phi_1\rangle$ so that $p = |||\Omega_p|||^2$. For each $X = (x_1, \ldots, x_t) \in X_t$, let:

$$\text{VALID}_X = \{Y = (y_0, \ldots, y_{2^l-1}) : \exists J \subseteq \{1, \ldots, n\}, \exists x_J = \{x_i \in \{0,1\}^n \}_{i \in J}, \forall i \in J, x_i \in X, y_{x_i} = \tilde{y}_i \text{ and } f(J, x_J, \tilde{y}_j) = 1\}$$

$$\text{INVALID}_X = \text{VALID} \cap \overline{\text{VALID}_X}$$

From the above, we have that for each $X \in S_t$, $(\text{VALID}_X, \text{INVALID}_X)$ is a partition of the set $\text{VALID}$. Therefore, we have

$$|\Omega_p\rangle = \sum_{(u,t,X,R) \in \Lambda} \alpha_{u,X,R} \sum_{Y \in \text{VALID}} (I_U \otimes |\eta^S_Y\rangle \langle \eta^S_Y|) |u\rangle U |\psi^S_{X,R}\rangle_D$$

$$= |\Omega_1\rangle + |\Omega_2\rangle$$

where

$$|\Omega_1\rangle = \sum_{(u,t,X,R) \in \Lambda} \alpha_{u,X,R} \sum_{Y \in \text{VALID}_X} (I_U \otimes |\eta^S_Y\rangle \langle \eta^S_Y|) |u\rangle U |\psi^S_{X,R}\rangle_D$$

$$|\Omega_2\rangle = \sum_{(u,t,X,R) \in \Lambda} \alpha_{u,X,R} \sum_{Y \in \text{INVALID}_X} (I_U \otimes |\eta^S_Y\rangle \langle \eta^S_Y|) |u\rangle U |\psi^S_{X,R}\rangle_D.$$  

This gives $p = |||\Omega_1\rangle + |\Omega_2\rangle||^2$.

**Step 2: Characterize $p'$.** Consider the second scenario and let $|\Phi_2\rangle$ be the state in $\text{UD}^{C,q}$ conditioned on the algorithm outputting $\tilde{y}$. We can write

$$|\Phi_2\rangle = \sum_{(u,t,X,R) \in \Lambda} \alpha_{u,X,R} |u\rangle U |\psi^{C,q}_{X,R}\rangle_D^{C,q}.$$
where we recall that

$$|\psi_{X,R}^{C,q}\rangle_{D_{c,q}} = \left( \bigotimes_{i \in \{1,\ldots,t\}} |x_i\rangle |r_i\rangle^H \right)_{D_{c,q} X} \left( \bigotimes_{j \in \{t+1,\ldots,q\}} |\perp\rangle |0\rangle^H \right)_{D_{c,q} X}.$$  

For any $Y = (y_1, \ldots, y_t)$, let

$$|\eta_{X,Y}^{C,q}\rangle_{D_{c,q}} = \left( \bigotimes_{i \in \{1,\ldots,t\}} |x_i\rangle |y_i\rangle \right)_{D_{c,q} X} \left( \bigotimes_{j \in \{t+1,\ldots,q\}} |\perp\rangle |0\rangle^H \right)_{D_{c,q} X}.$$  

Notice that the $|y_i\rangle$ are in the computational basis now and that $|\eta_{X,Y}^{C,q}\rangle \perp |\eta_{X',Y'}^{C,q}\rangle$ for $X \neq X'$ or $Y \neq Y'$. For $X \in S_t$ with $t \geq n$, let

$$\text{VALID}_X' = \{ Y = (y_1, \ldots, y_t) : \exists J \subseteq \{1, \ldots, n\}, \exists x_i = \{x_i\}_{i \in J}, \text{ st.}$$

$$\forall i \in J, x_i \in X, y_{x_i} = \tilde{y}_i \text{ and } f(J, x_i, \tilde{y}_J) = 1 \}.$$  

We have

$$p' = |||\psi_{p'}|||^2 \quad \text{with} \quad |\psi_{p'}\rangle = \sum_{t' \in \{0,\ldots,q\}} \sum_{X = (x_1, \ldots, x_{t'}) \subseteq X} \sum_{Y \in \text{VALID}_X'} \sum_{(u, t, X, R) \in \Lambda} \alpha_{u, X, R} |u\rangle |\psi_{X, R}^{C,q}\rangle_{D_{c,q}}.$$  

We write

$$|\psi_{p'}\rangle = \sum_{(u, t, X, R) \in \Lambda} \sum_{Y \in \text{VALID}_X'} \sum_{X' = (x_1, \ldots, x_{t'})} \sum_{Y \in \text{VALID}_{X'}} \alpha_{u, X, R} |u\rangle |\psi_{X, R}^{C,q}\rangle_{D_{c,q}}.$$  

where the second equality comes from the fact that $|\eta_{X,Y}^{C,q}\rangle \perp |\eta_{X',Y'}^{C,q}\rangle$ for $X' \neq X$.

**Step 3: Show that $p' = |||\Omega_1|||^2$.** Fix $X = (x_1, \ldots, x_t) \in S_t$. We write

$$|\psi_{X,R}^S\rangle = \left( \bigotimes_{i \in \{1,\ldots,t\}} |x_i\rangle |r_i\rangle^H \right)_{D_{c,q} X} \left( \bigotimes_{x \notin X} |0\rangle^H \right)_{D_{c,q} X} = |\psi_{X,R}^S(D_{X})\rangle_{D_{c,q} X} \otimes |\psi_{X,R}^S(D_{X})\rangle_{D_{c,q} X}.$$  

Similarly, we write

$$|\eta_{Y}^S\rangle = \left( \bigotimes_{i \in \{1,\ldots,t\}} |x_i\rangle |y_i\rangle \right)_{D_{c,q} X} \left( \bigotimes_{x \notin X} |y_x\rangle \right)_{D_{c,q} X} = |\eta_{Y}^S(D_{X})\rangle_{D_{c,q} X} \otimes |\eta_{Y}^S(D_{X})\rangle_{D_{c,q} X}.$$  

25
Notice that $\text{VALID}_X = \{Y = (y_0, \ldots, y_{2^n-1}) : (y_{x_1}, \ldots, y_{x_t}) \in \text{VALID'}_X\}$. We can therefore write
\[
\sum_{Y \in \text{VALID}_X} (I_U \otimes |\eta^S_Y\rangle \langle \eta^S_Y|) = \\
\sum_{Y' = (y'_1, \ldots, y'_t) \in \text{VALID'}_X} I_U \otimes (|\eta^S_{Y'}(D_X)\rangle \langle \eta^S_{Y'}(D_X)|)_{D_X} \otimes \left( \bigotimes_{x \notin X^0} |x\rangle \langle x| \otimes I \right)_{D_T}.
\]
Using the above decomposition, we rewrite $|\Omega_1|$ as follows:
\[
|\Omega_1| = \sum_{(u,t,X,R) \in \Lambda} \alpha_{u,X,R} \sum_{Y \in \text{VALID}_X} (I_U \otimes |\eta^S_Y\rangle \langle \eta^S_Y|) |u\rangle_U |\psi^S_{X,R}\rangle_D = \\
\sum_{(u,t,X,R) \in \Lambda} \alpha_{u,X,R} \sum_{Y' \in \text{VALID'}_X} I_U \otimes (|\eta^S_{Y'}(D_X)\rangle \langle \eta^S_{Y'}(D_X)|)_{D_X} \otimes \left( \bigotimes_{x \notin X^0} |x\rangle \langle x| \otimes I \right)_{D_T} |u\rangle_U |\psi^S_{X,R}\rangle_D = \\
\sum_{(u,t,X,R) \in \Lambda} \alpha_{u,X,R} \sum_{Y' \in \text{VALID'}_X} \langle \eta^S_{Y'}|D_X\rangle |\psi^S_{X,R}(D_X)\rangle |u\rangle \langle \eta^S_{Y'}(D_X)| \langle \psi^S_{X,R}(D_X)|.
\]
This gives us
\[
|||\Omega_1|||^2 = \sum_{(u,t,X,R) \in \Lambda, Y' \in \text{VALID'}_X} |\alpha_{u,X,R} \langle \eta^S_{Y'}(D_X)| \langle \psi^S_{X,R}(D_X)||^2.
\]
(4)
Using the expression and the end of Step 2, we have
\[
p' = |||\psi_{p'}|||^2 = \sum_{(u,t,X,R) \in \Lambda, Y' \in \text{VALID'}_X} |\alpha_{u,X,R} \langle \eta^S_{Y'}(D_X)| \langle \psi^S_{X,R}(D_X)||^2.
\]
(5)
We can conclude that $p' = \|||\Omega_1|||^2$ by noticing from the definitions that for each $X,Y,R$, we have $\langle \eta^S_{Y'}(D_X)| \langle \psi^S_{X,R}(D_X)| = \langle \eta^S_{Y'}(D_X)| \langle \psi^S_{X,R}(D_X)|$.

**Step 4:** $|||\Omega_2||| \leq \frac{2n}{2^n}$. Fix $X ∈ S_t$. For $β ∈ \{1, \ldots, n\}$ and $i ∈ \{0,1\}^n$, let $R^X_{β,i} = \{Y ∈ \text{INVALID}_X : Y_i = \bar{y}_β\}$. Notice that if $Y ∈ \text{INVALID}_X$, there exists $β$ and $i$ such that $Y_i = \bar{y}_β$ hence $\text{INVALID}_X = \bigcup_{β,i \notin X} R^X_{β,i}$, which implies $\sum_{Y \in \text{INVALID}_X} (I_U \otimes |\eta^S_Y\rangle \langle \eta^S_Y|) = \sum_{β,i \notin X} \sum_{Y \in R^X_{β,i}} (I_U \otimes |\eta^S_Y\rangle \langle \eta^S_Y|)$, where $M_1 ≲ M_2$ means that $M_2 − M_1$ is positive semi-definite. Let $P^X_{β,i} = \sum_{Y \in R^X_{β,i}} (I_U \otimes |\eta^S_Y\rangle \langle \eta^S_Y|)$. For each $β,i$, we have $P^X_{β,i} ≲ I_U \otimes \langle i \rangle \langle i| \otimes |\bar{y}_β\rangle \langle \bar{y}_β| D_i \otimes I_{D_{-i}}$. We write
\[ \|\Omega_2\| = \left\| \sum_{t \in \{0,\ldots,q\}} \alpha_{u,R} \sum_{Y \in \text{INVALID}_X} (I_U \otimes |\eta_Y^S\rangle \langle \eta_Y^S|) |u\rangle_U |\psi_{X,R}^S\rangle_D \right\| \]

\[ \leq \left\| \sum_{t \in \{0,\ldots,q\}} \alpha_{u,R} \sum_{\beta = 1}^{n} \sum_{i \in \{0,1\}^l} P_{\beta,i}^X |u\rangle_U |\psi_{X,R}^S\rangle_D \right\| \]

\[ = \left\| \sum_{\beta = 1}^{n} \sum_{i \in \{0,1\}^l} \sum_{t \in \{0,\ldots,q\}} \alpha_{u,R} P_{\beta,i}^X |u\rangle_U |\psi_{X,R}^S\rangle_D \right\| \]

Fix \( \beta \in \{1,\ldots,n\} \) and \( i \in \{0,1\}^l \). We have

\[ \sum_{t \in \{0,\ldots,q\}} \alpha_{u,R} |u\rangle_U |\psi_{X,R}^S\rangle_D = \sum_{t \in \{0,\ldots,q\}} \alpha_{u,R} |(i)\rangle_H^{D_i} \otimes |B_{X,R}^{-i}\rangle^{D_{-i}}. \]

for some quantum state \( |B_{X,R}^{-i}\rangle^{D_{-i}} \). From there,

\[ \left\| \sum_{t \in \{0,\ldots,q\}} \alpha_{u,R} P_{\beta,i}^X |u\rangle_U |\psi_{X,R}^S\rangle_D \right\| = \]

\[ \left\| \sum_{t \in \{0,\ldots,q\}} \alpha_{u,R} P_{\beta,i}^X |(i)\rangle_H^{D_i} \otimes |B_{X,R}^{-i}\rangle^{D_{-i}} \right\| \leq \]

\[ \left| I_U \otimes (|\beta\rangle \langle \beta|) \otimes |\bar{y}_{\beta}\rangle \langle \bar{y}_{\beta}| \right| \otimes I_{D_{-i}} \sum_{t \in \{0,\ldots,q\}} \alpha_{u,R} |(i)\rangle_H^{D_i} \otimes |B_{X,R}^{-i}\rangle^{D_{-i}} \right\| \leq 2^{-3l/2}, \]

where the last inequality uses the fact that \( y_{\beta} \in \{0,1\}^3 \) and

\[ \left\| \sum_{t \in \{0,\ldots,q\}} \alpha_{u,R} |u\rangle_U |\psi_{X,R}^S\rangle_D \right\| \leq \left\| \sum_{t \in \{0,\ldots,q\}} \alpha_{u,R} |u\rangle_U |\psi_{X,R}^S\rangle_D \right\| = 1 \]

27
from the initial definition of $|\Phi_1\rangle$. Using the triangle inequality, we can conclude:

$$\|\Omega_2\| = \left\| \sum_{\beta=1}^{n} \sum_{i \in \{0,1\}^j} \sum_{t \in \{0,\ldots,q\}} X=x, \ldots, x \in X \atop R=(r_1, \ldots, r_t) \notin R} \right\|$$

$$\leq n2^{l/2} - 3l/2 = n2^{l/2}.$$

Remark: this triangle inequality at the end is probably very loose but is enough for our setting. It should be possible to have an improvement here if needed.

Step 5: putting everything together

We can now put all things together. We have $\sqrt{p} = \|\Omega_1\|$ and $\sqrt{p} = \|\Omega_1\| + \|\Omega_2\|$ with $\|\Omega_2\| \leq n2^{l/2}$. Using the triangle inequality, we have $\sqrt{p} - \sqrt{p} \leq \frac{n}{2^{l/2}}$ and hence $p \leq \left(\sqrt{p} + \frac{n}{2^{l/2}}\right)^2 \leq 2p' + \frac{2n^2}{2^{l'/2}}$. □

5.4 Proof of Proposition 4

We are now ready to put the different pieces together in order to prove Proposition 4.

For each $J \subseteq \{1, \ldots, n\}$, we define $W_x^J(z_j) = \{c \in S_{ch} : I_c \subseteq J \land V'(pk, c, z_c) = 1\}$, and

$$S' = \{x : \exists J \subseteq \{1, \ldots, n\}, \forall j \in J, G(z_j) = x_j \land |W_x^J(z_j)| \geq \delta\}.$$ 

**Definition 11.** Consider an algorithm $A^{O^{St}}$ acting on registers $X,Y,Z$ where $X,Y$ are query registers and $Z$ is an extra register. Let also $D$ the internal database register of $O^{St}$. Let

$$ADV_1(A^{O^{St}}) = \Pr_{(pk,sk) \leftarrow \text{Keygen}(1^\lambda)} \left[ \exists J \subseteq \{1, \ldots, n\} : \forall j \in J, (z_j, x_j) \in D_x \land \frac{|W_x^J(z_j)|}{|S_{ch}|} \geq \delta \right].$$

where $D_x$ is the database register $D$ of the oracle $O^{St}$ measured in the computational basis, conditioned on the output $x$ of $A^{O^{St}}$.

**Definition 12.** Consider an algorithm $A^{O^{C}}$ acting on registers $X,Y,Z,D^C$ where $X,Y$ are query registers and $Z$ is an extra working register and $D^C$ is the compressed register. Let

$$ADV_2(A^{O^{C}}) = \Pr_{(pk,sk) \leftarrow \text{Keygen}(1^\lambda)} \left[ \exists J \subseteq \{1, \ldots, n\} : \forall j \in J, (z_j, x_j) \in D_x^C \land \frac{|W_x^J(z_j)|}{|S_{ch}|} \geq \delta \right].$$

where $D_x^C$ is the database register $D^C$ measured in the computational basis, conditioned on the output $x$ of $A^{O^{C}}$. 28
With these definitions, we can now prove Proposition \[4\] Recall we started from an algorithm \(\mathcal{A}^{G,\mathcal{O}_H}\), we defined

\[V_x = \{c \in S_{ch} : \exists z \in I_c, \forall i \in I_c, G(z_i) = x_i \land V'(pk, c, z, l_c) = 1\}, \]

and \(S = \{x : \frac{|V_x|}{|S_{ch}|} \geq \delta\}\). We also defined

\[P_1 = \Pr[V(x, H(x), z) = 1 \land x \in S : (pk, sk) \leftarrow \text{Keygen}(1^\lambda), (x, z) \leftarrow \mathcal{A}^{G,\mathcal{O}_H}]\]

and we want to show that \(P_1 \leq 2QADV_{\mathcal{I}_S}^{RS;\delta}(\tilde{O}(t), q_G) + \frac{2n^2}{2^t}\). First notice that \(S' \subseteq S\). Indeed, for any \(J \subseteq \{1, \ldots, n\}\) st. \(\forall j \in J, G(z_j) = x_j\), we have \(|W_x^J(z_j)| \leq |V_x|\). This means that if \(x \in S'\), we have \(\frac{|V_x|}{|S_{ch}|} \geq \frac{|W_x^J(z_j)|}{|S_{ch}|} \geq \delta\) hence \(x \in S\).

We consider calls to \(\mathcal{O}_G\) in Zhandry’s QRO framework. In this context, \((z, x) \in D\) means that \(G(z) = x\). Therefore, we can rewrite

\[ADV_1(\mathcal{A}^{G,\mathcal{O}_G}) = \Pr_{(pk, sk) \leftarrow \text{Keygen}(1^\lambda), x \leftarrow \mathcal{A}^{G,\mathcal{O}_G}(pk)}{\exists J \subseteq \{1, \ldots, n\} : \forall j \in J, G(z_j) = x_j \land \frac{|W_x^J(z_j)|}{|S_{ch}|} \geq \delta}

= \Pr_{(pk, sk) \leftarrow \text{Keygen}(1^\lambda), x \leftarrow \mathcal{A}^{G,\mathcal{O}_G}(pk)}{x \in S'} \geq P_1\]

Then, we use Lemma \[10\] with \(f(J, z_j, x, j) = 1\) if \(\frac{|W_x^J(z_j)|}{|S_{ch}|} \geq \delta\) to get

\[ADV_1(\mathcal{A}^{G,\mathcal{O}_G}) \leq 2ADV_2(\mathcal{A}^{G,\mathcal{O}_G}) + \frac{2n^2}{2^t}. \tag{6}\]

Finally, consider the algorithm \(\mathcal{A}^{G,\mathcal{O}}\) where we keep track of the compressed database register \(D^C\). Suppose the algorithm outputs \(x\) such that \(\exists J \subseteq \{1, \ldots, n\} : \forall j \in J, (z_j, x_j) \in D^C \land \frac{|W_x^J(z_j)|}{|S_{ch}|} \geq \delta\). This means we can go through \(D^C\) to find \(J\) and \(z_J\) that satisfies this property. \(D^C\) is of size \(q_G\) so this can be done in time \(q_G\). This step is the reason why we had to use the compressed oracle and not the standard one, which is way too large. This means we found \(x, J, z_J\), such that \(\frac{|c(V(x, c, z_J))|}{|S_{ch}|} \geq \delta\). From there we conclude

\[ADV_2(\mathcal{A}^{G,\mathcal{O}}) \leq QADV_{\mathcal{I}_S}^{RS;\delta}(t + \tilde{O}(q_G), q_G).\]

Putting everything together, we obtain

\[P_1 \leq ADV_1(\mathcal{A}^{G,\mathcal{O}_G}) \leq 2ADV_2(\mathcal{A}^{G,\mathcal{O}_G}) + \frac{2n^2}{2^t} \leq 2QADV_{\mathcal{I}_S}^{RS;\delta}(t + \tilde{O}(q_G), q_G) + \frac{2n^2}{2^t},\]

which concludes the proof of Proposition \[4\].
