Abstract

A proof is given for the Fourier transform for functions in a Hilbert space on a non-compact manifold in general relativity.

Keywords: Fourier transform, Hilbert space, manifold, general relativity

In a recent paper[1] discussing the embedding of the relativistic canonical classical and quantum theory of Stueckelberg, Horwitz and Piron[2-4] (see also [5][6]) into general relativity, the Fourier transform on the manifold, necessary for the construction of a canonical quantum theory, was introduced without proof. It is the purpose of this note to provide a proof and clarify the conditions for its validity.* Since we are working in a canonical framework[1] we do not make use of eigenfunctions of the Laplace-Beltrami operator [8]. Although there is a translation group along geodesic curves generated by the canonical momentum, we shall not be concerned here with the general problem of Fourier analysis on group manifolds.

We wish to construct the Fourier transform on a manifold with metric $g_{\mu\nu}(x) \equiv x^\mu$, $\mu = (0, 1, 2, 3)$, local flat space metric $(-, +, +, +)$ and (compatible) connection form $\Gamma^\lambda_{\mu\nu}(x)$. For a function $f(x)$ defined a.e. on the manifold $\{x\}$, we define the Fourier transform[1]

$$\tilde{f}(p) = \int d^4x \sqrt{g} e^{ip\mu x^\mu} f(x), \quad (1)$$

where $g = -\det g_{\mu\nu}$ and the integral is carried out (in the Riemannian sense) in the limit of the sum over small spacetime volumes with invariant measure $d^4x \sqrt{g}$. Provided that

$$\int d^4 p e^{ip\mu (x^n - x'^n)} = (2\pi)^4 \frac{\delta^4(x - x')}{\sqrt{g(x')}} \quad (2)$$

so that

$$(2\pi)^{-4} \int d^4x' \sqrt{g(x')} \int d^4p e^{ip\mu (x^n - x'^n)} = 1, \quad (3)$$

* Note that Abraham, Marsden and Ratiu [7] apply the formal Fourier transform on a manifold in three dimensions without proof.
to prove consistency of the definition (1) and the requirement (2), we must have

$$\tilde{f}(p) = \frac{1}{(2\pi)^4} \int d^4 x \int d^4 p' e^{i(p_\mu - p'_\mu) x^\mu} \tilde{f}(p').$$

(4)

Exchanging the order of integrations, on the set $\{\tilde{f}(p)\}$ of continuous functions in $L^2(R^4, d^4 p)$, we see that we must study the function (in a particular coordinatization $\{x\}$)

$$\Delta(p - p') = \frac{1}{(2\pi)^4} \int d^4 x e^{i(p_\mu - p'_\mu) x^\mu}$$

(5)

which should act as the distribution $\delta^4(p - p')$.

To prove this, following the method of Reed and Simon[9] in their discussion of Lebesgue integration, we represent the integral as a sum over small boxes around the set of points $\{x_B\}$ that cover the space, which we shall assume to be non-compact, and eventually take the limit as for a Riemann-Lebesgue integral. In each small box, the coordinatization arises from an invertible transformation from the local tangent space in that neighborhood. We write

$$x^\mu = x_B^\mu + \eta^\mu \in \text{boxB}$$

where

$$\eta^\mu = \partial x^\mu / \partial \xi^\lambda \xi^\lambda$$

(7)

and $\xi^\lambda$ is in the flat local tangent space at $x_B$.

We now write the integral (5) as

$$\Delta(p - p') = \frac{1}{(2\pi)^4} \Sigma_B \int_B d^4 \eta e^{i(p_\mu - p'_\mu)(x_B^\mu + \eta^\mu)}$$

$$= \frac{1}{(2\pi)^4} \Sigma_B e^{i(p_\mu - p'_\mu)x_B^\mu} \int_B d^4 \eta e^{i(p_\mu - p'_\mu)\eta^\mu}.$$  

(8)

Let us call the measure at $B$

$$\Delta \mu(B, p - p') = \int_B d^4 \eta e^{i(p_\mu - p'_\mu)\eta^\mu}.$$  

(9)

In this neighborhood, define

$$\partial x^\mu / \partial \xi^\lambda = \partial \eta^\mu / \partial \xi^\lambda = a^\mu_\lambda(B),$$

(10)

which may be taken to be a constant matrix in each small box. In (9), we then have

$$\Delta \mu(B, p - p') = \int_B d^4 \xi \det a e^{i(p_\mu - p'_\mu)a^\mu_\lambda(B)\xi^\lambda}.$$  

(11)

** It is shown in [1] that these statements are covariant under diffeomorphisms.
We now make a change of variables for which \( \xi'_{\mu} = a_{\mu\lambda}(B)\xi^\lambda \); then, since \( d^4\xi' = \det ad^4\xi \), we have
\[
\Delta \mu(B, p - p') = \int_{B'(B)} d^4\xi' e^{i(p_{\mu} - p'_{\mu})\xi''_{\mu}}.
\] (12)
in each box. We remark that the local coordinate transformation in each box \( B \) results in the metric \( g_{\lambda\sigma}(B) = \eta_{\mu\nu} \partial \xi^{\mu} \partial \eta_{\lambda} \partial \eta_{\sigma} \) so that \( \det g(B) = -(\det a)^{-2} \), and therefore \( \det a \) is well-defined.

However, the transformation \( a_{\mu\lambda}(B) \) in the neighborhood of each point \( B \) is, in general, different, and therefore the set of transformed boxes may not cover (boundary deficits) the full domain of spacetime coordinates. It is easy to show, in fact, that the contribution of the boundary deficits of this naive partition of the spacetime may diverge.

We may avoid this problem by assuming geodesic completeness of the manifold and taking the covering set of boxes along geodesic curves. Parallel transport of the tangent space boxes then fills the space in the neighborhood of the geodesic curve we are following, and each infinitesimal box carries an invariant volume (Liouville type flow) transported along a geodesic curve. For successive boxes along the geodesic curve, since the boundaries are determined by parallel transport (rectilinear shift in the succession of local tangent spaces), there is no volume deficit between adjacent boxes.

We may furthermore translate a geodesic curve to an adjacent geodesic by the mechanism discussed in [10], so that boxes associated with adjacent geodesics are also related by parallel transport. In this way, we may fill the entire (geodesically complete) spacetime volume.

We may then write (8) as
\[
\Delta(p - p') = \frac{1}{(2\pi)^4} \sum_{B} e^{i(p_{\mu} - p'_{\mu})x_{B}^{\mu}} \Delta\mu(B, p - p'),
\] (13)
Our construction has so far been based on elements constructed in the tangent space in the neighborhood of each point \( B \). Relating all points along a geodesic to the corresponding tangent spaces, and putting each patch in correspondence by continuity, we may consider the set \( \{x_{B}\} \) to be in correspondence with an extended flat space \( \{\xi(x_{B})\} \), to obtain
\[
\Delta(p - p') = \frac{1}{(2\pi)^4} \sum_{B} e^{i(p_{\mu} - p'_{\mu})\xi_{B}^{\mu}} \Delta\mu_{B}(p - p'),
\] (14)
In the limit of vanishing spacetime box volume, this approaches a Lebesgue type integral on a flat space
\[
\Delta(p - p') = \frac{1}{(2\pi)^4} \int e^{i(p_{\mu} - p'_{\mu})\xi^{\mu}} d\mu(\xi, p - p').
\] (15)
If the measure is differentiable, we could write,
\[
d\mu(\xi, p - p') = m(\xi, p - p') d^4\xi.
\] (16)
* This procedure is somewhat similar to the method followed in the simpler case of constant curvature by Georgiev[11] who, however, used eigenfunctions of the Laplace-Beltrami operator.
Since the kernel $\Delta(p - p')$ is to act on elements of a Hilbert space $\{\tilde{f}(p)\}$, the support for $p' \to \infty$ vanishes, so that $p - p'$ is essentially bounded, and we argue that therefore (16) is valid. In the small box, say, size $\epsilon$,

$$\Delta\mu(B, p - p') = \int_{-\epsilon/2}^{\epsilon/2} d\xi^0 d\xi^1 d\xi^2 d\xi^3 e^{i(p\mu - p'\mu)\xi^\mu} = (2i)^4 \prod_{j=0}^{3} \frac{\sin(p_j - p'_j)\xi^j}{(p_j - p'_j)} \to \epsilon^4 \sim d^4 \xi,$$

for $\epsilon$ sufficiently small, $m(\xi, p - p') = 1$, and we have

$$\Delta(p - p') = \frac{1}{(2\pi)^4} \int e^{i(p\mu - p'\mu)\xi^\mu} d^4 \xi,$$

or

$$\Delta(p - p') = \delta^4(p - p').$$

It is clear that the assertion (17) requires some discussion. For $\epsilon \to 0$ we must be sure that $p'$ does not become too large. In each of the dimensions, what we want to find are conditions for which, in (17),

$$\frac{\sin \epsilon p}{p} \to \epsilon$$

for $\epsilon \to 0$, where we have written $p$ for $p - p'$. As a distribution, on functions $g(p)$, the left member of (20) acts as

$$G(\epsilon) \equiv \int_{-\infty}^{\infty} dp \frac{\sin \epsilon p}{p} g(p).$$

The function $G(\epsilon)$ is analytic if $p^n g(p)$ has a Fourier transform for all $n$, since $G(0)$ is identically zero, and successive derivatives correspond to the Fourier transforms of $p^n g(p)$ (differentiating under the integral). This implies, as a simple sufficient condition, that the (usual) Fourier transform of $g(p)$ is a $C^\infty$ function in the local tangent space $\{\xi\}$. In this case we can reliably use the first order term in the Taylor expansion,

$$\frac{d}{d\epsilon} G(\epsilon)\big|_{\epsilon=0} = \int dp \cos \epsilon p g(p)\big|_{\epsilon=0}$$

so that, for $\epsilon \to 0$,

$$G(\epsilon) \to \epsilon \tilde{g}(0),$$

where $\tilde{g}(\xi)$ is the Fourier transform of $g(p)$. As a distribution on such functions $g(p)$, the assertion (17) then follows.

The structure of the proof outlined in this note emerges due to the factorization possible in the exponential function. In a simpler case, applying the same method to the integration of an arbitrary (integrable) function on the manifold, not necessarily compact, we could write

$$\int d^4x \sqrt{\tilde{g}} f(x) = \Sigma_B \int_B f(x_B + \eta)\sqrt{\tilde{g}}(x_B)d^4\eta,$$
where we again cover the spacetime, assumed geodesically complete, with small boxes related by parallel transport.

Since for a small interval $\xi^\lambda$ in $B$,

$$\eta^\mu = \frac{\partial x^\mu}{\partial \xi^\lambda} \xi^\lambda,$$

so that, as above, $d^4\eta = \det a d^4\xi$ and we have (in each box $B$, $g = -\det g(B) = (\det a)^{-2}$)

$$\Sigma_B \int_B f(x_B + a^\mu_\lambda \xi^\lambda) d^4\xi.$$ 

To lowest order, this is

$$\Sigma_B \int_B f(x_B) d^4\xi,$$

just our usual understanding of the meaning of $\int d^4x \sqrt{|g|} f(x)$ as a sum over the whole space with local measure $d^4x \sqrt{|g|}$.
